EDITORIAL NOTES

This book contains the complete texts of the Plenary Lectures and the abstracts of the oral and poster communications presented at the XXI International Congress of Entomology. Although all abstracts were revised by the Scientific Committee, in order to fulfill the abstracts rules, their contents are printed as received and are exclusive responsibility of the authors.

Dear Authorities Dear Members of the International Council Dear Directors of Entomological Societies Dear Entomologists Ladies and Gentlemen

Four years after the Florence Congress we have the chance to meet again to establish the state of the art on the entomological science. Nowadays, four years represents more than four centuries of the ancient Aristotele era, or four decades of a century ago. Some definitive scientific trues of last congress will be history at use end of this Congress. By force of my position as president of the XXI International Congress of Entomology, I had the chance to view each one of the abstracts, and read almost all of them. So, I realized that better than trying to make my own point, was using the findings and words of the lecturers to make an overview of the Congress, so I will use some of the presentations to anticipate how much we have advanced.

In about one hour we will have the unique chance to hear Dr. John Lawton's lecture. Entomologists preserving biodiversity was the challenge put to the session convenors, symposia coordinators and to all of you, to make an insight reflection of the importance of our science for the next generations. We know we have more species on the Order Lepidotera than birds in the world. Dr. Lawton will use this comparison to call the attention to the importance of insects for the biodiversity. Were the world to be almost destroyed by a catastrophe, if only a dozen species were to survive, they would surely be insects. They are present along all complex food chains, and are part of the ecosystems. Not only beneficials but even pests have a role on the natural systems, and more than philosophy this is something we should take into account on our daily tasks.

My country, Brazil, had the unique chance of helding the Rio de Janeiro Convention on Biological Diversity, a milestone for sustainable conservation of the earth's genetic resources. The preservation of biodiversity is an essential prerequisite for the future development of the earth as a viable habitat. New insights into processes and structures, and genes of animals and plants, will also help us to find new ways of combating disease, safeguarding the food supply of the world's growing population and protecting the environment. The preservation and sustainable utilization of the diversity of species is of vital importance for the interests of all mankind, for the countries that supply these resources and, last but not least, for the health and food industries.

We should consider insect diversity conservation beyond single species or endangered taxa, because of its importance on the natural systems, its stability and continuity. We can either think that "small is beautiful", by having this goal in mind every day, on the lab, on the field, on the university, on the institutes. But we have also to consider our role on the global society, helping planning, building or composing network mentality for conservation, taking part of concrete actions for preserving biodiversity. That will be our contribution for sustainability, a major claim of the contemporary society.

We have to consider the limitations of insect propagation to new geographic locations, due to climatic restrictions. Right now we are located at the edge of one of the Brazilian National Parks, essentially a tropical forest. In the tropical area live the majority of the insect species. The climatic change, or the global warming is one of the threats our society is facing and discussing right now. We know that warmer climates offer better possibilities of wintering and lead to a higher density of population, earlier presence of insects and an increased risk of invasion by migratory insects. Higher atmospheric CO_2 concentrations increase the carbon assimilation of plants and modify the carbon distribution pattern, and the secondary plant ingredients. The increase in bound carbon in a plant causes a reduction of the nitrogen concentration. The result is that nitrogen may become more and more a limiting factor for the development of insects. In economically important species, this will finally lead to an increased uptake of biomass.

Insect-dependent plant pollination will also change as a result of climatic changes and thus also the productivity of plants. Climatic changes do not only have effects on local and regional food chains, but even on complete food systems. Such changes will affect the biodiversity of some regions. We must also consider the insect services, under a new category that could be called natural services. I am talking about the services that are provided for free by Mother Nature, like the cleaning of air or water, or the natural pest control. In this sense, it is very important that all of us, that have the privilege of being on the entomology science, to understand that insects can survive very well without us, but we - like most other terrestrial organisms - would have no chance without them.

Sustainability should be a permanent challenge to us, scientists, aiming to leave a better world to future generations. Those of us dealing with all branches of entomology but focusing on agricultural improvement should understand how different is the concept of sustainability to rich societies and to poor countries. To ones that have food in the table every other day, and those that are exploiting resources far distant from the necessary care that would lead to sustainability, including biodiversity protection. Away from the widely accepted concept of sustainability which says that " the process over the long term that enhances environmental quality and the resource base on which agriculture depends; provides for basic human food and fiber needs; is economically viable; and enhances the quality of life of farmers and society as a whole". Dr. Marcos Kogan, one of our

Presidential Address

distinguished plenary lecturers will drive your attention to the Holly Bible of sustainability, by stating that a sustainable agriculture system

- a. is based on the prudent use of renewable and/or recyclable resources;
- b. protects the integrity of natural systems so that natural resources are continually regenerated;
- c. improves the quality of life of individuals and communities;
- d. is profitable;
- e. is guided by a land ethic that considers the long-term good of all members of the land community

Integrated Pest Management is largely based on sustainability, which is an empty concept if not linked to biodiversity preservation. Much of the complexity of an ecosystem resides in its biodiversity, and it is precisely this biodiversity that is most negatively affected by input-driven agriculture. We have to resist to the temptation of minimizing or making the issue linear, by just opposing two major points of view: the first defending that "agricultural intensification is necessary because the worldwide area of highly-productive arable land is limited and diminishing, and only by increasing yields per unit area we will be able to meet the demands of a growing world population." The argument from the 'high-input' side, however, assumes that this agricultural intensification is necessarily tied to high-inputs and mechanization. On the other side, the extreme situation is the claiming of new processes like organic agriculture being a final goal, and not a means to produce food and fiber. We will have the pleasure to listen to Dr. Settles experience on Southern Asia IPM Programmes implementation, addressing all these questions.

I beg your full attention now: In the next thirty years the world will have to produce more food than over the whole of the last 10,000 years According to widely accepted statistics, the real problem is:

- a. The world has 800 million people that are food insecure;
- b. Out of them, 180 million are preschool children;
- c. In 20 years, the Asian population will increase 1 billion people;
- d. During the same period, Sub-Saharan population will increase 80%;
- e. Setteris paribus, the food production will have to increase 60%;
- f. Increasing world wealth will demand 200% increase on meat production;

The dimension of the challenge will call for all our intelligence, creativity and cleverness, to design system approaches that will feed the people from one side and leave a better world for our sons on the other side.

Pests in general, insects in particular, represent serious threat to the full expression of the productivity and quality potential of all major crops. Some insect pests are so widespread, have a diversity of hosts and potential of damage that are considered key agricultural pests. Among them we have fruit flies and white flies. They deserve special space during this Congress. The organizing committee was especially wise on inviting Dr. Dan Gerling to revisit the white flies world. But why have whiteflies been chosen as the group to be revisited? The increased fitness, the ability to leave larger progeny relative to the abilities of other individuals or populations, has led to the emergence of new and better-adapted forms of life. Once detected, it is of special interest to learn in what way such forms stand out and how their traits contribute to greater fitness. Whiteflies have been schown and studied for over 250 years. The research conducted reflects the changes in their economic status and advances in biological theory and scientific methodology. During the last 100 years, whitefly species, differed from other economic species in defying attempts at classical biological control and have become economic pests of worldwide proportions. During the past 15 years, *whiteflies* has caused damages sometimes reaching \$500 million or more per year. Concomitantly, *Bemisia. tabaci* races and biotypes were found. The most prominent one, biotype 'B', showed increased fitness in relation to the former 'A' biotype. It eventually replaced it in extensive regions, and has been described as a separate species: *Bemisia argentifolii*.

You are all invited to carefully listen and discuss Dr. Gerling opinions regarding severe and widespread outbreaks of white flies. Will the growers be able to handle the problem, or should we think on national or regional programs? It is critical that nanagement, including employment of natural enemies, be implemented as soon as viable. This is especially important since the chances for resistance build-up already at the "invasive stage outbreaks" are substantial, and the resistant populations will be carried over to the "stable stage outbreaks" hampering IPM attempts in the future. And he will also claim your attention to the fact hat the mere discovery and description of new biotypes has little value unless the relationship to functional traits is elucidated as a ever for better biological, ecological and agricultural understanding, leading to better management.

The challenge will also arise a series of new questions. Dr. Gatehouse is provoking us asking "Transgenic Plants; an Environmentally-Friendly Method of Pest Control?". This question would be ridiculous if placed during the XXIV International Congress of Entomology, but the world society is asking to us to present a convincing answer right now, not in twelve years. Is the biotech, or the high tech world better than the present system? Do we have the same treats, risks, and hazards? Is the food safe, our health protected, the environment not endangered? Going to specific points, do we agree that the price for meeting the food lemands can be too high, with irreversible depletion or destruction of the natural environment?

Whilst pesticides are very effective in combating the immediate problem of insect attack on crops, and have been responsible for dramatic yield increases in crops subject to serious pest problems, non-specific pesticides are harmful to beneficial organisms including predators and parasitoids of those target pest species. In response to public concerns, the agrochemical industry has introduced a number of less harmful and less persistent pesticides. But, the real question is: what is the most convenient scenario for the world society, the biotechnological or the pesticide paradigm, both or none of them. How will the IPM programmes be conformed under the new concepts coming out of our laboratories.

Fortunately, transgenic plants are not the only breakthrough on the opening of the new millennium. Scientists participating in this Congress are responsible for continuous advancing of science, and new approaches on how to manage insects come out all the time. I carefully read Dr. Bernays review on Plant – Insect Interactions. Year after year we learn more and more on insect relations, including tritrophic interactions. Dr. Bernays will conclude that the details of behavior and physiology, especially neurophysiology, have suggested an approach to the study of insect-plant interactions, namely the constraints on neural processing and the diverse effects of these constraints in ecology and evolution. This approach will allow us to understand more about all aspects of the insect-plant interaction in a way that has been difficult in recent decades.

Dr. Hassell is responsible to elucidate the latest advances on insect – parasitoid interactions. Insect ecologists have always asked what determines the abundance and patterns of fluctuation of insect populations. Parasitoids play a major role on insect regulation, and are amongst the most abundant of all animals, comprising some 10% or more of all metazoan species. They have been popular subjects for ecological study for a variety of reasons. First, their importance in biological pest control programmes has stimulated a large amount of work seeking to identify and quantify the attributes that enhance the effectiveness of parasitoids as pest control agents. Second, the study of host-parasitoid population dynamics has greatly benefited from the way that parasitoids make ideal subjects for the development of relatively simple population models.

On studying plant-insect and insect insect-interactions, one major issue that comes to our minds is taxonomy (either plant or insect classification). The organizing committee understood to be important reviewing the impact of Hennig's 'phylogenetic systematics' on contemporary entomology, inviting Dr. Andersen to discuss Hennig's contribution with us. Phylogenetic systematics comprises the principles and methods by which we reconstruct the evolutionary histor of organisms and transform this reconstruction into a biological classification of these organisms. Whereas the contingency between classifications of organisms and their evolutionary history had been known since Darwin, it was not until the middle of the last century that real progress was made in designing the tools for phylogenetic reconstruction. This important progress was in part initiated by the German entomologist Willi Hennig, who clarified or redefined the goals of phylogenetic systematics in his today's classic book published in 1950.

The potential of practical use of insect interactions and insect communication is tremendous. Dr. Leal, from the University of California, have the mission to lead the discussion on chemical ecology, during the Congress. We know that chemical communication involves the production and release of specific chemicals by the emitter, and the detection and olfactory processing of these signals leading to appropriate behavioral responses in the receiver. Chemical attraction is the major means of sexual recruitment in scarab beetles. Females are normally the emitters and males the receivers, and in this case, the semiochemicals are referred to as sex pheromones. Male-released aggregation pheromones have also been reported for a few Dynastinae. Largely, the present research projects are aimed at the development of attractants (pheromones or food-type lure compounds) for possible applications in management programs. On the one hand, scientists have focused on the chemistry of the emitters (identification and synthesis of pheromones) and studied the biology, biosynthesis and physiology of pheromone production. On the other hand, investigation has been conducted to identify the molecular mechanisms of the olfactory processing in the receivers.

But are we exclusively talking about plants and insects? Not at all, animals and insect interaction are also a major interest during this Congress, and Dr. Nuttal will approach the tick-parasite interactions at the host interface. To survive, the ticks must attach and remain feeding on a host for several days, even weeks. The physical and chemical processes of feeding, and long duration of attachment provoke host haemostatic, inflammatory and immune responses. Ticks counterattack with anti-haemostatic, anti-inflammatory and immunomodulatory substances secreted in their saliva. Included in this armory are proteins that bind immunoglobulins, histamine, and serotonin, and various cytokine regulators that affect the production or activity of several cytokines, including interferon. As a result of the pharmacological activities of this rich cocktail of bioactive saliva molecules, the feeding pool within the skin becomes an immunologically privileged site. Any pathogens (viruses, bacteria, protozoa) transmitted by infected ticks into the feeding pool, or that are acquired by feeding ticks from infected hosts, will benefit from a supportive ecological niche created by the tick. Such a phenomenon, often referred to as 'saliva-activated transmission,' has been reported for several tick-borne pathogens. Then, the challenge is determining whether this immunologically privileged feeding site can be destroyed, and pathogen transmission prevented.

Some of the answers we are looking for are somewhat lost in the time, and that's why we have asked Dr. David Grimaldi to tell us something about the Mesozoic radiations of the insects and origins of the modern fauna. We know that insects are among

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

Presidential Address

the earliest terrestrial organisms, with a fossil record extending to the Devonian, pterygotes appearing in the Carboniferous, and some modern orders in the Paleozoic. In the 400 million years since the earliest hexapods, they have proliferated into the most diverse group of organisms in the entire Phanerozoic. Extensive radiations of modern faunas, however, did not occur until the Cretaceous, based on diversification of species of ecological keystone groups: Isoptera, cimicomorphan and pentatomorphan bugs, phytophagan beetles, aculeate wasps, cyclorrhaphan flies, and glossatan moths. These groups alone today represent well over half of all insect species, and their diversification can be related directly or indirectly to the angiosperm radiations in the mid Cretaceous.

And we also widely recognize the overall importance of the advances obtained on basic entomology for the benefit of the World Society. I happen to know Dr. Karel Slama on the European Congress of Entomology, and during the two and a half hours drive between Prague and Ceske Budejovice he spoke nothing but insect hormones and insect respiration. I felt all of you would love to hear the enthusiasm Dr. Slama put when speaking on a new look into insect breathing. As an entomology student, I was told that terrestrial arthropods either were able to ventilate actively the tracheal system in response to hypoxia or accumulation of CO₂, or that a simple passive diffusion of O₂ or CO₂ through the air-filled tracheal system could account sufficiently well for all respiratory requirements, without a need for active ventilation. Most insect physiologists accepted this "diffusional theory" as a model of insect respiration for the whole 20th century. But Dr. Slama discovered the presence of special, periodically repeated pulsations in mechanical pressure of the haemocoelic body cavity. These extracardiac pulsations were produced by simultaneous contractions of abdominal somatic muscles, which caused positive pressure peaks in the haemocoele. The movements of body segments, associated with this "abdominal pressure pump", were rather small and invisible by a naked eye, but still they were large enough to cause a bulk flow of gas through some spiracles that were just open. He also observed that spiracular valves pulsated selectively in synchrony with the upward or downward strokes of the pressure pulse, producing an actively regulated unidirectional stream of air. This type of active insect breathing was achieved by means of an autonomic cholinergic, neuromuscular system (coelopulse), driven by a nervous center in the thoracic ganglia of the ventral nerve cord. I am absolutely sure you all will benefit of Dr. Slama's lessons as I did.

I must also recommend that you all bookmark Dr. Tolbert speech on neural development during embryonic and metamorphic development in insects. Why study the development of insect nervous systems? Beyond satisfying sheer curiosity, knowledge of insect neural development holds the hope of revealing novel and specific paths for biologically sensitive intervention, to protect or to control specific populations of insects. Furthermore, for developmental biologists, insects offer a rich source of material. The development of the nervous system in insects follows different paths, depending on the life history of the species, yet many of the cellular and molecular mechanisms underlying neural development appear to be common across disparate insect species, and even common between insects and mammals. Individual species variations confer particular experimental advantages to the investigator using insects. For all of these reasons, recent years have seen a huge research effort to understand neural development in insects. Insect nervous systems develop along widely differing timetables, depending on the life stages of the species. Dr. Tolbert will provide background on embryonic development and metamorphosis of the nervous system, but will focus mostly on intercellular interactions that play key roles no matter what the timetable, no matter what the extent of post embryonic reorganization, of the developing nervous system.

Basic science can contribute much more. Dr. Eberhardt accepted to tell us why is it that male genitalia tend to evolve rapidly and divergently in so many animal groups. He will summarize data and ideas from insects and arachnids that have appeared in the last 15 years that relate to various hypotheses (species isolation by mechanical lock and key; pleiotropy; malefemale conflict of interests; cryptic female choice) that have been proposed to answer this question. Dr. Eberhardt will also present:

- a. demonstrations that multiple genitalic contacts and copulations by the female, a prerequisite for the male female conflict and cryptic female choice hypotheses, is more common than previously thought, even in groups previously thought to be monandrous;
- b. realization that there are many female processes that can affect the chances that a given copulation will result in fertilization of a female's eggs;
- c. documentation from literature reviews and a survey study that courtship during and following copulation is extremely widespread among insects and spiders, and also though apparently to a lesser extent, among scorpions;
- d and the realization that the well-documented evolutionary trend for male seminal products to stimulate several female reproductive processes that benefit the male's reproduction is probably a result of either male-female conflict or sexual selection by cryptic female choice.

We come to this congress to hear about insect genitalia, but also the role of the insect gut microbiota, which is the subject of Dr. Dillon's lecture. It is a premise that the success of the Class Insecta in our world is beyond dispute. What is less known is the extent to which microorganisms contribute to this success. The intestinal tract of many insects has been shown to harbor a large diverse microbial community. Although we are now aware of mutualistic associations between a number of insect species and their extra cellular gut microbiota, many species are known to contain a substantial microbiota whose impact on insect survival is unknown. There are still relatively few studies on the role of the normal microbiota of insects compared to their

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

obligate pathogens. This is partly due to the difficulty in recognizing beneficial relationships. One area of progress is the contribution of microbiota to the nutrition of the host. Nutritional contributions may take several forms; improved ability to live on sub optimal diets, improved digestion efficiency, acquisition of digestive enzymes and provision of vitamins.

We invited Dr. Manfred Kern to anticipate the most probable scenarios, and he will network with you all during the closing lecture, discussing the Entomology For The Third Millennium - Scientific And Technological Challenges. Food production, Food Security, Food Justice, Integrated Pest Management, Sustainable Agriculture, International Trade and Crop Protection, Biotechnology, all of them will be recurrent issues during this congress, dedicated to the present status, and will surely on the stage during the closing lecture, as big challenges as the door for the next millennium is opening.

Dr. Kern will go even further. He will tell us not only how will entomologists preserve biodiversity, help implementing sustainable agriculture, and feed a hungry world, but also what is the relationship between global warming and insects. How the continuous movement of people from rural to urban area, creating the megalopolis, will affect public health. Will insect vectors just accommodate to the new situation, or will they react to the new environment?

It will be particularly amazing to discuss with Dr. Kern the nano-insects technology. The "nano era" of the twenty-first century will revolutionize - or evolutionise - entomology. Biochips will be expressed in insects, and with the aid of nanotechnologies, nanoelectronics, nanomechanics, nanobiology, nanomanufacturing, nanocontrol and nanomicrology, it will be possible to construct mechanicai insectoids, hybrid cockroach robots and ant robots.

Just a fantasy or free thinking? What about genetechnology-based entomology. In fact, entomology in the twenty-first century will bear the title "Gen(e)ntomology". The large number of highly diversified insect species, the successful evolution of insects, their enormous adaptive potential, their many different survival strategies, their immensely efficient communication systems, and their highly organized society formation will become key fields for molecular biology and gene technology in the future. Transgenic strains of arthropod vectors will become commonplace. We will also be in a position to create and produce new insect species.

Just imagine the scope of possibilities: one thousand grams of DNA (dissolved in one cubic meter) would have a larger storage capacity than all computers which have ever been built, or about 100 billion times the storage capacity of our brain. Thirty grams of DNA work one hundred thousand times faster than the fastest computers we know today .The genetic code of life is a gigantic biological manuscript that we have scarcely yet begun to examine or decode. "Drosophila - completely decoded" was the great headline at the beginning of the year 2000. This means that we now know the 13,601 genes of each separate cell and also those for the development from egg to adult fruit fly.

At the same time as we are advancing our knowledge of the macro-world, we are also engaging in unremitting exploration of the micro-world. After undergoing the "catalysis" of modern science and technology, certain notions that used to be looked on as wild tales are now confronting mankind "as if coming to life". Some of man's fantasies are to manufacture extremely small-scale electrical machinery that can only be seen under a microscope, an "intelligence chip" that could be transplanted into the brain of an insect, or a "remote controlled submarine". We will have the responsibility of ensuring that all these things do not become a knife "cutting both ways" and threatening social stability. "Microscale electromechanical insects" or "modified insects" should never be used as nanotechnology weapons"!

Ladies and gentlemen, I must finish my speech. But before finishing, I have to mention some key persons: without their contribution that would never had happened the XXI International Congress of Entomology:

I would like all the members of the Council for the International Congresses of Entomology to stand up, to be recognized for their wisdom and for the help and support they provided to the Organizing Committee; I personnaly have to thank all of you for the unique professional opportunity you gave to me as President of this Congress.

I would also like the Session Convenors to stand up, to be recognized for their unique work on building the Session Programme;

Please, members of the Local Scientific Committee, would you mind standing up to be recognized for your almost secret work during all the Congress organization;

To you all I can only say: Very thank you, it was very easy to be leader of clever, cooperative and pro-active people.

I must also ask the President and the Director of Embrapa to stand up, to be recognized for the unconditional support to the Congress;

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

And I beg your pardon for some necessary personal acknowledgements:

To my first entomology professor, Dr. Elio Corseuil who opened my eyer to the amazing world of insects;

He was only fourteen years old when he designed and broadcasted for the first time the congress homepage, the most important tool we had to organize this Congress. He is my elder son, Decio;

He also was only fourteen years old when he first started check spelling and verifying the compliance of the Congress abstracts to the rules. I'm talking about my younger son, Bruno;

She stood up as an example of woman and companion. Looking back, I can not understand how she could stand these last 1460 days, when she had to give up of any chance of leisure time because I was completelly involved with the Congress organization at the time I was supposed to be with my family. Now I have to say to my wife Rose Mary: Darling, very thank you for being at my side during the last 4 years. You was really great.

Very thank you all.

ENTOMOLOGISTS AND THE CONSERVATION OF BIODIVERSITY.

J. H. Lawton.

Natural Environment Research Council, Polaris House, North Star Avenue, Swindon SN2 1EU, UK,

INTRODUCTION

Insects dominate global biodiversity. There are roughly an order of magnitude more named species of insects in the single Order Lepidoptera than there are species of birds in the world. But despite their numerical inferiority, global conservation efforts devoted to birds exceed those devoted to all insects (not just Lepidoptera) by several orders of magnitude (although reliable figures are hard to come by). I doubt that this imbalance in effort reflects conservation needs, in the sense that birds as a group are much more highly threatened than insects. Rather, it reflects conservation priorities set by society based on other criteria. Although as entomologists we might be reluctant to admit it, birds are more charismatic than bugs. In the UK, we have a Royal Society for the Protection of Birds. It is hard to imagine a Royal Society for the Protection of Beetles, and certainly not one with 1 million members. In other words, contemporary species conservation has more to do with people's wishes, desires and value judgements than it has to do with scientific logic or need. Indeed, deciding what to conserve and where to conserve it is not, first and foremost, a scientific question. We apply science to conservation after we have decided what it is we wish to conserve, and in the greater scheme of things, the 'what' may have no other basis than personal likes and dislikes. Unfortunately, a few charismatic groups of insects aside (butterflies, dragonflies and glow-worms are good examples), people prefer to devote considerably more conservation efforts to birds and mammals than they do to 'creepy crawlies'.

The shear diversity of insects also means that the approaches adopted by bird and mammal conservationists are ill suited to insect conservation. Again speaking in very general terms (all these comments admit of exceptions), we take a species-by-species approach to the conservation of birds and mammals: "Save Leadbetter's possum!" "Save the n-thousandth species of undescribed weevil" does not have quite the same ring to it. In Britain at least, we have had successful conservation programmes directed at individual species of insects, particularly butterflies, but also dragonflies and Orthoptera, but these are very much the exception. By and large, the overwhelming diversity of insects makes a species-by-species approach to their conservation quite impossible.

PROTECTED AREA NETWORKS

Against this background, entomologists confronted with pressing, not to say depressing, conservation issues need to take a broader view. Indeed it is a view that is also appropriate for the effective conservation of all taxa – not just insects – and it is being increasingly adopted by conservation biologists from all the different rooms in the Ark. We should seek to conserve habitats, better still intact ecosystems, not individual species. Some important consequences follow from taking this approach, to which I will return later. A logical starting point, however, is to focus on the core of any long-term conservation strategy, namely the establishment of a network of protected areas, be they called national parks, nature reserves, wildlife conservation and use areas, or what have you. How do we select such areas, how big should they be, how many, and where? There is a rich literature on these problems with, for example, extensive discussions of efficient reserve selection algorithms that seek to maximise the number of species represented on at least one reserve at minimum cost, or on a minimum total area. The approach is heavy on computing and mathematics, and rather little of it explicitly considers insects. I do not propose to review it here, except in passing. Rather, I want to deal with some more general biological issues.

USING MACROECOLOGICAL PRINCIPLES TO SET STRATEGY

An important set of guidelines for designing protected area networks is provided by macroecology. Macroecology is a rapidly emerging blend of biogeography, ecology and evolutionary biology, and seeks big, bold repeated patterns in the distributions and abundances of species. Three patterns, one very familiar, the other two less so, offer insights into designing conservation strategies based on protected area networks. If we focus on a particular taxon, say passerine birds, or freshwater fish, or butterflies, we find:

1. Across species, a positive correlation between average local abundance and the size of the geographic range of each species.

2. A positive correlation between the regional species richness of a taxon, and its local species richness.

3. A species-area relationship.

The third of these will be familiar to most people, and has been variously praised and criticised as a tool for designing reserve networks. But its basic message is very simple – a big conservation area will hold more species than a small area. One can then get into arcane arguments about whether one large, or several small, reserves is better, but for all sorts of reasons I have no doubt that given a choice conservation biologists should go for large reserves, not many pocket-handkerchief sized areas. This may seem obvious for large animals like birds and mammals, but in Britain at least, the existing network of generally small reserves is making a very poor job of protecting butterflies. Large reserves will aid insect conservation as much as they help bird and mammal conservation.

The first two macroecological patterns are less familiar, but they are also, now, well documented in the literature, and together argue that no reserve is an island. The systematic destruction of regional biotas by human activities threatens surviving populations of species, even in protected areas. Impoverished regional diversity must, sooner or later, lead to reductions in local diversity (pattern 2), with pattern 1 providing insights about the mechanism(s) involved. These are not yet fully understood, but metapopulation dynamic models predict that regional reductions in the geographic ranges of species (by habitat destruction, for instance) will lead to reductions in population abundances, even in surviving, unmodified habitat patches. The basic mechanism is increasing isolation of surviving habitat patches, which reduces or eliminates movement of animals between patches. These models predict that inevitably, populations in increasingly isolated protected areas will decline, and that some will decline to the point of local extinction. These forces can be counteracted by having networks of reserves, close enough together, or connected by corridors, to maintain significant dispersal of individuals between patches. Work on butterfly populations in Britain and Scandinavia illustrates these processes very clearly. The message for conservation is simple. Not only do we need large reserves, we also need inter-connected networks of reserves. Isolated reserves, even big ones, are unlikely to be as effective as we might hope.

Problems of reserve isolation are magnified or reduced by the nature of the greater landscape outside designated areas. 'Gently managed' landscapes may allow considerable movement of species between protected areas, decreasing the effects of isolation. Corridors may work in the same way. Intensively altered and managed landscapes - urbanisation and intensive agriculture in particular - may make it impossible for species to move between reserves, creating severe problems of isolation.

CHALLENGES

All this is fairly simple. But there are some challenges. For example, where should entomologists devote conservation efforts? Where should the protected areas be? Huge areas of the globe remain effectively unexplored entomologically. If we do not even know what is there, how can we design sensible conservation strategies? One hope would be to use indicator taxa, on the assumption that well-studied groups like birds or butterflies can act as indicators of unusually species-rich regions, or regions of high endemism, for all kinds of much less well known and more poorly studied creatures. I wish we could, but fear we cannot. There have been, and still exist, enthusiastic proponents of the indicator-species concept, usually suggesting their own favourite group as ideal. The data say otherwise. Patterns of endemism, species richness, and rarity are, more often than not, poorly correlated across different taxa, at any scale that is useful for the design of reserve networks. Ultimately, we may have to make some difficult choices on selecting protected areas, knowing that information is incomplete. Waiting until we have perfect knowledge is not an option. There will be little left worth conserving if we are unwilling to act until we have better information. In the end, any network of large reserves is better than none!

How many reserves do we need and how close together? Here the reserve selection algorithms referred to above can be useful for well known taxa – which rules out most insects. My belief is, in any case, that for most regions of the world the question is academic. We can never acquire, or manage, enough land to save everything (the species-area relationship proves that). Hence we must settle for as much as possible! We should seek to establish as many reserves as possible, that are as large as possible, and as close together or as well linked as possible. Whatever we get, it will not be enough to save everything.

The biggest challenge lies in global change. Even under 'normal' climatic conditions, Nature does not stand still. Communities gradually 'unravel' as species change in relative abundance, some rare species become common, formerly common species become rare, and other members of the original community disappear altogether. With global climatic change, these processes will inexorably accelerate, tearing apart existing assemblages and creating new ones. Experiments with insect assemblages in the laboratory reveal some very unexpected changes in the distributions and abundances of species under simulated global warming and rising carbon dioxide concentrations. We somehow have to design reserve networks that can cope with a rapidly changing world. One consequence of global change is that sooner or later, most reserves will be in the wrong place, as climatic conditions change markedly. A large, inter-connected network of reserves along the lines advocated above at least gives species a chance of migrating and hence of coping with climate change. Although some conservation biologists are arguing that it will be necessary to move species artificially from reserves where the climate no longer suites them, to areas where it does, we are extremely unlikely to be able to do this for anything other than a tiny handful of species. The vast majority of insects will have to find their own way to new homes, and my guess is that many will fail. Whatever we do, human-induced global change can only make conservation of biodiversity more difficult.

It will not have escaped your notice that the nature of the landscape that surrounds protected areas is now key to which, and how many, species will be able to track their preferred environment in a rapidly changing world. To this extent, butterflies may be more fortunate than buffaloes. Less frivolously, it draws attention to the fact that effective conservation increasingly has as much to do with what happens in the greater landscape as it has to do with what happens on reserves. Reserves are vital for the conservation of many species, and will continue to be so for the foreseeable future, but we can no longer ignore what happens outside reserves.

INSECTS AND NEMATODES

Finally I want to finish with a twist to the story that is sobering because it illustrates how little we actually know about global biodiversity, and hence the challenge of defining what it is we are trying to conserve, and why. I started this abstract with the statement that insects dominate global species richness. Being entomologists, I suspect few readers questioned that opening comment. But is it true? What about nematode worms? The tiny number of studies that exist on the species richness of terrestrial nematodes suggests that this group could be staggeringly diverse. If as entomologists we feel neglected and unloved in the conservation beauty contest that exists between insects and the more charismatic birds and mammals, think what it is like to be a nematologist! I believe we can learn from this lesson. Nobody can be an expert on everything, but we need to remember that insects are not the be-all-and-end-all of the biosphere. Nematodes play vital, albeit still poorly understood roles in virtually all ecosystems. For instance, we have no idea how loss of nematode species might impact on vital soil processes. Much the same could be said about the progressive loss of almost any taxon as we relentlessly simplify the earth's biota. Poor pollination and impaired pest control are two possible consequences of reductions in insect species-richness, for example.

CONSERVATION OF BIODIVERSITY IS REALLY ABOUT DELIVERING A SUSTAINABLE BIOSPHERE

In other words, rather than single-mindedly focussing on the conservation of individual species, or particular taxa, we need to design robust conservation strategies that focus on all taxa, upon the integrity of ecosystems, and on the 'goods and services' provided by biodiversity that sustain the biosphere, and ultimately ourselves. This means moving beyond a protected area network mentality for conservation, to consider how we treat and manage the entire biosphere. Or, in less grandiose terms, to consider not only networks of protected areas, but also the nature of the surrounding areas in which the reserves are embedded, and in which most of humanity live out our daily lives. If, in fifty or one hundred years time, most creatures that you and I regard as 'interesting' are found only on reserves, leaving the greater landscape to rats, cockroaches and sparrows, we will have failed, however many species survive in total on earth. The most important message that entomologists can give to the world is that conservation of biodiversity is not ultimately about ensuring the survival of the spectacular (*Morpho* butteflies) or the bizarre (giant wetas, *Deinacrida*), significant as this undoubtedly is. Nor is it just about the survival of that minority of species blessed with scientific names, or those that are charismatic and easily loved. It is about delivering a sustainable biosphere, and with it a fighting chance for all organisms to survive to the end of this new century and beyond. We must strive for sustainable ecosystems. If we can achieve that goal, many of the species that enrich our lives will be able to look after themselves. With so many species of insects to care about, we really have no alternative.

Index terms: global environmental change; macroecology; metapopulation dynamics; reserve networks; sustainability.

THE IMPACT OF W. HENNIG'S 'PHYLOGENETIC SYSTEMATICS' ON CONTEMPORARY ENTOMOLOGY

N. M. Andersen

Zoological Museum, Univ. of Copenhagen, Universitetsparken 15, DK-2100 Copenhagen, Denmark

INTRODUCTION

Phylogenetic systematics comprise the principles and methods by which we reconstruct the evolutionary history (phylogeny) of organisms and transform this reconstruction into a biological classification of these organisms. Whereas the contingency between classifications of organisms and their evolutionary history had been known since Darwin, it was not until the middle of the last century that real progress was made in designing the tools for phylogenetic reconstruction. This important progress was in part initiated by the German entomologist Willi Hennig (1913-1976; biography, see Anonymous 1978; Schlee 1981), who clarified or redefined the goals of phylogenetic systematics in a book published in 1950: *Grundzüge einer Theorie der phylogenetischen Systematik* (Hennig 1950).

For various reasons did Hennig's 1950 *Gründzüge* remain virtually unknown outside German-speaking countries. One of few exceptions was Lars Brundin, a Swedish entomologist of high international standing, who was among the first to apply Hennig's phylogenetic systematics in works written in English (e.g. Brundin 1966). An extensively revised version of the 1950 *Grundzüge*, translated into English by D. Dwight Davis & Rainer Zangerl of the Field Museum of Natural History in Chicago, was published in 1966: *Phylogenetic Systematics* (Hennig 1966) and soon became the main reference to Hennig's 'phylogenetic systematics' although Hennig himself in 1965 published a short review-paper in English (Hennig 1965). The original, German text of the 1966-book was published in 1982 by Willi Hennig's son, Wolfgang Hennig (Hennig 1982).

PHYLOGENETIC SYSTEMATICS

Although Hennig recognised the shortcomings of the biological species definition when it comes to delimiting species in time, he nevertheless regarded species to be 'real' organisms. In discussing group-categories of higher order by which he meant supraspecific taxa (genera, families, orders, etc.), Hennig argued that if species are real, higher taxa can also claim some reality because they originate by speciation. Thus, higher taxa are real because they are in a historical sense identical to their stem species. Higher taxa originate by speciation where a stem species splits into two sister-species. Hennig decided that the methodologically best solution is to consider the stem species extinct at the speciation event. Following this view of how higher taxa originate, phylogenetic relationships must be defined through the recency of common ancestry. This lead Hennig to redefine the term 'monophyly': "Only those species groups – and it applies to all group categories of higher order – can be called monophyletic which can be traced back to a common stem species. . . It has to be added that monophyletic groups not only ought to contain species that are descendants of one common species, but they must also include all species that come from that stem species." (Hennig 1950: 307-308, translated). As an example of a widely recognised taxon that is not monophyletic in the strict sense, Hennig used the now famous case of 'Reptilia' (Hennig 1950: 257). The term 'paraphyletic' for this kind of non-monophyletic group was not used in the 1950 *Grundzüge*, but first appeared in the 1965-review and the 1966-book.

After having introduced a strict concept of monophyly, Hennig took the initial steps towards designing methods for reconstructing systems exclusively composed of monophyletic groups. He introduced the terms 'apomorphic' for relatively derived species and 'plesiomorphic' for relatively primitive species and occasionally also applied these terms for higher taxa. Hennig soon realised, however, that the concept of apomorphy and plesiomorphy only have meaning when applied to characters instead of taxa. The most important tool in phylogeny reconstruction was the differentiation of ancestral or primitive similarity, which Hennig called 'symplesiomorphy', from advanced or derived similarity, which he called 'synapomorphy'. Only the last kind of similarity can be taken as evidence of phylogenetic relationship. When applied to a group of species or higher taxa, synapomorphies are identified and used to join sister-groups into more comprehensive, monophyletic groups as presented in Hennig's well known 'argumentation plan of phylogenetic systematics' (e.g., Hennig 1965: fig. 3).

During his scientific carrier, Hennig earned a high reputation as systematic entomologist and first and foremost as a specialist on Diptera. He published about 100 original papers and books of which his *Die Larvenformen der Dipteren* (Hennig 1948-1952) and his contributions to Lindner's *Fliegeń der paläarktischen Region* are outstanding. He also became interested in fossil insects embedded in amber and believed - unlike many contemporary neontologists - that knowledge of extinct insects also is important to understanding relationships among living insects. This view penetrates Hennig's most important contribution to insect phylogeny, the book *Die Stammesgeschichte der Insekten* (Hennig 1969) which was translated into English in 1981. The impact of Hennig's 'phylogenetic systematics' on modern paleontology is very obvious in a recent text book by Andrew B. Smith (Smith 1994) and a case study by the present author (Andersen 1998).

EARLY OPPONENTS

The reception of Hennig's 'phylogenetic systematics' in the world community of systematists and other evolutionary biologists was slow and reluctant, especially in North America. During the 1950s and 1960s, biological systematics was dominated by the 'new

systematics', named after a book edited by Julian S. Huxley (1940) and forcefully promoted by a group of Harvard systematists headed by Ernst Mayr. The new systematists, or evolutionary systematists as they more commonly are called, focused on specieslevel problems and largely neglected the study of higher taxa which, in their opinion, are not objective in the same sense as species are. Hennig took a completely different position and concluded that higher taxa are as real as species because they are in a historical sense identical to their stem species, given, of course, that the higher taxa are strictly monophyletic.

Ernst Mayr assumed a critical attitude towards Hennig's 'phylogenetic systematics' which he called 'cladism' or 'cladistics' to emphasise that Hennig's phylogenetic system only conveys information about the splitting events in evolution (cladogenese), but not about the changes that take place in between splitting (anagenese) (Mayr 1969; Mayr & Ashlock 1991). Mayr's major point of criticism concerned the conversion of phylogenetic relationships into classifications by recency of common ancestry or the position of branching points on phylogenetic trees. In an exchange of viewpoints with Mayr in 1974 (Mayr 1974; Hennig 1974), Hennig carefully addresses and refutes the arguments presented, in particular the notion that a phylogeny cannot be transformed into a hierarchic classification, that monophyly cannot be defined precisely and is unimportant for reconstructing phylogenetic system, and that strict dichotomous branching is a necessary principle of cladistics.

NEW DEVELOPMENTS

Almost simultaneously with the publication of Hennig's 1966-book did a new field of systematics arose, numerical taxonomy or 'phenetics', which took the advantage of the rapid development in computer-assisted techniques for analysing large data sets (Sneath & Sokal 1973). Through the inovative works of James S. Farris (e.g., Farris et al. 1970; Farris 1972), it soon became obvious that Hennig's 'phylogenetic systematics' could be formalised in a way that is well suited for quantification and computerisation. From this amalgamation of cladistics and numerical taxonomy emerged an approach to phylogenetic reconstruction that most appropriately can be called 'quantitative cladistics' (Andersen 1999). Along with this development, the theoretical and methodological foundation of cladistics was elaborated and modified through the 1980s and 1990s (Nelson & Planick 1981; Maddison & Maddison 1992; Kitching et al. 1998) and the methods of quantitative cladistics were implemented in a number of programs for personal computers which are routinely used in modern systematics (Hennig 1988; Maddison & Maddison 1998).

The past two decades or so have witnessed an enormous development in 'molecular systematics', including studies of the evolutionary history of organisms as inferred from molecular data (Hillis et al. 1996). Whereas early methods in molecular systematics estimated genetic distances between organisms (and therefore are essentially phenetic), the Polymerase Chain Reaction (PCR) technique yields sequences of nucleotides in strands of DNA and RNA. Following the principles of phylogenetic systematics, molecular data can be treated as a set of characters, each with four states (A, G, C, T or U), which can be used to reconstruct phylogenies in the same way as morphological characters. Furthermore, by applying the methods of quantitative cladistics, molecular data from different genes may be combined with each other and with morphological characters to yield phylogenies based on total evidence (Andersen 1999).

CLASSIFICATION

One of the main goals of biological systematics is to construct a general reference system or classification. Hennig forcefully advocated that only a phylogenetic system can achieve that goal: "Making the phylogenetic system the general reference system for special systematics has the inestimable advantage that the relations to all other conceivable biological systems can be most easily represented through it. This is because the historical development of organism must necessarily be reflected in some way in all relationships between organisms." (Hennig 1966: 22-23). The structure of phylogenetic relationships is hierarchic and consequently a hierarchic classification is an adequate form for representation for the phylogenetic relationships between species. The phylogenetic system only recognises strictly monophyletic groups, that is groups containing an ancestral species and all of its descendants. The most important task of phylogenetic systematics is therefore to recognise and possibly eliminate non-monophyletic groups in classification.

Hennig's 1953 paper Kritischen Bemerkungen zum phylogenetischen System der Insekten was the first major publication in which he applied his 'phylogenetic systematics' outside his own special group (Diptera). In a recent review, Niels P. Kristensen (1995) evaluated the status of the systematics of insects (or hexapods) and, in particular, the impact of Hennig's 'phylogenetic systematics'. No one questions that groups like 'Apterygota', 'Thysanura', Hemimetabola, 'Orthopteria', 'Hemiptera-Homoptera', 'Microlepidoptera', and 'Hymenoptera-Symphyta' are non-monophyletic. The monophyly of the 'Entognatha', 'Psocoptera', 'Hemiptera-Auchenorrhyncha', 'Diptera-Nematocera', and 'Mecoptera' has also been seriously questioned. In general, phylogenetic studies have lead to a better understanding of the evolution of insects and to more 'natural' classifications. This is particularly the case in the Hemiptera-Heteroptera, Lepidoptera, social Hymenoptera, so-called higher Diptera, and in the Coleoptera. This trend is likely to continue through the united efforts of taxonomists, comparative morphologists, and molecular systematists, applying methods developed within the framework of Hennig's 'phylogenetic systematics'.

Recently, de Queiroz & Gauthier (1992) have proposed a 'phylogenetic taxonomy' which abandon the Linnean system of biological nomenclature and replaces taxon names with apomorphy-based definitions without Linnean types and ranks. The merits of such a system are currently under debate and only the future will show if it is viable.

ECOLOGICAL PHYLOGENETICS

Firmly based phylogenetic hypotheses are significant in answering questions on the evolution of ecological and behavioural traits in insects. In a phylogenetic system, sister-groups by definition have the same age of origin (but not necessarily the same age of differentiation) which allows meaningful comparisons. In one of the first studies of this kind, C. Mitter et al. (1988) made independent comparisons of species numbers across wide-ranging taxonomic groups of insects. In all cases were phytophagous groups more diverse than their non-phytophagous relatives.

Thus, by integrating phylogenetic and ecological information we can infer the evolutionary history of ecological traits through an approach most appropriately referred to as 'ecological phylogenetics' (Spence & Andersen 1994). Phylogenetic information can be used in two ways: (a) ecological and behavioural data about extant taxa are placed on phylogenies to reveal probable patterns of evolution and to determine the sequence of changes that generated these patterns; (b) comparative analyses may be corrected for effects of phylogeny to explicitly measure so-called phylogenetic constraints. These methods have applied successfully to ecological and behavioural problems in many insect groups as reviewed by Miller & Wenzel (1995).

A recent collection of papers edited by Philippe Grandcolas (1997), report several case studies where phylogenetic inference tells us a different story than expected. Halictine bees (Hymenoptera: Apidae) include several genera comprising both social and solitary species and seem ideal to test the selective advantage of eusociality in insects. However, phylogenetic analyses indicate that in most genera it is the solitary behaviour that is the evolutionary novelty and eusociality is ancestral (Packer 1997). In primarily winged insects, wing polymorphism is usually treated as a derived trait which has evolved in species using the most stable habitats. However, in northern temperate pondskaters (Hemiptera: Gerridae), phylogenetic inference has shown that the polarisation must be reversed, and that obligatorily winged species most probably have evolved from wing polymorphic species (Andersen 1997). Finally, a study of European *Polistes* (Hymenoptera: Vespidae) tests Emery's rule stating that social parasites are more closely related to their hosts than to each other. Cladistic optimisation of traits associated with social parasitism on a reconstructed phylogeny leads to the rejection of Emery's rule (Carpenter 1997).

CLADISTIC BIOGEOGRAPHY

Hennig's 'phylogenetic systematics' has also had a significant impact on historical biogeography. The general acceptance of continental drift has confirmed the idea that disjunct biotic patterns and geological patterns are due to the same events in earth history. The pioneering work by Brundin (1966) superimposed the disjunct distribution of southern hemisphere chironomid midges (Diptera: Chironomidae) upon reconstructed phylogenies and showed that observed patterns were more or less congruent with hypothesised relations between Gondwanian land areas now widely separated. Fused with cladistics, historical biogeography has now become 'cladistic biogeography' which holds great promise as an equal partner to paleontology and paleogeography in explaining the historical causes of the present distribution of insects (Humphries & Parenti 1999). As principles of biogeography have a permanent place in conservation biology, phylogenetic systematics also has impact on issues related to the 'biodiversity crisis', for example in providing phylogenetic information about regional biotas as one of the criteria for choosing which areas to preserve.

CONCLUSIONS

Hennig's 'phylogenetic systematics' undoubtedly was a very significant contribution to systematics. It is now widely recognised that Hennig's redefinition and clarification of the concepts of monophyly and phylogenetic relationships created a sound foundation for systematics in general. His second contribution was perhaps equally important. After decades of focussing on species-level problems, Hennig redirected the interest of systematists towards the study of higher taxa and the reconstruction of phylogenetic relationships between them (Richter & Meier 1994). Hennig's 'phylogenetic systematics' has a significant impact on contemporary entomology. A phylogenetic system is now almost universally accepted as the most useful general reference system for biology. It has been able to accommodate new developments in systematics, evolutionary biology, historical biogeography, and information technology, and has also been suggested to found a new practise in classification and nomenclature.

PLANT-INSECT INTERACTIONS - A SYNTHESIS

E.A.Bernays

Entomology Department, Univ. of Arizona, Tucson, AZ 85721, USA. E-mail: schistos@ag.arizona.edu

Background

The study of plant-insect interactions is necessarily multidisciplinary. Historically, however, the leaps forward have usually involved specific aspects of the interaction. In the early the 20th century, several biologists recognized the importance of plant secondary metabolites in host choice (e.g. Vershaffelt, Brues, Fraenkel) and in the 1950s and 1960s the mechanisms of host-plant choice by insects was a major focus of study (e.g. Kennedy, Schoonhoven, Dethier, Jermy, Ishikawa). The 1960s and 1970s saw a flowering of theories invoking the importance of chemical defenses in the co-evolution of plants and their associated insects (e.g. Ehrlich, Raven, Feeny, Rhoades and Cates). Other groups, meanwhile, were contributing to our understanding of broader community-level interactions (e.g. Janzen, Root, Strong, Zwolfer, Gilbert, Southwood, Price). Eventually, sophisticated studies of chemicals and their roles in interactions evolved, and the field of chemical ecology was born (e.g. Eisner, Berenbaum, Brattsten, Rosenthal, Rothschild).

More recently, a host of additional approaches have been added. Nutritional ecology (e.g. Scriber, Slansky, Simpson) phylogenetics (e.g. Mitter, Moran, Farrell, Pasteels), biogeography and genetics (e.g. Singer, Gould, Rausher, Via, Jaenike, Futuyma, Feder, Thompson, Mitchell-Olds) have all provided unique insights, and the impacts of other trophic levels in herbivory are now better appreciated (e.g. Gilbert, Lawton, Strong, Dicke, Stamp, Denno). Finally, it has become abundantly clear that plants are quite active participants in their interactions with herbivores (e.g. Coley, Bryant, Baldwin, Tumlinson, Tallamy, Karban).

In addition to these topics and many new researchers in them, important contributions now come from morphologists, neurobiologists, palaentologists and molecular biologists. My presentation will focus on some new and little-tested ways to think about and study the interactions of plants and insects. My attempt to explain the pertinence of these novel interactions will require that I draw together a number of the disciplines involved, though I cannot attempt to review the whole field.

Introduction

My principal focus concerns the insect rather than the plant and, in particular, on how insect neurobiology affects the plant-insect interaction at all levels. Behavior, including host plant-related behavior is an expression of neurobiology that is modified by many physiological factors. Limitations inherent to the nervous system constrain how much information may be processed and can influence choices made, attentiveness to diverse stimuli, and responsiveness to risk (e.g. of predation). Evolutionary adaptations of the sensory system and brain for accommodating these constraints may govern how host affiliations evolve. Changes in the nervous system as a result of experience may also affect fitness in different ways. Both genetically and environmentally based neurological traits may help explain patterns of herbivore-host associations and diet breadth.

Making a choice among plants

Insects searching for an acceptable host plant must first locate and identify the appropriate plant species. We know that the speed of host-finding may be important. There may be time limits for various reasons, while other ecological circumstances commonly impose a need for speed, such as when resources are rare or

VIII

scattered and predators make searching risky. The accuracy with which host taxa are selected, and individual plant quality assessed, are also important, especially for insects with narrow host ranges and specific nutritional requirements for larval development. If the speed, accuracy and quality of choices are all to be maximized by very small animals in a very complex sensory world, strong selection for efficient neural processing might be expected as might the adoption of high-contrast signals (Bernays & Wcislo, 1994).

The majority of insect species use a very restricted number of hosts that typically share characteristic phytochemicals, some volatile and some nonvolatile. A subset of these compounds seems to be of great importance for identification of the host (see Bernays & Chapman, 1984; Städler, 1992; Schoonhoven et al., 1998), and in some extreme specialists great sensitivity to one or a few host-specific chemicals totally dominates in host selection (e.g. Ferguson et al., 1983; Pereyra & Bowers, 1988; Roessingh et al., 1997). Plant taxa heavily endowed with relatively unusual chemicals or suites of chemicals (non-apparent plant syndrome of Feeny, 1975) are often hosts for relatively large numbers of specialist insect species (e.g.Berenbaum, 1983). In addition, specialists tend to be deterred more than generalists by non-host secondary metabolites. I will make the case that specialists benefit from the strong contrasts between cues from hosts and non-hosts.

Additional mechanisms for acceptance/rejection used by different insect groups may heighten perceived contrast in various ways. An insect's response to a chemical mixture may not be predictable based on its responses to each chemical separately. Specifically, interactions among chemical stimulants at the level of the chemoreceptors can result in major changes in concentration-response functions of particular stimulants, with deterrents reducing input from positive inputs and vice versa (e.g. Shields & Mitchell, 1995; Schoonhoven et al., 1998)). I will demonstrate how such interactions could potentially alter the total input from a mixture of conflicting inputs to either a clear positive or a clear negative signal. Such process may be important in producing the particular and synchronous firing of a suite of taste cells, that appears to occur in some beetles only when the requisite mixture of plant chemicals is present (Sperling & Mitchell, 1991). In addition, highly synergistic effects of multiple host compounds are seen in some cases (e.g. Städler & Buser, 1984; Spencer et al., 1999), Thus a variety of mechanisms can provide the clear signal needed for rapid decision-making in a highly complex chemical world. Data so far suggest that the predominant mechanisms vary among insect taxa. In any case, the mechanisms could influence the evolutionary lability of host associations, and the trajectory for a clade of insect herbivores evolving with respect to host affiliation.

Some herbivorous insects alter their preferences as a result of experience. In some cases this results from increased or decreased sensitivity of their chemoreceptors to certain metabolites (Renwick & Lopez, 1999). So far, such changes have been recorded in species that feed on plants in at least several genera and lead to increased acceptability of the experienced food, sometimes with a concomitantly decreased acceptability of other potential foods - once again, an increase in contrast between alternatives. Diet quality also alters relative acceptability of alternatives depending on nutrient need - a flexibility dependent on variation in the strength of inputs from different nutrient chemoreceptors (Simpson & Raubenheimer, 1993).

A minority of insect herbivore species are extreme individual generalists, apparently adapted to situations where food plant quality or abundance is variable or unpredictable, or to situations where the food plants may all be very rich in potentially noxious secondary metabolites. Such herbivores engage in food mixing, eating a variety of plants and frequently making choices about what to eat and what to ignore. Such food mixers often appear to be stimulated by novel chemicals, potentially reducing the inefficiency and complexity of decision making (e.g. Bernays et al., 1997).

Evidence for limited efficiency among generalists

Data will be presented from experiments with butterflies (Janz & Nylin, 1997), caterpillars (Bernays & Minkenberg, 1997), whiteflies (Bernays, 1999), aphids (Bernays & Funk, 1999) and grasshoppers (Bernays, 1998), indicating that having a choice of suitable foods reduces efficiency of foraging, and that the specialists have significant advantages. These benefits include the amount of time taken to reach the host plant, the times taken to make decisions to accept or reject potential food, the time taken to begin ingestion and the time spent in pauses during a meal. In addition, the degree of fidelity to the most suitable host in the presence of less suitable host species and genotypes and the ability to choose superior hosts in the presence of a choice of mixed-quality hosts are shown to be greater in specialists than relative generalists.

Fitness benefits of behavioral efficiency in host choice

Data will be presented indicating that efficient decision-making has positive fitness effects. This appears to be true for ovipositing insects not just with respect to limitation on time overall, but also for evasion of predation through rapid oviposition. Evidence will also be presented for costs associated with the poor quality decisions made by the relatively generalized Lepidoptera and Hemiptera due to reduced growth rate, reduced survivorship and reduced fecundity (Janz & Nylin, 199 7; Bernays & Minkenberg, 1997). Locomotor activity is known to be risky with respect to predator and parasitoid attack, and field studies demonstrate that predation may be 100x more likely during feeding than during resting (Bernays, 1997), thus illustrating fitness costs of with reduced feeding rates. In addition I argue that intermittent, hesitant, or picky feeding behavior and any kind of dithering is dangerous not only because it is conspicuous, but because an animal attentive to food-related activities is unlikely to be attentive to simultaneous environmental risks (Dukas, 1998).

Since protein is often at low concentration in leaves (especially older leaves) and the nitrogen requirements of insects tend to be relatively high, herbivores often compensate by eating large amounts. Not only is high quality food better for growth, but the risk of mortality via predation is reduced on nutritious hosts since less time must be spent feeding and vulnerable to predators. Indeed, perhaps the fitness advantage associated with predator avoidance exceeds that enjoyed due to increased growth rate. Safety and growth are important together of course at a larger time scale - feeding on high quality foliage may also reduce development time, reducing the lifetime risk.

Leaves present very diverse physical challenges, and highly diverse solutions have been found by insects through adaptations of mouthpart morphology. The frequency with which certain mandible types have evolved in separate insect lineages with similar types of food indicates the adaptive value of these structures (Bernays & Janzen, 1988; Bernays, 1991). Furthermore, evolution of mouthparts can be very rapid (Carroll & Boyd, 1992). In view of the ever-present risk of predation, structures that determine handling time may be under great selection pressure. Indeed, the preponderance herbivores that feed on young easily-handled leaves, is probably a matter of safety as much as nutrition.

Secondary chemistry of plants

Among the hundreds of thousands of phenols, alkaloids, terpenoids, iridoids, flavonoids, steroids, and other chemical compounds of plants have been the subject of considerable study (Rosenthal & Berenbaum, 1991). Many appear to have no effects at all on insect herbivores, while others stimulate feeding and/or growth. Some are sequestered, and of these many are clearly toxic in general and serve as plant defenses against many herbivores Such chemicals have often been considered toxic when close study demonstrated they were actually deterrent only, the effects on test insects due to starvation. Some herbivores, however, suffer

deleterious postingestive effects and perform poorly in some way, or learn to avoid the plant as a result of feeding on it and move elsewhere, both of which can be bad outcomes. In many cases, it is not at all clear whether an ability to deal with toxins has been lost, as suggested in the case of grass-feeding grasshoppers (Bernays, 1990), or whether the plants have evolved specific defenses against particular insect herbivores (Berenbaum, 1983). It seems likely that both scenarios occur.

Sequestering these secondary metabolites for defense against predators is also common among herbivores (Bowers, 1990). Besides clear and well-documented fitness benefits of sequestration in highly aposematic species, there are many more subtle cases, in which insects deposit chemicals in the cuticle yet are not warningly colored (Bernays et al., 1991), and others where they gain protection from predators as a result of the gut contents alone (Sword, 1999). Although such processes are not specifically relevant to the theme of neuroecology, they do highlight once more the crucial importance of natural enemies in the lives of insects on plants.

In this presentation, I will also emphasize the very important roles of plant secondary metabolites in signaling. First of all the remarkable diversity chemicals found among plant taxa and within individual plants allows potentially clear signals for every specialist herbivores at taxonomic levels from plant species to plant family (Bernays, 1996). That butterflies such as checkerspots home in on plants from multiple families, simply because of the presence of iridoid glycosides in host plants that are otherwise extraordinarily diverse physically and chemically (Bowers, 1983), is startling evidence of the influence of simple chemical signals on insect behavior. Evidence is beginning to suggest that such cases are not unusual. In addition, deterrence of non-host compounds, being greater for specialists, increases sensory contrast between host and nonhost.

Diversity and the association of insect and plant clades

It has become clear from both fossil studies (Labandiera, 1998) and molecular phylogenies (Farrell & Mitter, 1993) that among all the herbivorous insect groups studied, great diversification is historically associated with the expansion and increased diversity of angiosperms. Although this could arise through coevolutionary processes associated with arms races, I argue that it could be at least partly the result of herbivore tracking diverse genotypes in a plant population and subsequent speciation of herbivores on established plant host races or species.

The selective pressures on the sensory system and its central nervous projections, would favor those insects that match the fine tuning of their detection of distinctive signals with particular plant chemotypes, and would thus be acting through the agency of ecological risk. So, as plants changed and diversified chemically, insect herbivores, being so dependent on specific cues, also changed and diversified so that discrimination of signals from hosts could be maintained at maximum levels of contrast. In this way, vigilance for predators could be maintained at maximum levels. Evidence for tracking chemicals in this way has been demonstrated in one study of a group of beetles and their host plants (Becerra, 1997), and a model is presented to further illustrate this scenario.

Although I will make the case for tracking of chemotypes, it is not impossible for diversification of insect herbivores, driven by such neural processes, to result from coevolutionary processes. However, rather than invoking toxins, the currency would be in terms of signal information.

Plants as active players

The widespread occurrence of herbivory-induced chemical changes in plants (Karban & Baldwin 1997; Agrawal et al., 1999) will be discussed not only as a direct defense but also as an indirect one, that plays on the vulnerability of these small herbivores to multiple risks from predators and parasitoids. Plants may encourage mortality of herbivores by causing them to decrease vigilance. This could involve increased searching and foraging activity, intermittent feeding, and restlessness that is induced by unusual or increasing levels of ingested secondary metabolites.

Conclusions

The synthesis presented here depends on knowing the insect - understanding it as an organism. The details of behavior and physiology, especially neurophysiology, have suggested a theoretical approach to the study of insect-plant interactions, namely the constraints on neural processing and the diverse effects of these constraints in ecology and evolution. I believe that this approach will allow us to understand more about all aspects of the insect-plant interaction in a way that has been difficult in recent decades. The importance of avoiding anthropomorphism and subjectivity in the study of animals may have mitigated against the study of them as individuals with behavioral and neural limitations that impact every aspect of their lives.

CHEMICAL COMMUNICATION IN SCARAB BEETLES

W. S. Leal, Dept. Entomology, University of California, Davis CA 95616, USA, Email: wsleal@ucdavis.edu

Chemical communication involves the production and release of specific chemicals (semiochemicals) by the emitter, and the detection and olfactory processing of these signals leading to appropriate behavioral responses in the receiver (Roelofs, 1995). Chemical attraction is the major means of sexual recruitment in scarab beetles, in particular, rutelines and melolonthines. Females are normally the emitters and males the receivers, and in this case, the semiochemicals are referred to as sex pheromones. Male-released aggregation pheromones have also been reported for a few Dynastinae. Although a few studies have reported the chemical ecology of the dung beetles (Scarabaeinae), most of the emphasis by research programs on chemical communication in scarab beetles has focused on the subfamilies Cetoniinae, Melolonthinae, Dynastinae, and Rutelinae because of their economic importance as agricultural and/or turf pests. Largely, these research projects are aimed at the development of attractants (pheromones or food-type lure compounds) for possible applications in management programs. In my laboratory, we have taken a comprehensive approach to chemical communication in order to gain a better understanding of both the emitters and receivers and pave the way for the development of environmentally sound control strategies. On the one hand, we focused on the chemistry of the emitters (identification and synthesis of pheromones) and studied the biology, biosynthesis and physiology of pheromone production. On the other hand, we investigated the molecular mechanisms of the olfactory processing in the receivers.

PHEROMONE CHEMISTRY

Recent studies have led to the identification of the sex pheromones of various species in the subfamily Rutelinae and Melolonthinae (Leal, 1998). In general, the pheromones of the former are fatty-acid derived compounds, whereas the latter utilizes phenolic, terpenoid, and amino acid derived compounds. Two interesting exceptions to this general rule are the pheromones of *Heptophylla picea* and *Phyllopertha diversa*. Although belonging to the Melolonthinae, *H. picea* utilizes (R,Z)-7,15-hexadecadien-4-olide (Leal et al., 1996), most likely biosynthesized from stearic acid. On the other hand, *P. diversa* (Rutelinae) produces an intriguing alkaloid pheromone, which also has medicinal properties (Leal et al., 1997).

Utilizing pheromone blends that consist of just a few semiochemicals or even a single constituent, closely related species have attained isolated chemical communication channels and reproductive isolation (Leal, 1999a; 1999b). Species that have the same pheromone system are isolated either temporarily or geographically. Interestingly, *Anomala osakana* and *Popillia japonica* utilize enantiomers of a chiral pheromone (japonilure), with one stereoisomer being an attractant and the other a behavioral antagonist. *P. japonica* and *A. osakana* produce (R)- and (S)-japonilure, respectively (Tumlinson et al. 1977; Leal, 1996). The pheromone of one species is a behavioral antagonist for the other. It seems that this agonist-anatagonist activities of the enantiomeric pheromones have evolved as part of the isolation mechanism between these two species that share the same habitats in Japan. In general, scarab beetles can detect only the enantiomer produced by the conspecific females, but *P. japonica* and *A. osakana* have evolved the ability to detect both enantiomers, one as an attractant and the other as a behavioral antagonist (stop signal).

PHEROMONE BIOLOGY

Pheromone gland cells in *A. cuprea* females were identified as modified integumental epithelia of the terminal abdominal sclerites (Tada and Leal, 1997). The gland cells are composed of round pheromone secretory cells with canal structures bearing an end apparatus. On the other hand, we determined that in *Holotrichia parallela* the pheromone is produced in the posterior part of a ball-shaped sac exposed during female calling. Light microscope observation of the posterior part of the gland revealed a cuticular epithelium layer composed of columnar cells, which was assigned as the tissue involved in the pheromone production (Kim and Leal, 1999).

PHEROMONE BIOSYNTHESIS AND PHEROMONE REGULATION

A typical structure of the sex pheromone of rutelines is the five-membered gamma-lactones having a long unsaturated hydrocarbon chain, such as (R,Z)-5-(—)-(oct-1-enyl)oxacyclopentan-2-one (buibuilactone) and (R,Z)-5-(—)-(dec-1-enyl)oxacyclopentan-2-one (japonilure), which are pheromones for a number of species. Using deuterated precursors, it has been demonstrated that the biosynthesis of these compounds starts from saturated fatty acids (palmitic and stearic acid), involves their desaturation followed by stereospecific 8-hydroxylation, chain shortening and cyclization (Leal et al., 1999). Various scarab species have developed pathways to produce unique pheromone molecules by changing either stereospecificity or regiospecificity of the hydroxylation step. Anomala cuprea and Popillia japonica utilize the (R)-8-hydroxylase, whereas the hydroxylase of A. osakana is specific to the (S)-substrate. It seems that A. rufocuprea is devoid of the enzyme so it makes methyl Z-(5)-tetradecenoate (Tamaki et al., 1985). Pheromone biosynthesis in scarabs is regulated by a PBAN-like factor. The pheromone titer

in the glands of decapitated females dramatically decreased 24 hr after surgery, but it resumed after injection of the brain extracts from virgin females. The activity of the brain extracts is lost after treatment with proteinase K. Because BmPBAN is also active, characterization of the gene encoding the peptide was pursued by library screening and PCR. Hitherto, none of the molecular approaches led to the identification of the PBAN gene in scarab beetles. On the other hand, a bioassay-oriented strategy lead to isolation of the active peaks by reversed phase HPLC and ion-exchange chromatography. The small amount of the isolated peptide prevented any further characterization.

MOLECULAR BASIS OF OLFACTION

For their survival, insects heavily depend on their ability to detect chemical signals from the environment, which are buried in complex mixture of odors from a myriad of sources. This has been highlighted in the literature by their highly sensitive and selective olfactory systems for the detection of sex pheromones, particularly in Lepidoptera, which approach the theoretical limit for a detector. While minimal structural modifications to pheromone molecules render them inactive (Kaissling, 1987), a single molecule of the native ligand is reported to be sufficient to activate the pheromone-specific olfactory neurons in the antennae of the silkworm moth, *Bombyx mori* (Kaissling and Priesner, 1970). There is growing evidence in the literature that this inordinate sensitivity is achieved by a combination of the roles of various olfactory specific proteins, including odorant receptors, odorant-binding proteins, and odorant-degrading enzymes. In order to gain a better understanding of the molecular basis of olfaction, we aimed at identifying and characterizing the pheromone-degrading enzymes, studying the neurophysiological details of pheromone perception "in vivo," and isolating, identifying, and cloning the genes encoding the pheromone- and odorant-binding proteins. In order to elucidate the function(s) of these proteins, we have been conducting structural studies in collaboration with Jon Clardy (Cornell University) and Kurt Wuthrich (ETH-Switzerland).

PHEROMONE-DEGRADING ENZYMES

Antennal proteins from the extracts of several species of scarab beetles can degrade buibuilactone and japonilure, even those from species that do not use this group of compounds as their pheromones. In some cases there was only one metabolite, identified as the corresponding hydroxy fatty acid. It seems that the deactivation of the lactone signal is obtained by the opening of the lactone ring. Some species, however, degraded the pheromone into several more products. The esterase from *A. octiescostata* showed significant preference for (R)-japonilure over that of the (S)-enantiomer. This observation is consistent with the fact that this species produces only the (R)-enantiomers of the two pheromone components and it is anosmic to the (S)-lactones.

Analysis of the degradation products of the unique pheromone from *P. diversa* revealed that only the antennal extract of this species can degrade the pheromone. The antennal extracts from 10 other scarab species and 4 lepidoptearn species produced no activity at all. Separation of the antennal extracts showed that the enzymatic activity was associated with the membrane fractions in the absence of cytosol. Analysis of the degradation reaction suggested that the major degradation product was due to a demethylation at the N-1 position; the second product was due to hydroxylation of the aromatic ring. Studies on the degradation along with potential cofactors or inhibitors showed that the enzymatic system requires NADPH and NADH for activity. On the other hand, the enzymatic activity was inhibited by proadifen and metyrapone, two general widely used inhibitors for cytochrome P450 (Wojtasek and Leal, 1999).

DEGRADATION OF PHEROMONES "IN VIVO"

The discovery of the unique pheromone-degrading enzyme in *P. diversa* and the identification of enzymatic inhibitors opened the way to study pheromone inactivation "in vivo." When metyrapone was introduced by diffusion into the pheromone-specific sensilla in the antennae of *P. diversa*, the pheromone detectors became "silent" to lower concentrations after application of a large concentration of the pheromone. The effect of the inhibitor is remarkably different from adaptation as will be discussed later. In addition, metyrapone treatment had no effect on the sensila of *P. diversa* tuned to (Z)-3-hexenyl acetate nor did it affect the pheromone-detecting systems in *P. japonica*, for which pheromone inactivation is achieved with a sensillar esterase.

IDENTIFICATION AND CLONING OF OBPs

We have identified, cloned, and characterized the odorant-binding proteins from a number of scarab species. It is now clear that scarab beetles possess two families of odorant-binding proteins, one with 116 and the other with 133 amino acids, which we named OBP1 and OBP2, respectively. While OBP1 is well conserved among all species of scarab beetles, OBP2 belongs to a more diverse group and, in contrast to OBP1, it has not been detected in all species. Interestingly, OBP2 possesses isoforms, which can be separated by native gel electrophoresis. These isoforms have different binding affinities. For example, one isoform of OBP2 from *P. diversa* binds bombykol, whereas the other conformation binds japonilure (Wojtasek et al., 1999). Microheterogeneity of the OBPs in scarab beetles is not derived from different gene products, but it is due to the conformational flexibility of the proteins. Consistently, we found only one gene encoding OBP2 in various species.

Plenary Lectures

Interestingly, in both *A. osakana* and *P. japonica*, we could detect only one PBP in the antennal extracts; the proteins from the two species showed a 96% similarity. Due to the limited sensitivity of the detection methods, one cannot rule out the possibility of the presence of proteins expressed at low levels. However, electrophysiological experiments suggest that if two PBPs were involved in the signal transduction of the enantiomers of japonilure they would be expressed at nearly the same level. Single sensillum recordings from the antennae of the Japanese and Osaka beetles showed that enantiospecific receptor neurons respond equally to (R)- and (S)-japonilure. These findings and the observation that a single PBP from *A. osakana* bound both enantiomers of japonilure apparently with the same affinity suggested that in the antennae of these species, the same PBP may recognize both the pheromone and the "stop signal", i.e., the enantiomers of japonilure (Wojtasek et al., 1998).

STRUCTURAL BIOLOGY AND FUNCTION OF PBPs

We envisaged that in order to determine the molecular basis of insect olfaction and elucidate the function of PBPs, we needed to study the three-dimensional structure of the pheromone-binding proteins and its interaction with ligands. We embarked in collaborations with two groups (Jon Clardy and Kurt Wuthrich) to determine the 3D crystal and solution structures of the pheromone-binding protein from *Bombyx mori*. Functional expression of BmPBP was achieved in *E. coli* periplasm. The protein appeared as a single band in gel electrophoresis and it was homgeneous in most chromatographic systems. However, NMR experiments conducted by the Wuthrich group indicated the existence of at least two conformations at pH 6.2. Throughout the analysis of both the native and recombinant proteins, a remarkable feature of the PBPs appeared. These proteins have dynamic structures, altering their conformations in pH-dependent ways. Studies with model membranes suggested that upon an interaction with the dendritic membrane, PBPs undergo a conformational change that may lead to the release of the pheromone ligand (Wojtasek and Leal, 1999).

The three-dimensional structure of the BmPBP with bound bombykol has been determined by X-ray diffraction (Sandler et al., 2000). BmPBP has six helices, and bombykol binds in a completely enclosed hydrophobic cavity formed by four antiparallel helices. Bomkykol is bound in this cavity through numerous hydrophobic interactions. It has been suggested that a pH drop would result in protonation of the histidine residues that form the base of a flexible loop and protonated histidines could destabilize the loop covering the binding pocket.

Although the crystal structure did not show clear evidence for dimers, a comprehensive study (Western immunoblotting experiments, mass spectral analysis, gel filtration estimation of molecular masses, and cross-linking reactions), showed that BmPBP is a monomer at acid pH and a dimer at basic, neutral, and slightly acid pH. This suggests that the physiologically relevant pH for the early olfactory processing is not only that of the sensillar lymph (bulk pH), but also the pH at the surface of the dendrides (localized pH) (Leal, 2000).

ACKNOWLEDGMENTS

I gratefully acknowledge the great contribution that my past and present collaborators and members of my research group made to this work. My research projects in Japan were financially supported by a special coordination fund for promoting science and technology by the Science and Technology Agency of Japan and by the Programe for Promotion of Basic Research Activities for Innovative Biosciences (BRAIN). Work in the US was made possible through direct financial support from the department, college, and Chancellors office at UCD.

TRANSGENIC PLANTS; AN ENVIRONMENTALLY-FRIENDLY METHOD OF PEST CONTROL?

A. M. R. Gatehouse¹ & J. A. Gatehouse², 1 Agric. & Environmental Science, Univ of Newcastle, Newcastle NE1 7RU, UK. 2 Dept Biological Sciences, Univ. of Durham, Durham DH1 3LE, UK.

With a projected increase in world population of 9-10 billion over the next four decades, an immediate priority for agriculture is to achieve maximum production of food and other products. Unfortunately the price for achieving such levels can be too high, with irreversible depletion or destruction of the natural environment making certain agricultural practices unattainable in the longer term. Whilst pesticides are very effective in combating the immediate problem of insect attack on crops, and have been responsible for dramatic yield increases in crops subject to serious pest problems, non-specific pesticides are harmful to beneficial organisms including predators and parasitoids of those target pest species. In response to public concerns, the agrochemical industry has introduced a number of less harmful and less persistent pesticides. The emergence of technologies that have allowed plants to be stably transformed with foreign genes has been timely, with the commercial introduction in 1996 in US of crops expressing genes encoding the insecticidal δ -endotoxin from *Bacillus thuringiensis*. Although not as yet a commercial reality, other strategies for engineering crops to give endogenous resistance to insect pests, such as the use of plant-derived genes encoding defensive proteins (enzyme inhibitors and lectins), genes encoding other insecticidal proteins, and novel solutions such as manipulating plant secondary metabolism, are actively being pursued. Combinations of these and other emerging transgenebased crop protection methods will increase both the range and durability of resistance. To avoid the possibility of pests becoming resistant to transgenic insect-resistant crops, and for a variety of other reasons, deployment of transgenic insect-resistant crops is taking place as part of a recommended stratgey of integrated pest management (IPM); consequently, the engineered crops must be compatible with the other components of IPM. Thus ideally, genes expressed in transgenic plants for control of pest species should at the same time produce no directly deleterious effects on beneficial insects (predators and parasitoids) which play an important role in biological control. Inevitably, the removal of the host or prey for beneficial insects will be deleterious, but any toxic effect of the transgene product will decrease the viability of biological control. It may also indicate that widespread use of transgenic crops could have undesirable ecological consequences, such as global reductions in beneficial insect populations; however, it is important that the effects of such crops on beneficial organisms are compared with the effects of current agricultural practices. This paper will discuss the role of GM crops in agricultural systems and their potential environmental impact on natural enemies of insect pests, and will consider both the deployment of Bt expressing crops, and those expressing a range of plant-derived genes.

MESOZOIC RADIATIONS OF THE INSECTS AND ORIGINS OF THE MODERN FAUNA

David Grimaldi Department of Entomology American Museum of Natural History Central Park West at 79th Street, N. Y., New York 10024-5192 USA E-mail: grimaldi@amnh.org

ABSTRACT

Insects are among the earliest terrestrial organisms, with a fossil record extending to the Devonian, pterygotes appearing in the Carboniferous, and some modern orders in the Paleozoic. In the 400 million years since the earliest hexapods, they have proliferated into the most diverse group of organisms in the entire Phanerozoic. Extensive radiations of modern faunas, however, did not occur until the Cretaceous (140-65 Ma), based on diversification of speciose, ecological keystone groups: Isoptera, cimicomorphan and pentatomorphan bugs, phytophagan beetles, aculeate wasps, cyclorrhaphan flies, and glossatan moths. These groups alone today represent well over half of all insect species, and their diversification can be related directly or indirectly to the angiosperm radiations in the mid Cretaceous (90-110 Ma). This scenario is in contradiction with the hypothesis by Labandeira and Sepkoski, that the angiosperm radiations had little or no effect on insect diversity in the Cretaceous. Differences in the two hypotheses are due to analyses of past diversity using the taxic approach (used by Labandeira and Sepkoski) and the phylogenetic approach, the latterespoused here.

Introduction

Twenty-four years ago, at the XVI International Congress of Entomology, the late Professor Frank Carpenter outlined the state of knowledge on the geological history of insects. He stated in the Proceedings (pg. 63) "...our knowledge of fossil insects has more than doubled during the past 30 years." Nearly 30 years later, that statement still holds true, particularly for discoveries of insects from the Mesozoic Era (230-65 Ma), but also with respect to theoretical and empirical developments in systematics, both molecular and morphological. Carpenter's review appeared six years after Willi Hennig's original, German edition of Die Stammesgeschichte der Insekten; the English, annotated edition (Insect Phylogeny) appeared in 1981, and promoted Hennig's synthesis much more widely. Although contemporaneous with Hennig, Carpenter was extremely conservative in the classification of living and fossil insects (Carpenter, 1992; Carpenter and Burnham, 1985; Carpenter, 1997). His approach was not cladistic; a result of which was the adoption of paraphyletic Martynov-Crampton taxa, such as "Apterygota," "Paleoptera," and "Endopterygota." Carpenter's conservatism had some advantages, though: he was very cautious not to over-interpret fossils, so his classifications were not highly hierarchical, and he discouraged the naming of new higher taxa in lieu of substantial evidence. Despite the fact that the fossil record of insects is relatively incomplete compared to that of vertebrates and marine invertebrates, for Carpenter and many others, the fossil record was virtually necessary for deciphering the evolutionary history of insects. For Hennig, completely preserved extant taxa would always provide the basis for phylogenetic studies of insects, and thus for understanding evolutionary histories. He spent, however, the last 15 years of his life largely with the study of Diptera in amber, along with living relatives of those fossils. His Insect Phylogeny is devoted largely to Paleozoic and Mesozoic insect fossils. With a cladistic framework established largely from living taxa, and given sufficient number and preservation of insect fossils, Hennig maintained that the "true phylogeny" could then be unraveled. This approach, unfortunately, has rarely been adopted in paleoentomology.

Within the past two to three decades there have been several very significant individual works, each representing a "quantum leap" in the study of insect paleontology. Besides Hennig's 1981 book, perhaps the

most significant work was Carpenter's 1992 Hexapod fascicle for the *Treatise on Invertebrate Paleontology*. It assembled an extremely arcane literature (up to 1984) that was widely scattered among entomology and geology. Also significant was the 1991 English translation of B.B. Rohdendorf's Arthropod volume of the *Fundamentals of Paleontology*; this edition of the 1962 Russian original allowed an accurate understanding of the extensive older Russian literature. Ironically, the study of insect fossils has its firmest foundation thus far in various studies of modern orders. Niels P. Kristensen (e.g., 1975, 1991, others) has focused exclusively on modern taxa, but the care and comparative extent of his research and his assessment of published data has set a standard far exceeding that of Hennig's work. Recent studies have generated abundant new molecular data on higher relationships in insects. These studies have stressed analyses of "total" (morphological and molecular) evidence (Whiting et al., 1997), although virtually all of the morphological data derives from the papers of Kristensen. With the exception of a few, enigmatic taxa like the Strepsiptera, these large molecular studies have been unable to substantially modify the hypotheses of Kristensen.

Methodology

There are several methods with which to examine the past diversity of insects, principally the taxic and phylogenetic approaches. In the former, taxa like genera and families are treated as equivalent historical units across all groups, and changes are examined in taxon number over time. The phylogenetic approach treats each group as a separate lineage, and focuses on the cladistic position of fossils. The study by Labandeira and Sepkoski (1992) examined the ordinal and family-level diversity of insects throughout the entire history of the Class; it is a widely cited paper that is a classic example of the taxic approach; another taxic study of insect history is by Jarzembowski and Ross (1996). Several patterns proposed by these studies were: the impact on insects incurred by the Permian/Triassic extinctions (the largest extinction event for all organisms in the Phanerozoic); a general lack of extinction of insect families through the Cretaceous/Tertiary boundary; and minimal effect of the angiosperm radiations on the diversity of insects. As I will elaborate below, angiosperm radiations had a dramatic impact on the radiations of insects, if the fossil record is analyzed phylogenetically. Smith (1994) compared attributes of the taxic and phylogenetic approaches, the main drawback of the former being substantial effects due to an indifference towards, and use of, paraphyletic groups. For a paraphyletic group, patterns of historical diversity can appear "bottom heavy" (that is, particularly diverse in nascent stages), and the latest fossil record for that "group" is not an accurate index of extinction. The so-called Protorthoptera, for example, are a paraphyletic group comprising primitive, extinct orthopteroid insects, to the exclusion of the Orthoptera. "Extinction" of the Protorthoptera in the Triassic is illusory, since one lineage derived from it (i.e., the Orthoptera) actually continued to flourish, much the way birds did after the demise of the rest of the dinosaurs. With the taxic approach, mass extinctions can be exaggerated. Another unrealistic assumption of the taxic approach is the equivalence of a taxonomic category (e.g., genera, families) among different groups (e.g., orders). Rank, of course, is inconsistently applied among groups and greatly affected by taxonomic conventions. The many families of lower Mesozoic Diptera described by Rohdendorf (1964), for example, are now being dramatically revised by the modern Russian paleoentomologists. Only the phylogenetic approach is capable of range interpolation and discerning gaps in the fossil record. There is, in general, a remarkable correspondence between the rank of a clade and its stratigraphic position for many groups of organisms throughout the Phanerozoic (Benton et al., 2000); marked departures from the correlation are powerful predictors of insufficient stratigraphic sampling.

Cladistic analyses employ parsimony in order to optimize a scheme of character evolution; so the number of characters has a great impact on the results of an analysis. As such, it is not at all surprising that cladistic analyses based on much more complete living taxa have dominated systematic entomology and the classifications of insects. But, some fossils are much more complete than others. Insects from the Upper

Triassic of Virginia, USA, for example (Fraser et al., 1996), are preserved in an extremely fine-grained shale that preserves even microtrichia, but they are entirely two-dimensional. No fossilization can compete with the exquisite, life-like preservation in amber, which preserves external and soft internal morphology with fidelity (Grimaldi, 1996). Much of my work has focused on insects in amber, in order to have as complete an array of fossilized characters as possible. Such preservation strengthens the phylogenetic interpretation of extinct taxa. Preservation in amber biases against larger insects that could extract themselves from the miring resin, but tiny insects (<3-4 mm) are the most diverse, and amber preserves components of faunas rarely seen in compression deposits. No pre-Cretaceous amber insects are known thus far, and any found are likely to be very rare.

Mesozoic Radiations

Cuticular remains of primitively wingless hexapods occur in the Devonian (400-360 Ma). By the Carboniferous, 300 Ma, 14 orders appeared, including the Ephemeroptera, Protodonata, Paraplecoptera, Orthoptera, and the extinct, beaked insects in the paleodictyopteroid orders. By the Permian, 14 other orders appeared, some of which were short lived, and others, like the Coleoptera, endured to the present. A Paleozoic history is reviewed by Kukalová-Peck (1991)(but see also Willmann [1997]). The Permian was clearly a period of impressive radiation of basal clades of insects. Numerous Paleozoic records exist of welldocumented insect-plant interactions, as based on feeding damage and structure of insect mouthparts (reviewed by Labandeira, 1998a). Despite an ancient and intimate association of insects and plants, Labandeira and Sepkoski (1993) concluded from their taxic analysis of insect families that diversity was unaffected by the radiations of the angiosperms that occurred in the mid-Cretaceous (Crane et al., 1995). This hypothesis is probably an effect of taxic analysis, and it also does not account specifically for those insect groups that depend today on angiosperms. Insects infiltrated several "adaptive zones" in the Mesozoic, among the most significant being freshwaters (Ponomarenko, 1996; Pritchard et al., 1993; Wootton, 1988), breeding in carrion (Grimaldi and Cumming, 1999), and vertebrates ectoparasitism (e.g., Borkent, 1995, 1996)(see also Labandeira, 1998b). Here, however, I am focusing on the origins of the predominant adaptive zone of modern insects: their association with angiosperms through herbivory and pollen+nectar feeding. A phylogenetic treatment of the history of insect pollinators was provided elsewhere (Grimaldi, 1999), parts of which I refer to below.

DICTYOPTERA. Relationships based on studies of DNA and morphology of the Mantodea, Blattaria, and Isoptera are currently contentious (e.g., Kambhampati, 1995; Thorne and Carpenter, 1992; Klass, 1995). The geological record is inconsistent with the apparent cladistic relationships of these orders, in that Mantodea and Isoptera have much younger records than the Blattaria. By Blattaria, I refer specifically to the extant group of roaches that possess a highly vestigial, internalized ovipositor (Klass, 1995); as distinguished from the Blattodea s.l., which include those Paleozoic and Mesozoic roach-like insects possessing an ovipositor. The Blattaria apparently had their origins in the Triassic and appear to have derived from some group within the Blattodea s.l. (Grimaldi, 1997), which would help explain the discrepancy in cladistic rank among living dictyopteran orders and their fossil records (Grimaldi, 1997). The oldest mantises are from the Upper Jurassic of Eurasia and the Cretaceous of several continents. The oldest, Cretaceous Isoptera are primitive Hodotermitidae, Termopsidae, and possible Mastotermitidae; the extant derived families Kalotermitidae, Rhinotermitidae, and Termitidae did not appear until the Tertiary (reviewed in Thorne et al., 2000). Indications are, thus, that origins of the Isoptera were no earlier than the Upper Jurassic. Cretaceous termites are uncommon and Tertiary fossils of them usually common, indicative also of much greater ecological success in the Tertiary. This chronology reflects the evolution of grasses in the mid-Tertiary (Jacobs et al., 1999); grasslands today comprise one-third of the earth's vegetative cover. Radiation of

Plenary Lectures

grasses probably fueled the impressive diversification and biomass of grass-feeding termites in savanna and prarie ecosystems.

THYSANOPTERA. The oldest definitive thrips is a very primitive genus, as yet undescribed, from the Upper Triassic of southern Virginia (Fraser et al., 1996). It is very similar to *Jurassothrips*, from the Jurassic of Eurasia, and another undescribed genus in mid-Cretaceous amber from New Jersey USA. All have wings that are broader and with a venation more complete than any other thrips; they possess some venational apomorphies of the Thysanoptera, as well as the wing fringe. All Mesozoic thrips known thus far in Cretaceous ambers from Burma, Canada, Lebanon, New Jersey, Siberia, and Spain, are no more derived than the extant Merothripidae. This is a small cosmopolitan family of mycelial-feeding species, and the apparent sister group to all other thrips (Mound et al., 1980). The Eocene Baltic amber contains the first evidence of modern families like Aeolothripidae, Heterothripidae, Thripidae, and Phloeothripidae (most of which feed on higher vascular plants), indicating that origins of modern groups of thrips did not occur until sometime in the Cretaceous.

HETEROPTERA. Interpreting the fossil record of this group has benefited greatly from recent cladistic work (e.g., Schuh and Slater, 1995). Unfortunately, relationships among the "Homoptera" (Auchenorrhyncha and Sternorrhyncha) are not nearly as well understood, even though homopterans have a more extensive fossil record that extends to the Permian. Homopterans are also one of the major groups, besides Lepidoptera and Phytophaga beetles (below), that are entirely phytophagous or virtually so, so their evolution is likely to be intimately related to the evolution of plants. Many heteropterans, however, are predacious (particularly the basal lineages), and even mycophagous. The oldest definitive heteropterans are gerromorphs and nepomorphs from the Upper Triassic and Lower Jurassic (e.g., Fraser et al., 1996; Grimaldi and Fraser, 2000); like living relatives, they were almost certainly freshwater predators. The most primitive infraorders, the Enicocephalomorpha and Dipsocoromorpha, have an incomplete fossil record that doesn't extend beyond the Lower Cretaceous. The earliest phytophagous heteropterans are Cimicomorpha and Pentatomorpha from the Upper Jurassic of Karatau and the Cretaceous (Popov, 1986; Grimaldi, 1990). These two infraorders are the most speciose groups of the Heteroptera, and most species are phytophagous on angiosperms, so diversification was probably greatly affected by radiations of the angiosperms in the mid Cretaceous, as the fossil record suggests.

DIPTERA: This order is abundant and diverse in fossil sediments of lacustrine origin, and the oldest definitive flies are found in the Triassic of Kyrgystan, Australia, France, and Virginia (USA)(the attribution of Permotipula to the Diptera [Willman, 1989] being unlikely [Shcherbakov et al., 1995]). A taxic-based account of Mesozoic Diptera would conclude that the order was extremely diverse, with 76 Mesozoic families, but this is very inflated because of Rohdendorf's (1964) taxonomy. By the Triassic and Jurassic, though, Tipulomorpha, Ptychopteromorpha, Psychodomorpha, Culicomorpha (especially Chironomoidea), and Bibionomorpha were present, as well as several families whose affinities are not entirely clear. Interpretation of the early dipteran fossils is currently compromised by confusion over relationships of the nematocerous Diptera (Wood and Borkent, 1989; Oosterbroek and Courtney, 1995; Michelsen, 1996; Shcherbakov et al., 1995; Yeates and Wiegmann, 1999). Notwithstanding, there are several significant features of the early fossil record of the Diptera: A. A recent, well-supported scheme hypothesizes that the extinct, Triassic-Jurassic "family" Procramptonomyiidae is a paraphyletic stem-group to the living groups Cramptonomyiidae, Pachyneuridae, Anisopodidae s.l., and the Brachycera (Coram and Jarzembowski, 1999). B. The Anispodidae s.l., and Mycetobiinae in particular, are among the most ancient Diptera, and even hypothesized to be the living sister group to the Brachycera (Shcherbakov et al., 1995). Identity of the oldest brachyceran is controversial. Krzeminski (1992) placed the Viriginia Triassic fossil Alinka (Alinkidae) as the first brachyceran. It is certainly not a true brachyceran since the multisegmented antennae have filiform flagellomeres (Stuckenberg, 1999). Also, Shcherbakov et al. (1995) and Fraser et al. (1996)

indicated that, on the basis of venation, that *Alinka* is actually in the Procramptonmyiidae or thereabouts. The oldest definitive brachyceran is from the Lower Jurassic, *Protobrachyceron*. C. The evolution of biting (bloodsucking) culicomorphan midges is largely a Cretaceous phenomenon, with their earliest origins in the Upper Jurassic. Only very primitive Simuliidae, Ceratopogonidae, and Culicidae occur in the Cretaceous; phlebotomines were diverse by the lower Cretaceous (Azar et al., 2000). Studies by Borkent (1995, 1996) indicate remarkably good correlation between clade rank and stratigraphic age of Ceratopogonidae preserved in various Cretaceous ambers. Vertebrate blood feeding, at least by extant ectoparasitic insect groups, is relatively recent in the history of tetrapods.

Relationships of extant lower Brachycera are better understood than for nematocerans (Woodley, 1989; Yeates, 1994; Sinclair et al., 1994). Rhagionids were diverse in the Jurassic and Cretaceous (e.g., Grimaldi and Cumming, 1999). Nemestrinidae with long proboscides from the uppermost Jurassic may have been the earliest obligate pollen feeders and pollinators (Ren, 1998; Grimaldi, 1999). Cretaceous ambers have yielded a remarkable diversity of Eremoneura, especially Empidioidea (25 genera) and the oldest Cyclorrhapha (Grimaldi and Cumming, 1999). In Lower Cretaceous amber from Lebanon are the oldest and most plesiomorphic members of the Ironomyiidae, Lonchopteridae, Platypezidae, and Sciadoceridae; the oldest Phoridae occur in slightly younger amber from the Lower Cretaceous of northern Spain. An unusual genus of Eremoneura occurs in Lebanese and Spanish amber, *Chimeromyia*, which has features of Empidoidea and Cyclorrhapha. Cretaceous ambers have also revealed a strikingly diverse fauna of microphorines (Empidoidea), which is a group that is clearly relict today. With the exception of a fossil pupa of controversial age (putatively Upper Cretaceous), the oldest Schizophora did not appear until the Tertiary. The oldest and most diverse fauna in the Tertiary is in Eocene Baltic amber (Hennig, 1965). The Baltic amber Schizophora all represent modern families, but virtually all are primitive at generic levels. Indications are that the radiation of some 50 Schizophora families did not occur until the Paleocene.

HYMENOPTERA. Like Heteroptera and Diptera, interpreting the fossil record of Hymenoptera is vastly improved by good understanding of phylogenetic relationships among living families (Brothers, 1999; Gibson et al., 1999; Ronquist et al., 1999). Comprehensive paleontological work on the order is by Rasnitsyn (e.g., Rasnitsyn, 1988, for summary). The oldest fossil wasps are Xyeloidea from the mid and Upper Triassic of Australia and Eurasia. This is consistent with position of the living Xyeloidea as the sister group to all other Hymenoptera. Other primitive, symphytan wasps appear in the Jurassic. Extant xyeloid larvae feed predominantly on conifers, as do diprionids and anaxyelids, but major evolutionary shifts of host use in symphytans are obscure since many symphytans also feed on angiosperms. By the mid and Upper Jurassic there occur various families of lower Apocrita, like Anomopterellidae, Ephialtitidae, Jurapriidae, Karataidae, Praeaulacidae, and primitive megalyrid-like taxa (Rasnitsyn, 1988). Their relationships and ovipositor structure indicate that most (probably all) were parasitoids, especially of wood-boring insects. The oldest aculeates are the extinct family Bethylonymidae, from the Upper Jurassic and lowermost Cretaceous. Evolution of the Aculeata, then, has taken place virtually entirely within the Cretaceous and Tertiary. Not only does this encompass an impressive number of families, but also includes several of the most ecologically important groups of insects. The oldest ants include a primitive ponerine and the Sphecomyrminae (monophyly of the latter doubtful) in 90 Ma amber from New Jersey, USA (Grimaldi et al., 1997); sphecomyrmines and other primitive ants also occur later in the Cretaceous. Ants today, some 14,000 species, are an ecological keystone group, particularly in the tropics, and their origins certainly did not extend beyond the upper part of the Lower Cretaceous. They must have undergone a spectacular radiation in the Lower Tertiary, which is revealed best by the rich fauna in Baltic amber. Bees are a very special case. The Apidae sensu lato is one of the largest and most successful families of insects (ca. 20,000 species), and virtually all bees feed obligately from flowers. There is, however, only one record of ambiguous Cretaceous age (Michener and Grimaldi; Engel, 2000); Grimaldi (1999) hypothesized that the amber fossil originated from latest Cretaceous (Maastrichtian) strata. Like the ants, the first impressively
diverse and well preserved assemblage of bee fossils occurs in Baltic amber, now under monographic revision (Engel, 2000.). All bee genera and most tribes in Baltic amber are extinct. In the context of the fossil record for the sphecoid relatives of bees and aculeates in general, which is fairly extensive throughout the Cretaceous, the time of origin of bees must be constrained to the upper part of the Lower Cretaceous. Clearly the mid Cretaceous angiosperm radiations greatly affected the diversification of bees, and vice versa. The ecological success of ants and some bees (only some are social) is due at least in part to their sociality, which greatly increases the efficiency of resource utilization and, thus, competitive ability. Why the origins of eusociality in the three major groups of insects (ants, bees, and termites) coincided in the Cretaceous is unclear.

COLEOPTERA. Higher-level relationships within the Coleoptera are the least understood of all the major orders of insects. This fact, plus the general lack of wing venation characters compromises full interpretation of fossil Coleoptera. Yet, some coarse and important evolutionary patterns are apparent. Archostemmatan cupedoids were clearly among the first on the scene and quite diverse in the Permian and Triassic; today they are relict. Primitive adephagans and even some polyphaga like Staphylinidae appeared by the Triassic (Fraser et al., 1996; Grimaldi and Fraser, 2000). The earliest "Phytophaga" (Curculionoidea and Chrysomeloidea), which comprise well over half of all beetles, originated in the Triassic (Curculionoidea: Obrienidae). By the Jurassic, definitive weevils and putative chrysomelids are quite diverse (Arnoldi'i et al., 1991). Farrell (1998) addressed the phylogeny of the Phytophaga using sequences for the 18S rDNA gene and 115 exemplar genera, and 212 morphological characters from other sources. On the basis of this phylogeny several patterns were apparent: A. The most primitive living clades of weevils and chrysomeloids are conifer feeders, including araucarians. B. Species diversity among clades is highly correlated with angiosperm feeding, indicating yet another example of where the angiosperm radiations had a major impact on the diversification of insects.

LEPIDOPTERA. This is the largest clade of phytophagous insects; rare appearances of fungivory, coprophily, and even parasitism are obviously secondarily derived. A recent review of the Mesozoic history of the order was presented by Grimaldi (1999), based on phylogenetic results of basal Lepidoptera by Kristensen, Nielsen, and Davis (op. cit.), and some 20 records of Mesozoic Lepidoptera. The oldest *definitive* lepidopterans appear to be several genera from the Upper Jurassic of Eurasia. All Cretaceous Lepidoptera sufficiently preserved to display critical features (e.g., wing scales, mouthparts) occur mostly in amber, and these are all either primitive mandibulate moths or basal glossatan ("tongued") moths. Lepidoptera is apparently the most recently evolved insect order, and it clearly explosively radiated in the Upper Cretaceous and even the Tertiary, doubtless due to the angiosperm radiations.

Conclusions

Interpreting the fossil record is a highly imprecise science. Historical hypotheses are greatly influenced by gaps in the fossil record, the incompleteness of fossils, and how data are interpreted (e.g., the taxic vs. phylogenetic approaches). Methods of analysis, as discussed here, can dramatically alter interpretations of the same fossil record. While I view the phylogenetic method as essential to interpreting the fossil record, a few new analytical methods are still required that aid in interpreting historical patterns like radiations. There is already considerable dialogue, for example, on statistically assessing clade-age rank correlations. Given the dramatic effect that angiosperm radiations had on insect diversification, the next step would be to analyze patterns and timing of angiosperm cladogenesis with that of pertinent insect groups. It is essential not to become too preoccupied with analytical methods, though, since data are the ultimate source of hypotheses and controversy. Besides exploration for diverse new Paleozoic and Mesozoic deposits of insects, the study of fossil insects fundamentally depends on rigorous comparative morphology.

SUSTAINABLE DEVELOPMENT AND INTEGRATED PEST MANAGEMENT

M. Kogan, Integrated Plant Protection Center and Dept. of Entomology, Oregon State Univ., 2040 Cordley Hall, Corvallis, OR 97331 USA, Email <u>koganm@bcc.orst.edu</u>.

INTRODUCTION

Sustainable Development, as applied to agriculture and Integrated Pest Management (IPM), are complementary concepts that emerged in the last third of the 20th century. Early proponents of these concepts reflected the growing awareness of the fragility of the environment in the face of mounting human interference. Both concepts were born in controversy because, while they found broad popular appeal, there arose sharp distinctions among different constituencies as to the intrinsic meaning and practical use of the terms. Just as IPM has generated numerous interpretations and as many different definitions (Bajwa and Kogan 1996), sustainable development has been variously defined to suit the views of specific interest groups. In its broader sense sustainable development is "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (The Brundtland Report, in Conway 1993). Sustainable development, when applied to agroecosystems, was defined as "the ability of an agroecosystem to withstand disturbing forces – particularly threats to its overall productivity" (Conway 1993). This definition evokes the idea of ecosystem resilience. Sustainable development is a multidimensional concept that reaches far beyond agriculture. It permeates all levels of human endeavor, economic, social, and cultural. The following discussion attempts to focus on the broad issues of sustainability as applied to agricultural development and IPM as a fundamental component of sustainable agriculture.

The sustainability of agroecosystems is challenged by severe social, economic, and environmental problems. There are positive models of sustainable agricultural systems deployed around the world and effective IPM systems have been implemented in many countries, but the persistence of those systems themselves is threatened by the same factors that undermine the long-term sustainability of agriculture as a whole. At issue here is not just the preservation of effective methodologies of crop production or pest control. We must not only try to understand and anticipate the factors that may affect the permanence of established IPM programs, but much more importantly, consider that those same factors threaten the very integrity of the ecosphere. Most of those factors arose as consequence of the explosive growth in human population coupled with an unevenly distributed but considerably improved standard of living in many developing countries. The discussion that follows is divided into four main topics: 1. The impact of demographics on essential resources for sustainable development in agriculture; 2. Sustainable development, agriculture and IPM; 3. Anthropogenic disasters and the permanence of IPM; and 4. IPM achievements and expectations.

DEMOGRAPHICS AND SUSTAINABLE DEVELOPMENT

Between 1950 and 2000 world population increased from 2.5 to 6.1 billion, an increase of 3.6 billion. Another 2.6 billion people will be added to the planet by 2050, at a rate of 80 million per year to reach 8.9 billion. More people were added to the Earth from 1950 through 2,000 than in the 4 million preceding years since humanoids appeared on the planet (Brown 1999). Thomas Malthus in the late 18^{th} century was one of the first to call attention to the potential risk in the disparity between population growth rates and rates of increase in food production. Technological developments of the 19^{th} and 20^{th} centuries may have postponed the day that Malthusian predictions became a reality. But, the carrying capacity of the Earth is limited and, in many parts of the world, we are quickly exceeding it and irreversibly exhausting key finite resources. The population issue has been amply debated since Paul Erhlich's 1968 publication of the "Population Bomb". Relevant demographic figures that have potential impact on sustainability have been summarized (Brown 1999, FAO 1999). Essentially demographics determine the pressure to increase food production, which in turn leads to the often unsustainable use of fundamental resources for food production – land, water, and energy.

SUSTAINABLE DEVELOPMENT, AGRICULTURE, AND IPM

The need to adopt a sustainable approach to development stems from both affluence and poverty. Affluent societies tend to overexploit resources through excessive consumerism and waste. Poverty and under development, on the other hand, exacerbate environmental degradation often as the only short term solution to survival. Sustainable agriculture (SA) is an obvious extension of the more inclusive concept of sustainable development. The American Society of Agronomy defines a sustainable agriculture as one that "over the long term, enhances environmental quality and the resource base on which agriculture depends; provides for basic human food and fiber needs; is economically viable; and enhances the quality of life of farmers and society as a whole".

Five guiding principles and goals have been proposed for the sustainable management of agroecosystems: "a sustainable agriculture system a) is based on the prudent use of renewable and/or recyclable resources; b) protects the integrity of natural systems so that natural resources are continually regenerated; c) improves the quality of life of individuals and communities; d) is profitable; e) is guided by a land ethic that considers the long-term good of all members of the land community. An agroecosystem is a dynamic interdependent community composed of soil, water, air and biotic species. All parts are important because they contribute to the whole" (Cavanaugh-Grant 1999). These principles generally coincide with the basic tenets of IPM.

With a theoretical foundation in agroecology (Altieri 1987, Gliessman 1990), proponents of the sustainability concept for crop production have found great affinity with the principles and approaches of IPM. Indeed, IPM provided both a conceptual and an

implementation paradigm for SA. From an IPM perspective, the concept of SA provides a platform for propelling IPM to higher levels of integration (Kogan 1998). Entomologists seem to have had priority in the use of the terms "Integrated Management" when they coined the expression IPM in 1972 (Kogan, 1998). Since then the concept of integrated management received widespread acceptance in a range of agricultural, industrial, and social activities. It is fundamental to SA. Figure 1 depicts the relationships of the components of a crop or livestock production system, suggesting that the whole system, as well as its components, is under integrated management. A key feature of the integrated management paradigm is the analysis of benefits and costs of management decisions. Sustainability increases along a continuum depending on whether the costs and benefits are limited to the farm enterprise, or whether they also include values for societal and environmental costs and benefits. There are difficulties in setting monetary values for environmental and social (Turner and Pearce 1993) but once the methodologies are agreed upon they will be equally applicable to SA and to IPM decision making.

Figure 1. Integration of management components in an agricultural system.

<u>IPM and Food Production</u>: Increased food production was the highest priority at the end of World War II. With pest (insect, plant pathogen, and weed) damage accounting for over 30% of losses in total agricultural production, pre- and post harvest, plant protection specialists and producers were eager to adopt any new technology that had potential to reduce those losses. That technology was assumed to be the newly discovered organo-synthetic pesticides. It is estimated that since 1947 2.985 billion kg of chlorinated hydrocarbon insecticides were used. Initial results were spectacular leading to predictions that "some pests will become extinct". Early on, there was little awareness or concern about the possible side effects of what would become one of the most pervasive intrusions of man-made chemical molecules into the environment. Early success overshadowed obvious signs of problems and abuses. The need to keep food production apace with population growth overwhelmed any environmental considerations. Success of the green revolution varieties was to a large extent dependent on the availability of insecticides, as many of those varieties were susceptible to insect pests and pathogens. The health and environmental risks of the heavy reliance on pesticides were, however, too real to ignore. Rachel Carlson's 1962 book was a wake up call that helped concerned scientists more aggressively pursue the path that led, 10 years later, to establishment of IPM. Despite recent advances in pest control technologies and IPM program expansion worldwide, world crops in the 1990s still suffered up to 30 percent losses to the aggregate impact of pre- and post-harvest pests, a level similar to those suffered at the beginning of the century (Schwartz & Klassen 1981). These losses persist even while pesticide use continues to rise worldwide.

ANTHROPOGENIC DISASTERS AND THE SUSTAINABILITY OF IPM

IPM programs, by definition, should tend to be sustainable, despite the need to resort to inputs that are energy demanding, e.g., pesticides, motorized sprayers, complex synthetic semiochemicals, to mention only a few (Pimentel and Pimentel 1996). After almost 30 years of IPM implementation, there is an impressive record of achievements documented in many publications (Kogan 1998). The permanence (=sustainability) of these programs, however, is threatened by the same environmental, social, and economic pressures that also threaten the sustainability of agriculture. Those pressures stem from resource limitations, from human generated (anthropogenic) environmental disasters, and from societal pressures.

Impact of Resource Limitations: The pressure that rising populations exert on all components of an agricultural production system -- air, land, water, and energy --have a direct impact on the sustainability of IPM. Plants growing on sub-standard soils are stressed and usually susceptible to insect pests and diseases and are less competitive against invading weeds (Dale 1988, Heinrichs 1988). Scarce water supplies force growers to increase intervals between irrigation cycles or reduce the amount of irrigation; water stressed plants exacerbate arthropod pests (Holtzer 1988). Energy enters the IPM equation through equipment, monitoring equipment, pesticides. The potential indirect effect of shortages would be felt through price increases for essential inputs. Cost already is a limiting factor on crops of a few developing countries of Africa where pesticides are needed as part of the IPM system

(Abate 1996). Thus resource limitations that add to plant stress or impede use of desired IPM tactics tend to aggravate the impact of insect pests and may eventually set back established IPM programs. However, the most serious impacts on the sustainability of IPM systems come from human activities that are independent of demography, albeit magnified by population pressures.

Impact of Anthropogenic Disasters: Despite available scientific means, it has been difficult to anticipate environmental disasters. The best models of natural phenomena behavior tend to be linear and rather simplistic. Yet, nature is complex and full of surprises (Bright 2000). Small incremental changes suddenly result in a major catastrophe. Events in Honduras illustrate the convergence of multiple factors such as shifting land use, climate change, overuse of pesticides, deforestation, and malaria epidemics, coupled with natural meteorological events (hurricanes) to magnify environmental disasters as well as social calamity. The anthropogenic disasters that potentially impact on IPM systems may be grouped into two categories: a) those resulting from shifting environmental pressures, and b) those resulting from shifting social pressures.

<u>Shifting Environmental Pressures</u>: Examples of disruptive environmental phenomena are climate change, biological invasions, and loss of biodiversity.

Climate change no longer is a matter of opinion or speculation. Of concern now is the assessment of the extent of the changes and their potential impacts. Expected consequences of global warming trends include a shifting of climatic zones, changes in species composition and productivity of ecosystems, increases in extreme weather events, and impacts on human health (UNEP 2000). Atmospheric CO2 concentration, a major contributor to the greenhouse effect, has been both negatively and positively affected by agriculture. Negative effects include: a) changing the amount of carbon stored in the vegetation of terrestrial ecosystems (deforestation and reforestation) and in soils, b) burning fossil fuels in all phases of agricultural production and associated industries. Potentially positive effects are: a) providing renewable energy resources to substitute for fossil fuels, e.g., sugar-cane for ethanol production, and b) producing energy from biomass that recycles carbon rather than allowing it to be released to the atmosphere (Pimentel and Pimentel 1996). In addition to the direct effect on climate, the increase in atmospheric CO2 concentrations affects several plant and ecosystem processes, in turn capable of magnifying the "greenhouse" effect.

Fruit IPM in the USA offers an example of potential impact of climate change. Fruit IPM has reached a high level of sophistication and adoption among producers (Prokopy and Croft 1994). The codling moth, *Cydia pomonella* (L), is a key pest of apples, pears, and other fruit and nut tree-crops. Its management is based on accurate monitoring following a biofix date and events predicted by phenology models. The pest usually has one and a half or two generations per year. A yearly increase of but 2° C in average daily temperatures would cause a third generation to occur forcing growers to spray exactly at the time when fruit is closer to harvest and spray restrictions are most strict. Such warming trend in the region could derail one of the most advanced IPM systems in the USA.

Biological invasions have increased with globalization of trade and intensification of tourism. The potential economic impact of invasive species is not only when they becomes pests, but also results from restrictions imposed on imports by quarantine regulations. A comprehensive assessment of the number and frequency of invasions worldwide would be difficult. There are, however, useful regional studies that provide a basis for extrapolating to other parts of the world. These provide an approximation of the magnitude of the problem (Kiritani 1999, Wilson 1983, OTA 1993). According to Sailer (1983) of the over 2000 non-indigenous insects introduced into the USA, intentionally or not, 235 species have become serious agricultural and forestry pests having caused cumulative losses of about 92.6 billion dollars between 1906 and 1991 (OTA 1993). Invasive species can seriously impact established IPM systems. The 1980s' invasion of Brazilian cotton fields in São Paulo and Paraná by the boll weevil, *Anthonomus grandis grandis* Boheman, set back established IPM systems at the time.

Loss of biodiversity is associated with the gradual destruction of natural ecosystems both marine and terrestrial, biological invasions, pollution, and over-hunting. The GEO-2000 report states that "At the broadest level, biodiversity loss is driven by economic systems and policies that fail to value properly the environment and its resources, legal and institutional systems that promote unsustainable exploitation, and inequity in ownership and access to natural resources, including the benefits from their use. While some species are under direct threat, for example from hunting, poaching and illegal trade, the major threats come from changes in land use leading to the destruction, alteration or fragmentation of habitats." For example, two-thirds of Asian wildlife habitats have been destroyed with the most acute losses in the Indian sub-continent, China, Vietnam and Thailand and, in the Latin American region, the average annual deforestation rate during 1990–95 was 2.1 per cent in Central and South America (UNEP 2000). It has been suggested that we live "amid the greatest extinction of plant and animal life since the dinosaurs disappeared some 65 million years ago, with species losses at 100 to 1000 times the natural rate" (Brown 1999).

In addition to the loss in species diversity, food crops around the world face an alarming narrowing of genetic diversity. With advent of high yielding varieties associated with the "green revolution" many local races were replaced by new varieties. China reduced the number of planted wheat varieties from ca. 10,000 in 1949 to ca. 1,000 in the 1970s' (Brown 1999). Both loss of traditional land-races and loss of wild relatives make breeding of new varieties increasingly dependent on a restricted genetic base. From an IPM perspective, the loss of genetic diversity increases crop plants' susceptibility to insects and diseases and reduces the chances for incorporating host plant resistance as a component of IPM systems.

The relationship between biodiversity and stability of ecosystems is still being debated in ecological circles (Schowalter 2000). The debate has a direct bearing on the argument about the importance of biodiversity for IPM. Altieri (1993) defends the argument that "biodiversity is a salient feature of traditional farming systems in developing countries and performs a variety of renewal processes and ecological services in agroecosystems." He argues that it is important to understand the role biodiversity plays in reducing pest problems, when vegetation management is used as a basic tactic in small-scale sustainable agriculture. Altieri concludes that "the ensemble of traditional crop protection practices used by indigenous farmers represents a rich resource for modern workers seeking to create IPM systems that are well adapted to the agroecological, cultural and socio-economic circumstances facing small farmers throughout the developing world."

<u>Impact of Shifting Societal Pressures</u>: Established IPM systems also are vulnerable to pressures that derive from real or perceived societal problems with pests and the techniques used for their management. Examples of such pressures are: 1. concerns about the safety of food supplies, particularly to infants; 2. the public debate about the introduction of genetically modified organisms (GMOs') in agriculture; and 3. the intermittent and often muffled rural/urban conflict.

Food safety is monitored by several U.S. agencies. Analyses of over 8500 samples in 1998 showed no residues in 64.9 percent of domestic samples and 68.1 percent in import samples. None of the samples of grains, grain products, fruits, or vegetables had detectable residues above levels that violate current limits (FDA 1999). The food supply appeared to be reasonably safe. Yet, whether real or perceived, public pressure in developed countries has led regulatory agencies to revise existing standards for food safety. Meanwhile, in most developing countries of the world the plight of chronic starvation often overwhelms any concern about food safety.

In the USA the revision of food safety standards produced new guidelines usually known as the "Food Quality Protection Act" (FQPA) of 1996. The potential impact of these new regulatory laws on current IPM programs in the short run may be potentially disruptive. For example, removal of OPs' for use in fruit crops may increase incidence of codling moth and reduce effectiveness of established mating disruption programs. In the long run, however, FQPA may force producers and researchers to look hard for alternatives and propel IPM to higher levels of adoption and integration

Genetically modified organisms (GMOs') were met with a mix of excitement, controversy, and skepticism. The advent of cotton, potato, soybean, and other major crop varieties genetically modified to incorporate δ -endotoxin-producing genes of the bacterium *Bacillus thurigiensis* was heralded by some as the next silver bullet in agricultural pest control. The level and tone of the criticism, however, has exceeded expectations. Is there is a place for GMOs' in IPM systems? It is questionable whether GMOs' will be the silver bullet that some have anticipated. It is likely, also, that they are not the Pandora's box that some fear to open. The true role of GMO's will probably be as yet another tactic in the IPM arsenal that if used wisely will provide new and potentially powerful strategic options. It is essential to remember that "integration" is the key term in the IPM equation. If GMOs' are carefully integrated within IPM systems, taking into account resistance management prescriptions, interactions with other control tactics, and careful monitoring of undesirable side effects, all within the context of ecosystem integrity, then the answer to the question is an emphatic YES, there is a place for GMOs' in IPM systems.

The urban/rural dichotomy often is cause for friction and misunderstanding. Generations of urbanites, growing up in huge megalopolises, distant from rural areas, are generally oblivious of the intricacies of how food is produced. The lack of understanding of farming practices and intensive marketing lead grocery shoppers in big cities to demand fresh produce both unblemished and free of chemical residues. In many instances, cosmetic standards alone determine the level of pesticide use in a crop. Organic farming is helping educate the public that a certain amount of bruising in an apple or a few aphids in a head of broccoli are acceptable. This lack of understanding is a key factor in the slow adoption of IPM practices, if they fall short of guaranteeing the desired cosmetic standards. Food exporting countries of the third world must abide by the standards of their import markets. Even if farmers would adopt IPM practices for the local market, they would still be pressured to rely on chemicals for the export market.

Other areas of potential rural/urban conflict that impact IPM systems are the acceptance of the need to prevent biological invasions through eradication of incipient infestations of potentially serious pests. Large urban areas in the USA Pacific Northwest must be occasionally sprayed to eradicate nuclei of gypsy moth infestations. Eggs often hitchhike on trailers and campers of cross-country vacationers. Should the gypsy moth become established in the highly forested region, the result would be disastrous and a real challenge to pest managers. Authorities in charge of spray programs are often the target of irate urbanite critics who often misunderstand the nature of the problem and the safe nature of the approach. At the interface of city and farm other problems arise. In fruit growing areas of Oregon and Washington, for instance, it is common to find backyard grown apple and pear trees. Management of these isolated trees is often deficient allowing them to become reservoirs of insect pests and diseases that spread to adjacent commercial orchards. These three aspects of the urban/rural dichotomy serve to demonstrate that IPM within the broader context of sustainable agriculture, must encompass society as a whole. When this is achieved then IPM is truly moving toward higher levels of integration.

IPM ACHIEVEMENTS AND EXPECTATIONS:

The concept of "sustainability" is relative because it all depends on a time scale. Even if agriculture has been practiced for at least 10,000 years in some parts of the world, this represents but a brief moment in evolutionary time. Yet, even in this relatively short time span, we have witnessed the consequences of failing to consider the fragility of the environment and the disruptive impact of agriculture to natural ecosystems. IPM has the potential to demonstrate that humans can reach the level of agricultural production needed to feed the 8 billion people expected to inhabit the planet in 2050, and still maintain harmony with the environment. If, through effective IPM, we can reduce the over 30 percent annual production losses to pests, we would be contributing an additional 750 million tons of food grains, enough to feed 1.8 billion people at an adequate level of 400 kg per year. To reach this goal there have been some remarkable achievements in the development of new environmentally benign control tactics that can replace more disruptive tactics. We have been less creative in the advancement of new strategic approaches. Areawide IPM is a recent example of what can be accomplished with a modest strategic shift. Sustainable agriculture, like IPM, also needs a strategic leap. Both IPM and SA seem to remain at level I of integration, i.e., a narrow focus on single crops or limited mixed cropping systems, within small agroecological units (small farms or microregions). Models that consider entire ecological regions are rare. When SA adopts the ecoregion as the fundamental planning unit, then IPM also will have reached level III integration, because at this level the two approaches to agricultural development will be indistinguishable.

A NEW LOOK AT INSECT BREATHING

K. Sláma, Inst. of Entomology, Czech Academy of Sciences, Drnovská 507, 16100 Praha 6, Czech Republic; slama@entu.cas.cz.

INTRODUCTION

At the beginning of 20th century, a comprehensive textbook of invertebrate respiration by E. Babák demonstrated clearly that terrestrial arthropods were able to ventilate actively the tracheal system in response to hypoxia or accumulation of CO_2 . In 1920, however, a new theory of insect respiration was created by A. Krogh. He concluded that a simple passive diffusion of O_2 or CO_2 through the air-filled tracheal system could account sufficiently well for all respiratory requirements, without a need for active ventilation. This "diffusional theory" was accepted by most insect physiologists as a model of insect respiration for the whole 20th century. In 1927, Hazelhoff studied spiracular functions and found that Krogh's theoretical calculations about gaseous diffusion through spiracles were not practical, because spiracular valves of most insects and spiders were tightly closed for long periods. Later, the diffusional theory was tested and questioned several times, but there was no sufficient experimental evidence for its disproval (for more details and references see Sláma, 1999).

In 1976, I discovered the presence of special, periodically repeated pulsations in mechanical pressure of the haemocoelic body cavity. These extracardiac pulsations were produced by simultaneous contractions of abdominal somatic muscles, which caused positive pressure peaks in the haemocoele. The movements of body segments, associated with this "abdominal pressure pump", were rather small and invisible by a naked eye but still they were large enough to cause a bulk flow of gas through some spiracles that were just open (Sláma, 1984). It was also observed (Sláma, 1988), that spiracular valves pulsated selectively in synchrony with the upward or downward strokes of the pressure pulse, producing an actively regulated unidirectional stream of air. This type of active, "accordion-like", insect breathing was achieved by means of an autonomic, e. g. brain independent, cholinergic, neuromuscular system (*coelopulse*) driven by a nervous center in the thoracic ganglia of the ventral nerve cord (Sláma, 1988, 1994). The coelopulse system consists from thoracic and abdominal ganglia, lateral ganglionic nerves and perisympathetic neurohaemal organs. Its function depends on regulation of homeostatic balance in gas exchange and haemolymph circulation, which prevents water loss and respiratory acidaemia.

This contribution describes some recent advances in the study directed to elucidation of the role of the coelopulse system in insect breathing.

METHODOLOGY

The present topic has been restricted to immobile metamorphosis stages of

various endopterygote insects. The statements are based on a large amount of individual recordings with 96 species of Lepidoptera, 17 species of Coleoptera, 6 species of Diptera, 5 species of Hymenoptera, 2 species of Aphaniptera and 7 species of Neuroptera. The cardiac and extracardiac pulsations, O_2 consumption, CO_2 release, heartbeat and respiratory movements were monitored in these insects during the whole period of larval-pupal-adult transformation. With respect to rather small size of most investigated specimens, it appeared necessary to develop some novel, highly sensitive, electronic recording techniques. In addition, certain measurements required simultaneous monitoring of several physiological functions in one body. For example, extracardiac haemocoelic pulsations together with the heartbeat, respiratory movements together with the passage of air through individual spiracles, or continuous monitoring of O_2 consumption and CO_2 release. The description of the utilized differential transducers of haemocoelic pressure, thermographic cardiographs, position sensors, microanemometers or ultramicro-respirographs, that were used in these studies, would be beyond the scope of this abstract. However, some technical details required at least for understanding of the data in the Figures have been given in the text. A full description of the related methods can be found in my earlier publications (see Sláma, 1984-2000).

RESULTS AND DISCUSSION

The feeding larvae and adults of phytophagous insects show relatively simple respiratory adaptations. Their rate of O_2 consumption usually exceeds 500 µl $O_2/g/h$, the output of CO_2 is more or less continuous and, due to the dietary supply of water, these stages can freely breathe and ventilate the tracheal system. The situation changes substantially after cessation of feeding, when the retention of internal water becomes a major condition for insect survival. The nonfeeding stages generally keep spiracular valves tightly closed. Occasionally, they flash for a few msec, here and there and this is always associated with a brief gulp of air. This kind of respiratory scenario has been discovered long ago in diapausing saturniid pupae. It is known as the "passive suction inspirations".

It is generally assumed that the passive suction of insect body results from the decreased internal pressure due to continuous O_2 consumption, while CO_2 is dissolved in bicarbonate buffers of haemolymph and tissues. I have measured the haemocoelic pressure in immobile metamorphosis stages of a large number of insect species. Certainly, the internal body pressure of these stages is almost exclusively subatmospheric, including the soft bodied caterpillars, soft prepupae and soft pupae of various endopterygote groups. The relative pressure differences are rather small in larvae or pupae with soft, elastic integument (-100 to -

400 Pa), but some lepidopteran pupae with hard integumental case often develop negative haemocoelic pressures of several kPa below the local atmospheric values.

Under the described conditions of passive suction, air is inspired mechanically into the body whenever a spiracular valve opens. The factors affecting the velocity and volume of these intermittent inspirations are determined by relative difference between exterenal and internal pressures, by maximum aperture of the opening valve and by duration of the opening. The largest **instantaneous inspirations of 50 to 150 µl of air have been found in large pupae of saturniids. The inspirations are made by the left** and right thoracic spiracles whose valves alternatively open for some 200-300 msec., after a deep internal vacuum caused by complete closure of all spiracles for 15-30 min. The symptoms of passive suction respiration are absent in nondiapausing pupae of Coleoptera, Hymenoptera, Diptera-Nematocera and Neuroptera. I was also unable to detect the symptoms of passive suction in small diapausing pupae of Lepidoptera, in pupae enclosed within a hard puparial case of Diptera-Cyclorrhapha and generally in the adults of both Exopterygota and Endopterygota. The nondiapausing adult stages and larvae of exopterygotes exhibit frequent, periodically repeated extracardiac pulsations. Characteristic example of spiracular functions during a passive suction inspiration can be found in Fig. 1.

Fig. 1 shows the result of simultaneous anemometric recording of inspirations through 8 different spiracles (TR-right thoracic, TL-left thoracic, AL-2,4,7 left abdominal, AR-2,4,7 right abdominal) in diapausing pupa of *Manduca sexta*. The bottom trace shows synchronized record of "passive suction inspiration", which has been obtained indirectly, by recording contractions of terminal abdominal segments by a strain-gauge sensor mounted at the tip of abdomen. The characteristic, saw-tooth pattern of the bottom record has been associated with brief intermittent inspirations of air in 1-2 min. intervals.

The peculiar feature in Fig. 1 is that the inspirations of air proceed exclusively through the left throracic spiracle, while all other spiracles were kept hermetically constricted. Additional recordings with a substantial number of diapausing pupae of *Manduca* revealed that most of these pupae were able to show the pattern in Fig. 1 uninterrupted for 16 hours or more. Most of them used only TL as a master spiracle, although some used also the contralateral TR. After artificial occlusion of the functional TL, the pupa switched automatically to TR and, when this was also disabled, it switched successively to 2AL, then to 2AR, 4AL and so on. It is important to say that each of the consecutive spiracles opened at different intervals for different length of time, creating the saw-tooth pattern with different size of the teeth. This shows that there is a hierarchy of spiracular functions; each spiracle being programmed to whistle with a different sound. Originally, I thought that all pupae of *Manduca* could perhaps show the same spiracular hierarchy and thus could play identical spiracular music. This was true, however, only with respect to the thoracic, not the abdominal spiracles.

The exact physiological nature of the phenomenal, neurophysiological mechanism which is used by the coelopulse system for determination of the active master spiracles is still unknown. Obviously, it should be somehow related to the metameric, perisympathetic neurohaemal organs, whose axons lead to the spiracles. The method of indirect recording of changes in haemocoelic pressure from the tip of abdomen (see Fig. 1) has excellent practical implication for simple determination of pupal metabolic rate. The steady fall of the haemocoelic pressure during the suction inspirations is directly proportional to the rate of gas consumption, which can be easily recorded according to contractions of the abdominal segments.

The regular pattern of suction inspirations, as shown in Fig. 1, is very common in most developing or diapausing lepidopteran pupae, which have a compact integumental cover. By contrast, developmental stages of most other insect groups, including diapausing lepidopteran pupae of very small size, evolved a substantially different respiratory adaptation. They also keep spiracular valves closed for long periods of time, however, one of the thoracic spiracles remains incompletely constricted. In this case, the typical saw-tooth pattern is camouflaged by a constant stream of air into the thoracic tracheal compartment. The aperture

of the incompletely constricted, active spiracular valve is kept very small, so that the continuous bulk inflow of air is fast enough to prevent a possibility of the countercurrent diffusion and escape of the vital water vapour.

The most characteristic feature of the above described respiratory adaptation is that the exhausted hypoxic intratracheal gas has to be periodically renewed by actively regulated tracheal ventilation. This is executed mechanically by a coordinated interplay between the pulsations of spiracular valves and pulsations of the extracardiac abdominal pressure pump. The selective advantage of this type of breathing ,which is actively regulated by the coelopulse nervous systém, depends on minimalization of spiracular opening, e. g. reduction of water loss by avoiding gaseous diffusion between the tracheal system and the surrounding air. Paradoxically, this most common, widespread case of insect breathing appears to be in serious conflict with the mechanistic doctrine of Krogh. The reasons that most insects notoriously avoid to use diffusional principle and rather use active breathing is most probably again linked with prevention of water escape. It is also curious to imagine that insect physiologists trusted for such a long time into the diffusional doctrine, which most insects cautiously avoid to use.

The actively regulated breathing is common among developing stages of insects whose metabolic rate equals or exceeds 100 μ l of O₂/g/h. It occurs especially in insects of relatively small body size, which exhibit a generally hihger metabolic rate per unit of body mass. I am convinced that a respiratory water loss might be lethal to all very small insects within a few seconds, provided that they used diffusional principle of gas exchange. Unfortunately, the mechanical measures of active respiratory regulations in small insects are extremely delicate, being discernible only after use of the supersensitive electronic devices. For example, the periodically repeated ventilatory pulsations in a 10 mm pupa of a tineid moth have a maximum amplitude as small as 15 nm, and the associated changes of internal body pressure are smaller than 1 Pa (i. e. less than 0.1 mm of hydrostatic pressure). In larger specimens these measures are more pronounced, see Fig. 2.

Fig. 2 shows the result of differential anemometric recording from the anterior body compartment A (with spiracles on the rigid, 2nd to 4th abd. segments) and posterior compartment B (with spiracles on flexible, 5th to 7th abd. segments) in a pupa of *Galleria mellonella*. These pupae are missing functional thoracic spiracles so that the voluminous frontal part needs to be actively ventilated from the posterior abdominal spiracles. The mirror image traces of the two compartments in Fig. 2 reveal unidirectional inspirations of air through A, with simultaneous expirations from B. The frequency of air oscillations corresponds to the frequency of the extracardiac haemocoelic pulsations.

The described pattern of tracheal ventilation is rather common but not universal. The pupa of *Galleria* in Fig. 2, for example, was able to revert the flow of air in opposite direction and, curiously enough, it could deliberately alternate the forward and backward oriented ventilatory streams in short intervals of time. Moreover, recordings through individual spiracles revealed that the pupa could actually use only one or two master spiracles located at different part of the body. With these results I originally concluded that the function of extracardiac haemocoelic pulsations was only to serve for ventilatory movements. Later I found numerous instances, however, when vigorous extracardiac pulsations occurred with all spiracles closed. In this case the pulsations apparently did not serve for respiratory but circulatory functions. The differential, quite independent performance of individual spiracles during the extracardiac pulsation can be observed in Fig. 3.

Fig. 3 shows the result of anemometric recording through 4 spiracles (TL-left thoracic; 2AL, 3AL, 4AL- left abdominal) in a pupa of the chinese moon moth (*Actias selene*). We can see that the individual spiracles can be instantly opened or closed with the velocity that is at least equivalent or higher in comparison with the frequency of the current extracardiac pulsation. This relatively simple result shows that the nervous and neurohormonal mechanisms operating the spiracular valves can be fully synchronized with individual strokes of the abdominal pressure pump. It thus occurs to me that the phenomenal "accordion-like" type of active insect breathing represents an ultimate solution of evolutionary adaptations leading to insect survival under dry terrestrial environmental conditions. It is a pity that the study of such an important neurohormonal mechanism (coelopulse) has been hindered for a long time by orthodox beliefs into the diffusional doctrine.

The mechanism underlying the active insect breathing can be perhaps best portrayed by its comparison with the functions of an electronic microprocessor: The internal proprioceptive sense organs perceive the actual input signals about the momentary situation in gas exchange and convey these signals to the thoracic ganglionic center of the coelopulse system. The center then repairs the signalized excess or defficiency by increased ventilation of the concerned spiracles or by the increased circulation of the haemolymph.

A second established myth of insect respiration postulates that haemolymph is not involved in the transport of respiratory gases. This can be partly true with respect to transport of O_2 through the air filled tracheal spaces. The aerial transport is some 500million-fold faster in comparison with the penetration of oxygen through haemolymph or tissues. By contrast, the reciprocal transport of CO_2 to spiracles is highly problematic. The solubility of CO_2 in haemolymph or tissues is 36-fold greater than that of O_2 . The respiratory CO_2 is rapidly absorbed from its mitochondrial origin by carbonate buffers of haemolymph or tissues. The expected liberation of gaseous CO_2 into the tracheal system by means of simple diffusion would be associated with profound acidification of metabolizing tissues. Due to this, the carbonic acid of respiratory origin needs to be at first absorbed by the buffering capacity of the haemolymph. The bicarbonate ions are then transported to special loci of the tracheal system, where gaseous CO_2 is produced by enzymatic reaction with carbonic anhydrase. It has been recognized quite recently that insects with extremely high metabolic rate (*Galleria*) develop special carboniferous tracheal organs, which are specifically involved in periodic discharge of the concentrated CO_2 through a few selected spiracles.

The management of respiratory acidaemia is different in different species and developmental stages of insects. Nondiapausing pupae of most insect groups exhibit more or less continuous CO_2 output, which is apparently associated with a continuous supply of gaseous CO_2 from bicarbonate haemolymph buffers into the tracheal system, from which it is constantly released outside the body. This type of more or less continuous elimination of CO_2 and its transport into the tracheal system can be found in all pupae of Coleoptera and Hymenoptera. In *Tenebrio molitor*, for example, the pH reaction of the pupal haemolymph is constantly shifted towards acidic range of pH and the liberation of CO_2 is always continuous. Surprisingly, the strong extracardiac haemocoelic pulsations do not enhance the CO_2 output. In some other investigated models, however, the strong extracardiac pulsations may be absolutely essential for successful elimination of CO_2 from the body, which is illustrated by coordinated CO_2 elimination and extracardiac pulsation in Fig. 4.

Fig. 4 shows the result of simultaneous recording of extracardiac pulsations (lower trace from the strain-gauge sensor transducing abdominal contractions) and CO_2 output (upper trace from the flow-through IR sensor) in adult American cockroach (*Periplaneta americana*), which had been immobilised one day before recordings by decapitation. The dependence of CO_2 elimination on ventilatory function of the extracardiac pulsation is quite obvious. Moreover, the data in Fig. 4 leave no doubt that a perfectly coordinated function of the coelopulse system can take place in a complete absence of the entire cephalic nervous or neuroendocrine centers.

Our contemporary knowledge concerning CO₂ elimination from insect body is mostly based on results of IR based, flowthrough techniques. These techniques are very sensitive and practical, but they are usually blind with respect to short outpuffs of CO_2 in small specimens. In 1989, we investigated respiration of a small, 5mg, diapausing bruchid beetle, using a novel respirographic technique that was sensitive to pl amounts of O_2 consumption or CO_2 releease. We found that this miniature beetle produced curious respiratory microcycles, which were characterized by brief intermittent outpuffs of 30 to 40 nl of CO_2 in 3 min. intervals. The velocity of CO_2 elimination surpassed more than 30-times the rate of O_2 consumption. Later, we found these so called "Prague respiratory cycles" in a number of other stages and species, but especially in all instances where carbohydrate was the main source of metabolic fuel. The rate of CO_2 production was in this case usually equal or higher than that of O_2 consumption (aphids, aphidophagous Neuroptera, coccinellid beetles, food store beetles, ants and the like). In addition, we discovered the presence of similar microcycles of brief discharge of concentrated gaseous CO_2 from tissue buffers in Arachnida (ticks, pseudoscorpions and solifugae). We have recently realized that the "Prague respiratory cycles" were similar in nature with curious physiological cycles found in adult *Dytiscus* beetles by Babák in 1918. Although he did not realize, at that time, that the cycles could be associated with elimination of CO_2 , I propose to change the terminology and call these cycles as "the respiratory cycles is shown in Fig. 5.

Fig. 5 shows the result of respirographic scanning with a diapausing adult of *Chrysopa carnea* (Neuroptera) sitting on the wall of the respiratory vessel. The method is based on a constant volume, differential barographic principle. Volumetric changes associated with O_2 consumption and CO_2 output are recorded by means of an electronic transducer. The Babak's cycles in CO_2 elimination are manifested by periodically repeated, 30-50 nl deflections on the O_2 consumption curve (note that large perpendicular lines indicate electronic zeroing of the scanning system).

ABSTRACT BOOK I – XXI-International Congress of Entomology, Brazil, August 20-26, 2000 XXXVII

The ability to vaporize and eliminate gaseous CO_2 from internal bicarbonate buffers is not uniform with respect to different groups of insects. The pupae of *Galleria*, for example, produce CO_2 in special carboniferous tracheal organs located selectively under spiracles of the proximal abdominal segments. Ants also produce and release CO_2 exclusively from tracheal sacs located at the base of the abdomen. By contrast, adult Neuroptera, like *Chrysopa* in Fig. 5, release CO_2 only from the thoracic, not from the abdominal body compartment. When I discovered the brief, selective outpuffs of concentrated CO_2 through some determined spiracles, I immediately imagined that this physiological adaptation would perhaps constitute a principal, though so far neglected, condition of insect survival in dry atmospheric environments. There are experimentally well supported indications that the periodically repeated discharges of gaseous CO_2 through some determined spiracles are also actively regulated by the neuroendocrine system (coelupulse) by means of the programmed activation of carbonic anhydrase. I regret to say that our knowledge about physiological functions of this very important enzyme, the carbonic anhydrase of insects, remains still poorly understood due to persistent belief into the Krogh's diffusion doctrine. When combined with respiratory functions of the metameric perisympathetic neurohaemal organs, these problems represents a real challenge for the new millenium.

CONCLUSIONS

Insects and some other terrestrial invertebrates evolved fascinating mechanism for active regulation of real breathing. The mechanism is mediated by an autonomic, cholinergic, neuro-endocrine system (coelopulse), whose centers are located in thoracic ganglia of the ventral nerve cord. The system regulates opening, constriction, or pulsation of individual spiraclular valves. This type of active ventilation of spiracles is fully synchronized with exteracardiac haemocoelic pulsations and other changes in internal pressure. The changes are produced by intersegmental abdominal muscles ("abdominal pressure pump"). The unused spiracular valves are always tightly closed, the respiratory acidaemia is usually restrained by periodic vaporization of CO_2 and its immediate elimination through some determined spiracles. Selective advantage of active regulation of insect breathing depends on reduction of respiratory water loss, elimination of dangerous respiratory acidaemia and survival under relatively dry atmospheric conditions.

Key words: Coelopulse system, Respiratory acidaemia, Spiracular functions.

HYPOTHESES REGARDING GENITALIC EVOLUTION: AN UPDATE

W. G. Eberhard

Smithsonian Tropical Research Institute, and Escuela de Biologia, Universidad de Costa Rica, Ciudad Universitaria, Costa Rica E-mail: webe@biologia.ucr.ac.cr

Why is it that male genitalia tend to evolve rapidly and divergently in so many animal groups? An attempt will be made to summarize data and ideas from insects and arachnids that have appeared in the last 15 years that relate to various hypotheses (species isolation by mechanical lock and key; pleiotropy; male-female conflict of interests; cryptic female choice) that have bee proposed to answer this question. Major new developments include: the first detailed presentation of the male-female conflict hypothesis for genitalic evolution, and a general model of the possible role of male-female conflict in sexual selection (Alexander et al. 1997, Holland and Rice 1998); a major new test of the prediction made by some hypotheses that remating by females is associated with increased divergence between male genitalia (Arnqvist 1998); paternity and sperm transfer analyses which show biases favoring males with certain naturally occurring genitalic traits in three groups of insects (Rodriguez 1994, 1995, Arnqvist & Daniellson 1999, Daniellson & Askenmo 1999, Tadler 1999); additional data on genitalic mesh and behavior in a variety of groups; discovery of an apparently general trend in genitalic allometry that does not fit the predictions of some hypotheses (Eberhard et al. 1998); and indirect support for the female choice hypothesis from a considerable strengthening of support cryptic female choice in general (Eberhard 1994, Eberhard 1996). This indirect support includes the following: demonstrations that multiple genitalic contacts and copulations by the female (a prerequisite for the male female conflict and cryptic female choice hypotheses) is more common than previously thought (even in groups previously thought to be monandrous); realization that there are many female processes (at least 20) that can affect the chances that a given copulation will result in fertilization of a female's eggs; documentation from literature reviews and a survey study that courtship during and following copulation is extremely widespread among insects and spiders (and also, though apparently to a lesser extent, among scorpions - Peretti 1997); and the realization that the well-documented evolutionary trend for male seminal products to stimulate several female reproductive processes that benefit the male's reproduction is probably a result of either male-female conflict or sexual selection by cryptic female choice.

Related developments include: a careful demonstration that the character displacement in genitalic structures predicted by species isolation hypotheses does not occur in some spiders (Ware & Opell 1989); a possible explanation for the unusually consistent rapid divergent evolution and complexity of female as well as male genitalia in spiders, based on the unusual fact that the secondary male genitalia of spiders are completely lacking in innervation (Eberhard & Huber 1998); and documentation of receptors and nerve endings at sites in the female genitalia that are contacted by the male's genitalia in odonates and scorpions (Cordoba-A, 1999, A, Peretti ms).

Discriminating between the female choice and male-female conflict hypotheses is complicated by the fact that they make similar predictions in some contexts. One prediction associated strictly with the male-female conflict hypothesis, that species-specificity in genitalic structures will be associated with coercive (as opposes to luring) precopulatory interactions between male and female, is not born out by data from groups such as spiders (Huber 1998). Direct observation of the behavior of species-specific male genitalic structures that remain on the outside of the female during copulation is another, perhaps especially useful way to make critical distinctions. A concrete example in sepsid flies will be discussed in which the genitalic behavior and morphology give clear support to the sexual selection hypothesis and evidence against other hypotheses. Mapping of genitalic evolution on phylogenetic trees in groups in which the mechanical roles of male and female genitalic structures during copulation have been determined could also provide useful tests, because the male-female conflict and the female choice hypothesis predict different sequences of development of some types of structures.

Several continuing mysteries are associated with sperm. What is the functional significance of sperm gigantism and sperm polymorphism, and why does sperm morphology so often diverge rapidly? In the several groups in which the male genitalia do not reach the spermatheca but spermathecal morphology is nevertheless species-specific, are spermathecal traits related to sperm traits?. And how can one explain the elaborate divergent sperm of apparently strictly monandrous termites?

It is obviously dangerous to try to summarize the current state of a field in which one has proposed one of several currently competing hypotheses. For what it is worth, here is my current assessment. Both the lock and key and the pleiotropy hypotheses have been further weakened since they were last extensively discussed (and found inadequate) (Eberhard 1985, Shapiro & Porter 1989). The male-female conflict of interest hypothesis has been clarified, and has been supported indirectly by studies of the physiological effects of male semen on female <u>Drosophila</u> (Rice 1996); this interest hypothesis (along with the female choice hypothesis) is favored by the demonstrated association between female remating and rapid genitalic divergence. But several specific predictions made by the conflict hypothesis have failed in empirical tests.

The female choice hypothesis, by a process of elimination, is favored by these data, and is currently the strongest. This hypothesis has the practical disadvantage, however, of being very difficult to reject on the basis of testing its predictions. In particular, because of the variety of possible female choice mechanisms; it is very difficult empirically to check all of the possibly important effects that the hypothesis predicts that male genitalia may have on the female: it is thus empirically very difficult to rule out the possibility of female choice. It is possible, nevertheless, to search for predicted positive effects. Failure to find them will often not constitute definitive reason to reject the female choice hypothesis for a particular species; but if repeated tests of this sort fail to find positive effects, the hypothesis will be weakened. To date few direct tests of genitalic effects on female processes that have been published; several sets of results argue in favor rather than against the female choice hypothesis. If further direct tests also generally show predicted positive effects, the importance of the female choice hypothesis will be consolidated.

THE ROLE OF SMALL-SCALE FARMERS IN STRENGTHENING LINKAGES BETWEEN BIODIVERSITY AND SUSTAINABLE AGRICULTURE

W. H. Settle¹ and M. J. Whitten²

- 1. Consultant to The FAO Programme for Community IPM in Asia, J1 Jati Padang Raya No. 38B, Jakarta 12540, Indonesia

Index Terms: sustainable agriculture, biodiversity, rice, vegetables, farmer education, participatory training

Introduction

The Green Revolution saw pesticides aggressively introduced on a vast scale throughout much of Asia, based mostly on the unexamined assumption of need and in the absence of an understanding of the ecology of the agricultural systems targeted. In Indonesia—in order to qualify for the Green Revolution rice "package" of credit, seeds, fertilizers and pesticides—farmers were required to follow strict recommendations for the use of all inputs, including calendar-based applications of insecticides. This model in which extension agencies are set up as a conduit for "inputs" is still the prevailing model in most of the developing world. The high-yielding varieties have, without question, increased productivity several fold, however the associated inputs of synthetic fertilizers and insecticides have without question led to a progressive deterioration of soil fertility, water quality, and human and environmental health.

This "input-driven" model for research and extension is a difficult one to change for many reasons, most obviously because it tends to promote financial linkages between chemical companies and government agencies. The input-driven model promotes economic self-interest among producers and distributors such that chemical companies and government agencies are profiting at the expense of the long-term well-being of farmers and their agricultural systems. The farmer, in this model, is viewed as merely one parameter in a production function, or a "market" for sales. While there may be debate on what exactly "sustainable agriculture" is—the model that predominates in much of the developing world today is surely an example of what sustainable agriculture is not.

The past 10-15 years have seen a concerted effort to try and substantially change the input-driven research and extension model. Specifically, participatory farmer education approaches, often under a bewildering array of names and styles, are increasingly seen as the tool of choice among non-governmental organizations (NGOs) as well as some of the larger development organizations. Although our experience is limited to Asia and Africa, we know that some of the very finest models of farmer-based education and research programs have been developed here in Latin America.

In this paper we would like to share a brief look at a model for farmer-participatory programs for Integrated Pest Management (IPM) for rice and vegetables in Asia that holds much promise as one alternative to the input-driven model. While IPM is ostensibly about crop protection, the programs we present here have necessarily taken on a larger scope of responsibility, including a full range of agronomic, economic, social and pedagogical issues.

IPM in its simplest form is a set of guidelines for farmers on how best to manage pests of a specific crop. Like any good management system IPM should be based on extensive experience, solid data and well-established theories, including a clear understanding of the ecological functioning of agroecological systems. However, in practice this has not always been the case. As a consequence we have the current situation around the world in which a multitude of highly diverse and often contradictory guidelines for IPM exist, often for the same crop (for a recent review see Ooi 2000)

In response to a major threat to their commercial interests, agrochemical companies in the 1990's attempted to take on the mantle of IPM or ICM (Integrated Crop Management). Most Industry advocates maintain that IPM is simply about reducing the amount of pesticides used in the system, usually advocating use of inappropriate Economic Threshold Levels (ETL) for pests and "pseudo-pests). Some of these ideas are illustrated by the suite of papers published by Ciba for the International Congress of Entomology in Florence, August 1996 where they equate IPM with a 'measured' reduction in pesticide use (Ciba 1996).

Plant protection for tropical rice has become a battle ground with respective parties attempting to retain the high ground for their respective positions vis-à-vis pesticides - and with all parties adopting IPM as their symbol. With the international legitimacy provided to IPM by the Rio de Janeiro Earth Summit in 1992, IPM has come to mean 'all things to all people' (Whitten 1996).

However, a closer look at the IPM programs promoted by the chemical industry show them to be input-driven and lacking any foundation of solid ecological thinking supported by good field data. While the chemical companies are capable of generating huge amounts of data (see Oerke, Dehne et al. 1994), there is no underpinning based on a coherent theory of how specific agroecosystems are structured and how they function. As a result, their experiments-no matter how abundant-are logically and methodologically flawed and their data and conclusions suspect because, in the absence of a coherent theory, data can be variously represented and misinterpreted (Rosenzweig 1995). To be realistic, the task of actually developing a sound understanding of the ecology of agroecosystems is no small task, and not one likely to be deemed worthy of investment by a large multinational concerned principally with "the bottom line" and mostly happy with the status quo.

The principal barrier faced by scientists interested in developing an ecologically-based agriculture is the same problem for those interested in understanding the ecology of "natural" systems-that is, the overwhelming diversity and complexity of these systems. Besides the formidable job of data acquisition and analysis, the task involves a difficult optimization problem: capturing the details of highly complex systems sufficient to explain the mechanisms of importance in the functioning of the systems, while developing conceptual models sufficiently simple to be understandable by a broad range of audiences. Scientists and extensionists taking on the task of addressing applied problems with a "sustainable" approach face the challenge of formulating their conceptual models in not just one, but a variety of forms that are appropriate for a variety of audiences, e.g., scientists in other disciplines, program administrators, government policy makers, and most importantly, farmers.

Biodiversity within agricultural systems

Much of the complexity of an ecosystem resides in its biodiversity, and it is precisely this biodiversity that is most negatively affected by input-driven agriculture. In addition to land clearing, specific practices that have impacts on biodiversity include: tillage regimes, drainage, crop rotation methods, multiple cropping methods, and pesticide and fertilizer use (McLaughlin and Mineau 1995). Suggestions to mitigate negative effects may range from simply "optimizing" inputs by cutting back on inefficient overuse of seed, fertilizers and pesticides, to employing fully organic practices involving zero synthetic inputs and minimal tillage regimes. Advocates at the two extremes of the input continuum engage in often lively debates, pitting organic agriculture against high-input agriculture.

Most experts in the field agree that agricultural intensification is necessary because the area of highly-productive arable land, worldwide, is limited and diminishing, and that only by increasing yields per unit area will we be able to meet the demands of a growing world population. The argument from the 'high-input' side, however, assumes that this agricultural intensification is of necessity tied to high-inputs and mechanization.

An earlier World Bank report questions this assumption (Srivastava et al. 1996) and introduces the term "agro-ecological intensification" in reference to the question of how agriculture can be intensified while enhancing biodiversity. The World Bank report suggests that: "the neglect of agro-biodiversity in the portfolios of lending and development organizations, as well as in treaties and conventions that deal with environmental conservation, is striking."

Vandermeer and Perfecto (1995), go further to say that: "we know as little about biodiversity in traditional tropical agroecosystems as we know about biodiversity in the tropical rainforests". They further state if important biodiversity exists in traditional systems, then transforming them into modern, intensively managed systems represents a potentially significant loss of biodiversity.

Whereas high species richness may be an end in itself from a conservationist's perspective, and intuitively appealing as a correlate to sustainable practices for agroecology in general, and crop protection specifically, the question still remains to what extent, and by what mechanisms biodiversity translates into more productive and sustainable systems and better pest control.

Rice fields on Java: a case study

The discussion that follows is based on work done over a five-year period on the island of Java in Indonesia (Settle et al. 1996). One might ask if it is even possible to develop useful conceptual models for pest control for something as geographically dispersed, complex and heterogeneous as, say, tropical rice ecosystems. For example, will knowledge gained on the island of Java have any bearing on a rice agroecosystem in West Africa? The answer to both questions is yes, and lies in the fact that ecological systems, even highly complex ones like tropical irrigated rice, tend to be structured by a very few key variables. Research over the past 20 years in applied ecology of managed systems shows that ecosystem dynamics in general tend to be organized around a small number of nested cycles, each driven by a few dominant variables (Gunderson et al 1995; Holling 1992).

Cereal monocultures in general and rice fields in particular are frequently viewed as the bottom rung on the biodiversity ladder. In fact there are good reasons to believe that as great a range in species richness exists across a continuum of habitat types for a single crop species, as between systems dominated by different principal crop species. For example, the diversity of arthropod species found in a swidden rice field in the forests of Borneo, or the fine-scale matrix of paddy fields on the island of Bali or Central Java, are far more rich in species than rice systems observed on the vast plains of North-west Java, Central Thailand or Southern China. Settle and colleagues found in the region of 835 morphospecies in samples from 12 locations for one season each on Java. The International Rice Research Institute (IRRI) estimates that one hectare of irrigated rice holds in the region of a thousand species of arthropods, probably placing it near the top of any list of agricultural systems for biodiversity (A. Barion, pers. comm.). The truth in the assumption that a tropical rice field is significantly less bio-diverse than say a coffee, tea, teak or oil palm plantation (Smith, 1996) or the traditional Javanese "Village gardens", (Vandermeer and Perfecto 1995) is likely to depend on which habitats for growing rice are observed for comparison.

Of course, from a purely crop-protection perspective the goal is not primarily the conservation of species, but rather the maintenance of pest populations at consistently low and stable levels, such that neither production nor profits are diminished. The question to which we return is to what extent does overall species diversity relate to this goal of low and stable pest populations?

Intrinsic mechanisms lead to low pest pressure in tropical rice

The past decade has seen an increase in serious efforts to look at tropical rice with the tools of the ecologist (Schoenly et al. 1996; Settle et al. 1996; Ives and Settle 1997; Schoenly et al. 1997; Schoenly et al. 1998). Settle and colleagues studied the structure and function of arthropod communities in Javanese rice fields. Their general conclusions are phrased in terms of the structure the foodweb structure in the irrigated rice system (Fig. 1).

From the time that rainfall or irrigation water floods a farmer's rice field prior to planting, organic matter, derived from residues of the previous crop cycle, allochthonous transport of organic materials in irrigation water, and the growth of various forms of algae and decaying weeds—provide energy and nutrients for a complex foodweb of micro-organisms and larger organisms in both the soil and the water column. At the base of this foodweb phytoplankton and various species of algae provide an important source of nutrients, feeding an array of aquatic plankton. Floating algal mats feed populations of shore flies (family Ephydridae) and several species of collembolans. Bacterial populations rapidly multiply as a result of the flush of nutrients. Bacteria are fed upon by both protozoans and rotifers, which in turn are fed on by various microcrustacea (dominated in our samples by the Branchiapoda), or directly consumed by the larvae of true midges (Family Chironomidae). The death of all these organisms cycles nutrients back to the bacterial populations, forming a "positive feedback loop" characterized by accelerating growth rates during the brief period in which water and sunlight are available.

Larval densities of chironomids often reach densities of tens of thousands per square meter within the first 30 days. Collembolans, chironomids and ephydrid flies represent approximately 28% of the total abundance of macroarthropods collected in 12 locations on Java, and are the dominant fraction of arthropod biomass found in the first 40 days. These detritus-feeding and plankton-filtering insects function to channel the high productivity of the below-water planktonic food web to an above-water array of generalist predators—principally the surface-dwelling predatory Hemiptera (Veliidae and Mesoveliidae) the ubiquitous wolf spiders (Family: Lycosidae) and various families of predacious beetles and flies.

Fig.1. Proposed foodweb for tropical rice ecosystems. Organic matter drives the development of high early-season populations of predators through parallel pathways: 1) microorganisms (zooplankton and phytoplankton) are fed on by filter-feeders (mosquitoes and midges), and 2) organic matter directly feeds detritous-feeding insects (Diptera larvae, Collembola, and some Coleoptera larvae). Each of three pathways dominates at different times of the season: microorganism/filter-feeders early-season; plant/herbivore mid-season, and detritivores post-harvest.

This ubiquitous, highly-abundant and well-dispersed source of alternative prey, emerging from the water very early in the rice-growing season, effectively "decouples" populations of generalist predators from the usual dependence on herbivore populations, and promotes the development of predator populations well in advance of the arrival of pest populations. Consequently, high rates of pest mortality from the very earliest part of the season ensues, minimizing the chance that pest populations will escape control and cause yield losses (Fig. 2a).

Support for the mechanism

Settle and colleagues tested this hypothesis experimentally by manipulating organic matter in test plots compared with low organic matter control plots, and were able to show significant and substantial positive responses by the detritivore, filter-feeder, and predator populations, both above and below the water (Fig. 3).

Seasonal samples often show high abundance of both predators and the complex of plankton-feeders and detritivores, while herbivore numbers are almost nil in comparison. Furthermore, early season insecticide applications can cause induced resurgence of chironomid populations as well as pest populations later in the season (Takamura 1993; Settle et al. 1996)—a strong indication that both groups are significantly suppressed by natural enemies (Fig. 2b).

Fig. 2. Seasonal dynamics of a rice field in West Java. A. An early-season peak in "neutrals" (detritivores and filter-feeders) at 30 DAT is mirrored by a rise in predator populations. Mid-season (50 DAT) predator populations again rise in response to the rise in herbivore populations. This early-season "boost" of predator populations is the major reason why yields in irrigated tropical rice ecosystems are rarely damaged by insect pests (in the absence of insecticides) B. When the system is disrupted by early-season pesticide use, classic pest "resurgence" is seen in the herbivore populations (mostly brown planthopper). Note as well resurgence in the "neutrals" populations. (after Settle et al., 1996).

Researchers in China reached similar conclusions through different experimental tactics, showing that eliminating midge and mosquito larvae—by using a highly selective *Bacillus sphaericus* insecticide—predator populations in irrigated rice were diminished, and pest populations were subsequently higher compared with untreated controls (Wu et al. 1994).

Recent studies in southern China using ELISA techniques have shown that chironomids represent up to 80% of the diet of spiders early in the season (Zhang Wenqing, Institute of Entomology and State Key Laboratory for Biological Control, Zhongshan University, Guangzhou, pers. comm. to W.H. Settle, September 1997).

The importance of ecological "context"

The mechanism described above suggests high levels of natural pest suppression can be brought about in tropical irrigated rice through the early season boosting of predator populations by abundant alternative prey, in turn linked to a highly productive aquatic foodweb. The degree to which this mechanism could be called a 'general' mechanism will depend, at the very least, on the degree to which the key functional groups are present in any location at the appropriate times in the season. We are suggesting this, in turn, will depend on large-scale historical factors in the ecosystem—what we would like to call the "ecological context" of a locale. This might include landscape characteristics (topography and soil), vegetational and seasonal planting patterns, water availability, overall toxic load (pesticides) and weather.

In brief (but see Settle et al. 1996; Ives and Settle 1997), experimental result and observations throughout the region suggest several hypotheses, including the following:

- 1. that organic matter amendments not only are essential for plant nutrition and soil health, but substantially boost levels of generalist predators in the system,
- 2. that the lower elements of the foodweb are ubiquitous—that is, bacteria, aquatic plankton, and even the chironomid midges, can be found in any rice field in the tropics (Asia and West Africa). In contrast, substantial variation can be seen in the upper-level elements of the foodweb (the natural enemies), which are correlated with large-scale factors of landscape, seasonal planting patterns and toxic load,
- 3. (specifically relating to #2): large-scale synchronous planting (greater than 500 ha) and long dry fallow periods (greater than 2 months) are correlated with: a) substantial reductions in species richness of predators and parasitoids, and b) delays in the return arrival of predators and parasitoids into the system after the long fallow period, thereby missing the early-season peak in alternative prey, and allowing pest populations to more easily escape control,
- 4. that early-season application of insecticides suppresses natural enemy populations, causing insecticide-induced pest resurgence (the literature on this is by now overwhelming).

But does greater biodiversity mean better pest control?

Substantial experimental efforts have been made to try and link a simple metric of species number to an overall measure of ecosystem functioning (e.g., Naeem et al. 1994; Tilman and Downing 1994; Naeem et al. 1995; Tilman 1996). What is clear is that such efforts are fraught with ambiguities linked to the inevitable existence of indirect effects and the "hidden variables" that confuse the interpretation of experiments (see Huston 1997, for an elegant analysis). As Huston concludes, the metric of species number is a simple concept that is distinct from the identities and behavioral properties of the species involved. In other words, the question "are more species better" is essentially unanswerable because, at scales larger than bacteria, it matters to a great extent which species you choose to look at.

We have tried to show that the issue is best approached by first asking what are the intrinsic mechanisms that support "good functioning" of the ecosystem (for our purpose, meaning consistently high levels of pest suppression), and how are these mechanisms affected by variations in the large-scale factors that underlie any ecosystem (the "ecological context").

Once having answered these questions we can then ask to what degree these specific mechanisms and large-scale factors correlate with species diversity. For our example of tropical rice we have evidence that the landscape characteristics, vegetational patterns, and chemical use patterns that lead to robust pest suppression (e.g., short dry-fallow periods, small-to-intermediate scales of planting synchrony, little or no insecticide use) are also positively correlated with species richness (Sawada 1993; Settle et al. 1996). Including, perhaps surprisingly, herbivore species richness.

We are suggesting that for the issue of crop protection—and we believe sustainable agriculture in general—we should avoid asking 'how many species is enough?', and focus instead on understanding the mechanisms and large-scale factors that constitute a robust and sustainable system. This has important operational implications in that farmers are unlikely to be able to quantify and manipulate complex arrays of species, but they are able to understand mechanisms and to a large extent are able to manipulate at least some of the key large-scale variables that directly contribute to a stable and robust system.

The role of farmers in managing their rice crop

Given the above, it should be distressing to discover that rice continues to account for more insecticide than any other crop in the world and that 80% of this amount is used in Asia. Yet after 30 years of "top down" and input-intensive approaches to research and extension, more than a generation of farmers have been caught up in a system that promotes fear and ignorance. The two most common perceptions among untrained farmers is a) that almost all the insects found in a crop will cause damage, and b) that all levels of damage translate into roughly equivalent levels of crop loss. The aggressive promotion of insecticide use in Asian rice led directly to massive outbreaks of pests—especially the rice brown planthopper *Nilaparvata lugens (Stal)*, yet because of the indirect nature of the causal mechanisms, and the inherent time delay between application and outbreak, farmers were not seeing the cause-and-effect relationship between insecticide use and pest outbreaks; hence, only adding to the conviction that pesticides were indeed needed. How to break such a cycle is the task faced by IPM in Asia.

Beyond Rice - IPM in vegetables and other crops in Asia

The ideal 'IPM' approach to pest and disease management in tropical rice paddies is sometimes described as 'informed nonintervention'. Rice, as a traditional crop with a history of cultivation of over 6000 years, has evolved a rich biota of invertebrates and micro-organisms. Understanding and manipulating the food web is the key to managing pests and diseases of rice. However, many important food (e.g. most vegetables) and fiber crops (e.g. cotton) grown in Asia are exotic to the region. Similarly, many of the pests and diseases of these crops are presumed not to be native to Southeast Asia (e.g. Diamondback moth, some thrips spp, and the leafminer, *Liriomyza huidobrensis*). Therefore it is common to find farmers using chemical pesticides as a component of IPM for vegetable and cotton IPM in Asia, and hence the term 'informed intervention'. Surprisingly, the indigenous biota can play a role in pest and disease management. For example, Shepard and colleagues estimated that in Indonesia the better use of the native biota could allow for a 75% reduction in pesticide usage without yield losses in a range of vegetable crops (Shepard, B. M. and E. F. Shepard. 1997). Indeed, enterprising IPM farmers in West Sumatra have isolated and cultivated a range of insect pathogens which they apply as bio-pesticides to various vegetable crops, thereby reducing pesticide dependency and usage greatly. These same IPM farmers have succeeded in manipulating the level of parasitism of the recently introduced leafminer, *Liriomyza huidobrensis*, by a native parasitoid, from more normal levels of 1-2% up to levels in excess of 80%. This intervention reduces the need to apply chemical pesticides for controlling *L huidobrensis*.

Examples of the use of the indigenous biota for controlling pests and diseases of vegetable crops and cotton can be found in the Proceedings of two recent workshops conducted in Asia (FAO Technical Report, 1998; CABI Biosciences/FAO Liriomyza Workshop Proceedings 1999). It would be unrealistic to say that vegetables, cotton and fruit crops could be grown economically and sustainable by small scale farmers in Asia without any use of chemical pesticides. But there is abundant evidence to support the claim that pesticide dependency and usage could be greatly reduced with significant economic, social and environmental benefit by these farmers. Greater knowledge about the existence and potential role of predators, parasites and diseases for controlling weeds, pests and plant diseases is needed; and this knowledge must be in the hands of the farmers. Recent IPM activities in Asia have shown that farmers can play a valuable role in creating, owning and sharing this knowledge with other farmers. The fact that many of the crops are relatively recent introductions seems only of secondary importance.

The evolution of Community IPM in Asia

The FAO Programme for Community IPM in Asia currently collaborates with some 12 Asian countries with the goal of training farmers in IPM. The program began in the early 1980s, but really began in earnest with a new model for farmer training in Indonesia in 1989. The program developed a farmer-training approach based on principles and techniques derived from adult, non-formal education (NFE). The NFE or "participatory" approach aims at helping farmers develop a broad range of skills related to agronomy, entomology, and critical thinking based on observation, experimentation, and the construction of conceptual models.

The objective is to put farmers in a position to make their own decisions based on an understanding of the ecological context and mechanisms underlying the functioning of their agroecosystems. Farmer training follows essentially the same path of discovery learning as followed by a researcher. By studying the field, asking questions, making systematic observations, discussing with others and coming together to test possible solutions, the IPM farmers develop real and practical knowledge based on fundamental scientific methods. IPM farmers have a saying: "the field is our book, go to the field to learn". This is far more than just a slogan, and represents an operational model that has proven highly successful.

Overall, the program has moved through four identifiable phases in development:

1) Farmer Field Schools (FFS). In the first stage, farmers in a village meet once each week for ½ day, over the course of an entire rice season (usually 12-14 weeks). The group consists of 25 farmers and a trainer. The observation field site is a simply a farmer's field, totaling around 1000 m². The group decides at the first meeting which half will be the IPM treatment, and which half the control, or "farmer practice" treatment. The latter is treated with insecticides, herbicides, and other management practices as per the usual practice for that area. Each week the farmers begin by breaking into small groups of five and spend the first hour in the field observing both treatment and control plots. Sweep net use by farmers is discouraged, rather farmers are encouraged to observe closely the life and activity in and around their paddy fields: in the mud, the water, on the water surface, on the plant, in the seedbeds, on the bunds, and eventually, in the stubble after harvest. Insects and spiders are collected by hand and placed into plastic bags to be brought back to a common meeting place. There, small groups construct representative drawings of the rice plant, including assessments of conditions of soil, water, weather, and the stage and needs of the plant (e.g., plant nutrient status). In addition, the captured insects are drawn in color on large blank newsprint, subsequently used for presentation to the larger group for discussion and decision making. The process encourages everyone to participate.

Other activities in the FFS often include:

- samples of aquatic plankton are taken in plastic bags and tubes for discussion and viewing,
- foodweb and energy-flow diagrams are constructed to discuss the structure and strength of rice ecosystems,
- studies of the effects of pesticides on natural enemies are carried out to show that pesticides are "poison" and not "medicine". The term "medicine" is commonly used in local languages around the world in place of "pesticide". This is a subtle but powerful (and incorrect) message,
- studies of plant compensation (via mechanical de-tillering and defoliation to simulate damage by insects). This is a critical point of which untrained farmers are often unaware. Early-season rice is highly tolerant of pest damage, with many varieties being able to incur from between 40-60% damage by insect borers and defoliators during the first third of the growing season, and as much as 10% loss by borers late season, without incurring yield loss (Shepard et al. 1990; Rubia et al. 1996),
- Studies on plant spacing, water control management, fertilizer choice and timing, seed cleaning, varietal selection, soil composition and methods of improvement
- insect "zoos", which compare pests caged on plants both with and without natural enemies (usually planthoppers and spiders), in order to show the effectiveness of natural enemies in controlling pests,
- various group-dynamic and team-building exercises.

Several important ideas farmers learn from the field training include:

- 1) that most of the insects they find in the IPM plot are either "neutrals" (a convenient term for plankton-feeders and detritivores) or natural enemies, very few are herbivores, and even fewer are pests,
- 2) that rice plant can compensate for a surprising degree of physical damage to leaves and stems with no loss of yield,
- that natural enemies can control populations of pests through predation and parasitism (but without natural enemies, pest populations build quickly), and
- 4) that insecticides are poisonous to natural enemies (and most other animals, including humans), and
- 5) that farmers are capable of doing their own experiments to answer important questions regarding farming.

On the social side, farmers learn:

- 1) how to do structured analyses of ecological, economic, and social problems,
- 2) how to work in a "facilitated" group discussion so that ideas are shared equally and no one person dominates,
- 3) how to do group planning exercises for season-long research and training activities.

The Farmer Field School approach, far from being an end-in-itself, seems to have led to a process of change driven, not by design from project management, but rather through an evolutionary process where the vision and creative potential of farmers, farmer-trainers and staff has been allowed to 'bubble-up' to create modifications in design, new materials for existing programs, and entirely new directions in program development.

2) <u>Follow-up Farmer Studies and Action Research Labs</u>. Starting in about 1991 a second stage in the program emerged when farmer FFS alumni solicited help in conducting follow-up farmer studies. In these studies groups of alumni farmers focused on issues of particular concern for their location. Examples include chronic stemborer problems, Golden snail, Seed bugs and tungro

virus. Some farmer groups chose to organize FFS on other crops (e.g., soybean and vegetables), while others chose to focus on specific studies. In especially difficult areas of chronic pest problems the farmers, together with program assistance, have developed Action Research activities. These are longer-term sets of studies geared toward helping farmers explore problems over several years and coming up with and carrying out action plans at the village-level and above. These studies are conceived of and carried out by alumni farmers with assistance by a project staff member who may live in the village, or visit periodically.

3) <u>Farmers-training-farmers</u>. The third stage has been the emergence of farmers-as-trainers. This happened at first quite spontaneously in Indonesia and was first noticed in 1991when alumni farmers in several districts were found to have organized training for neighboring farmers using local village funds for materials and transportation. The program staff immediately recognized the tremendous potential here, and formally began training farmers-as-trainers in 1993--now there are more than 25,000 farmers having spent at least one season training other farmers in Indonesia, with the number growing each year. Much of the training done by these farmers is financed by local IPM clubs, village funds, or sub-district and district-level government. In an increasing number of areas entire sub-districts have moved to self-funded IPM training by farmer-trainers with little or no financial support by the National Program.

4) <u>Farmer Networks and Community IPM</u>. Most recently we have witnessed a "fourth stage" –the emerge of networks of farmer-trainers within subdistricts, across subdistricts and across districts. Activities within these networks include farmer planning meetings, to develop strategies for training the remaining untrained farmers; to conduct farmer technical workshops, to plan and discuss the results of farmer studies; and meetings to develop strategies to influence local agricultural policy. This fourth stage we are calling *Community IPM*.

Results to date

Indonesia was the country in which the FFS model was first developed and the first country in which these additional evolutionary stages have emerged. Somewhere around 1,000,000 farmers have gone through an FFS in Indonesia. Vietnam is second having passed the 500,000 farmer mark. The China program started only in 1998, is showing remarkable growth. Overall in Asia somewhere around two million farmers have undergone at least the core FFS training. Critics state that this is still such a small number. The strategy, however, has never been to train every farmer, but rather to establish an IPM capacity in every farming community, and then to support lateral spread of IPM. This approach of follow-up and focused effort on farmer capacity development also creates pressure on the operational environment supporting pesticide use.

The model for farmer education presented here is not without controversy. There are individuals and institutions who feel the old models for extension, such as the Training-and-Visitation (T&V) system, were perfectly adequate. Similar approaches to the old T&V system can be seen today. Motivated by concerns for the cost of educating so many farmers, some promote the idea that "simple messages" transmitted through mass media will be sufficient to change the thinking and behavior of farmers. Our feeling is that this "ferment" of a collective global experience involving different approaches to farmer education is healthy and that in the long run, a diverse "toolbox" of proven methods will emerge as a core framework for extension models in this new century. Whereas the latter half of the 20th century was the time of the Green Revolution, we feel the 21st century must develop a "revolution" for farmer empowerment through education, and a farmer-based, bio-intensive agriculture.

L

TICK-PARASITE INTERACTIONS AT THE HOST INTERFACE

P. A. Nuttall, CEH Institute of Virology and Environmental Microbiology, Oxford OX1 3SR, United Kingdom.

Ticks were once described as "..disgusting parasitic animals.." (Aristotle) but now they are considered "supreme pharmacologists." This change of attitude has arisen from a greater understanding of how ticks feed on the blood of their hosts, and how the pharmacological properties of tick saliva promote the transmission of tick-borne pathogens. Ixodid ticks in particular face one of the greatest challenges of all parasites. To survive, they must attach and remain feeding on a host for several days or weeks. The physical and chemical processes of feeding, and long duration of attachment, provoke host haemostatic, inflammatory and immune responses. Ticks counterattack with anti-haemostatic, anti-inflammatory and immunomodulatory substances secreted in their saliva. Included in this armoury are proteins that bind immunoglobulins, histamine, and serotonin, and various cytokine regulators that affect the production or activity of several cytokines, including interferons. As a result of the pharmacological activities of this rich cocktail of bioactive saliva molecules, the feeding pool within the skin becomes an immunologically privileged site. Any pathogens (viruses, bacteria, protozoa) transmitted by infected ticks into the feeding pool, or that are acquired by feeding ticks from infected hosts, will benefit from a supportive ecological niche created by the tick. Such a phenomenon, often referred to as 'saliva-activated transmission,' has been reported for several tick-borne pathogens. The challenge now is to determine whether this immunologically privileged feeding site can be destroyed, and pathogen transmission prevented. Index terms: ticks, blood-feeding, immunomodulation, vector-borne pathogen transmission.

RE-ASSESSMENT OF THE ROLE OF THE INSECT GUT MICROBIOTA

<u>R.</u> J. Dillon, Department of Biology and Biochemistry, University of Bath, Bath BA2 7AY, England. E-mail r.j.dillon@bath.ac.uk

The success of the Class Insecta in our world is beyond dispute. What is less acknowledged is the extent to which microorganisms contribute to this success. The intestinal tract of many insects has been shown to harbour a large diverse microbial community. Although we are now aware of mutualistic associations between a number of insect species and their extracellular gut microbiota (Tanada and Kaya, 1993), many species are known to contain a substantial microbiota whose impact on insect survival is unknown. Lysenko (1985) stated that the role of the normal insect microbiota has not been determined. There are still relatively few studies on the role of the normal microbiota of insects compared to their obligate pathogens, this is partly due to the difficulty in recognizing beneficial relationships. One area of progress is the contribution of microbiota to the nutrition of the host (Tanada and Kaya, 1993). Nutritional contributions may take several forms; improved ability to live on suboptimal diets, improved digestion efficiency, acquisition of digestive enzymes and provision of vitamins. The purpose of this paper is to reassess other subtle, but nonetheless potentially important, ways in which the gut microbiota benefits the insect host.

TERMINOLOGY

The lack of consensus on the terminology used to describe the insect microbiota reflects our ignorance about the stability and role of microbial communities in the gut of most insect species. Terminology is based on that of the intestinal microbiota of humans and domesticated animals (Savage, 1977). The criteria for inclusion of a microbial species as indigenous, or autochthonous include the following; always found in normal adults, colonize particular areas of the intestinal tract, colonize their habitats during succession in the young animal, maintain stable populations in climax communities in adults and associate intimately with the epithelium of the area colonized. In insects where there is a highly complex biota usually required for nutrition (see above) and the bacteria are passed from generation to generation, many of the criteria described for autochthonous microbiota in other animals are appropriate. Each species will presumably have a niche in the gut habitat and thereby contribute to the economy of the whole insect. An indigenous biota is present in all individuals of the species and maintains stable climax communities. However, apart from a few exceptions, the microbial colonization of most insect species has not been studied and the terminology is unclear. The assumption is that many species initially derive their microbiota from the surrounding environment such as the phylloplane of food plants or the skin of the animal host but the persistence of strains of the ingested species is unknown. Do strains of these species engage particular niches in the gut and colonize gut epithelia? Presumably they are not present in all members of the same insect species. The critical distinction is whether a microbial species is able to colonize the gut habitat in contrast to allochthonous (transient) microbes that cannot colonize it except under abnormal circumstances. Locusts (Schistocerca gregaria) derive their relatively simple microbiota from the ingested food plant, starved insects develop a larger population of gut bacteria than fed insects (Dillon, Vennard, Charnley, unpublished). Here the term 'locally indigenous microbiota' will be used to describe the microorganisms acquired by individual insects, which multiply within the gut, but are not necessarily present in all members of a single community. This term implies that a range of microbial species acquired from the external environment may occupy the same niche but allows that the microbial species involved may interact positively with the insect host.

Where a positive interaction between insect and microbe is identified the terms commensalism and mutualism are useful. Commensalism occurs where the microbe while doing no harm, benefits from the host but provides no advantage in return. Mutualism is a less flexible association where the microbe and insect mutually benefit each other. In practice there is a continuum between the two extremes, from a commensal, locally indigenous microbiota through to the total integration found between the host and intracellular prokaryotes in specialized cells such as mycetocytes. One example of the integration of bacteria with its host are the intracellular symbionts (genus Buchnera) of aphids which share common ancestory with aphid gut microbes (species of Enterobacteriaceae) and the bacteria ingested from the food plant (Harada, *et al*, 1996).

DIVERSITY OF THE INSECT GUT MICROBIOTA

It is now realized that we cannot culture the vast majority of microorganisms using traditional techniques. Molecular studies have revealed unrecorded microbial sequences in many natural samples to the extent that new kingdoms of life have been discovered in the Domain *Archaea*. The number of investigations of the diversity of the insect gut microbiota using molecular phylogenetic approaches is limited but we already have a glimpse of the information that this will reveal about the microbial diversity of the gut environment. Two thirds of clonally isolated 16s rDNAs from the gut microbiota of termites (*Reticulitermes speratus*) had less than 90% sequence identity with known bacterial species (Ohkuma and Kudo, 1996). Ten of these clones failed to show close similarity with any recognized bacterial phyla.

In situ hybridisation with species specific rRNA probes provides a complementary approach to cloning for the characterization of gut microbiota. Fluorescently labelled probes can be used to visualize phylotypes, establish morphology and determine number and spatial arrangement of cells. Fluorescently labelled probes were used to survey gut microbiota of five cricket species (Santo Domingo *et al.*, 1998a). Species that are difficult or currently impossible to cultivate were detected eg. *Bacteroides* and *Prevotella*

spp. and species of Archaea, the probes were able to detect changes in the profile of the microbial community due to dietary changes. Fractionation of microbial DNA according to guanine plus cytosine content was used to give an overall measure of microbial community composition and structure in the cricket (Acheta domesticus) hindgut (Santo Domingo et al., 1998b). The cricket microbiota provides a supply of fermentation products to the insect. Changes in the insect diet resulted in the emergence of a new microbial community structure together with changes in the microbial fermentation activity. These results show that fundamental shifts in the microbial profile can occur even in insects with an indigenous mutualistic biota.

NON-NUTRITIONAL ROLE FOR MICROBIOTA A) COLONIZATION RESISTANCE

The most important beneficial function of the indigenous intestinal microbiota in humans and domesticated animals is their ability to withstand the colonization of the gut by non-indigenous species including pathogens and therefore prevent enteric infections (Berg, 1996). The term colonization resistance (CR) is used to describe this function. The notion that this sort of function might be widespread in insects has received scant attention. Several approaches have been used to study colonization resistance. Insects whose resident microorganisms have been suppressed by antimicrobial agents are compared with insects containing an undisturbed microbiota. Alternatively, germ free insects are compared with their conventional counterparts or insects associated with one or two bacterial species. These studies can only be undertaken in insects with a non-obligatory microbiota unless specialized diets are used. Use of antimicrobials has a number of drawbacks. Apart from toxic effects towards the host even a broad antimicrobial regime may be overcome by resistant microorganisms. Some insect species such as locusts can be reared free from extracellular microorganisms using surface sterilized eggs and kept in sterile isolated environments. This system enables the production of gnotobiotic (defined biota) insects where bacterial species can be eliminated or reintroduced and population An isolator system, based on that developed for rearing gnotobiotic animals, was used to study the changes monitored. colonization resistance of the locust gut microbiota (Charnley et al., 1985). Another approach to the study of colonization is to use bacteria containing molecular markers (eg antibiotic resistance, Murphy et al., 1994).

Locusts (Schistocerca gregaria) contain a relatively simple locally indigenous microbiota (Hunt and Charnley, 1981) located primarily on the hindgut cuticle. Axenic locusts were reared in an isolator system on y-irradiated dict (Charnley et al., 1985) The insects were able to breed through several generations and there was no obvious nutritional requirement for a microbiota; indeed axenic locusts were physiologically comparable to conventional insects.

Colonisation resistance of the locust gut microbiota was implicated in the inability of fungal entomopathogens to germinate and infect via the conventional locust gut (Dillon and Charnley, 1986ab, 1988, 1991). Axenic insects were susceptible to fungal infection. Antifungal phenolic compounds detected in the gut fluid or frass of conventional locusts were absent from the axenic locusts. The phenolic compounds inhibited germination of 10 species of insect pathogenic and plant pathogenic fungal species. Moreover the phenolics were present in concentrations sufficient to account for the antifungal activity of the gut. Hydroquinone, 3,4 dihydroxybenzoic acid and 3,5 dihydroxybenzoic acid were identified. Similar antifungal activity has been located in the gut of seven other Orthopteran species. Monoassocation experiments of axenic locusts with a commonly isolated bacterial component of the microbiota, Pantoea (Enterobacter) agglomerans resulted in the appearance of one of the antifungal phenolics and established germination inhibitory activity in the gut fluid (Dillon and Charnley, 1995). The presence of only one of the three phenolics detected in conventional locusts suggests that several bacterial species cooperate in their production. A wider role for these antimicrobial phenolics in colonization resistance is suggested by the finding that they are selectively bactericidal; the indigenous species were able to survive in comparison to other species.

A few studies have examined the impact of the gut microbiota on the establishment of human pathogens and parasites in their insect vectors. Gnotobiotic insects (Greenberg et al, 1970) were used to provide evidence of the bacterial pathogen-suppressing ability of the microbiota of Musca domestica and Lucilia sericata. Erdmann et al, (1987) suggested that aromatic metabolites of the gut bacterium Proteus mirabilis are involved in the suppression of allochthonous bacteria in Calliphorid larvae. The possibility that CR is involved in suppressing medically important parasites such as Plasmodium and Leishmania in their Dipteran vectors has been discussed (Pumpuni et al, 1996; Dillon et al, 1996). The transmission of Chagas' disease by its vector provides the first example of a gut bacterium that has been genetically modified to provide CR towards a parasite (Durvasula et al., 1997). The role of the tsetse fly midgut microbiota in promoting trypanosome development (Maudlin and Welburn, 1994) will not be considered here.

B) SEMIOCHEMICAL PRODUCTION

Some insects sequester plant compounds for use directly as pheromone components or make minimal modifications to a dietary precursor (see review Tillman et al., 1999). The production of pheromone components by bacteria in the insect gut has also been inferred in a number of studies but conclusions were based solely on their ability to produce the relevant compound in vitro. Alternatively they have used antibiotic treatment to link the microbiota to pheromone production. Given the shortcomings of this approach in studies on gut microbiota (see earlier) it is not surprising that subsequent studies demonstrated an insect origin for the compounds.

Nolte *et al.* (1973) suggested that bacteria in the digestive tract of the locust *Locusta migratoria migratorioides* convert lignin to locustol (5-ethylguaiacol), a pheromone involved in aggregation. Subsequent studies failed to isolate locustol (eg. Fuzeau-Braesch *et al.*, 1988). Considerable advances have been made in the last 10 years in understanding the process that causes solitary locust populations to turn gregarious. There is interplay of visual, tactile and chemical stimuli (Byers, 1991; Pener and Yerushalmi, 1998). Pheromone involvement in attraction, group cohesion and transformation of locusts has been studied (Pener and Yerushalmi, 1998). Some of the pheromone compounds that modulate locust behaviour are phenolic compounds released from the insect faeces (Fuzeau-Braesch *et al.*, 1988; Obeng-Ofri *et al.*, 1994). These compounds do not elicit the gregarization process but seem to function as cohesion pheromones. The phenolic compounds guaiacol and phenol are the predominant electrophysiologically active components released from juvenile and adult faecal pellets of the locust *Schistocerca gregaria* (Obeng- Ofri *et al.*, 1994), adult male pellets also contained phenylacetonitrile. Phenylacetonitrile is probably derived from cuticular glands, but the origin of the other phenolics is unknown. In view of the finding that gut microbiota are involved in the production of related phenolic compounds in locusts the possibility that the gut bacterial biota were involved in the production of components of the locust cohesion pheromone has been recently investigated (Dillon *et al.*, 2000).

Volatile compounds collected from faecal pellets from conventional adult and juvenile locusts contained guaiacol and phenol. In contrast, there was a marked absence of guaiacol-like odour emitted from axenic locust faecal pellets compared to conventional locust pellets. GC-MS analysis revealed that the difference in odour was indeed due to the absence of guaiacol and the low level of phenol detected in volatiles collected from axenic faecal pellets (Dillon et al., 2000). The monoassociation of the bacterium P. agglomerans with newly hatched axenic locusts, subsequently reared on γ -irradiated diet, resulted in the detection of the 2 phenolics in 5th instar larvae although phenol was already present at a low level. These results indicate a bacterial origin for guaiacol and a proportion of the phenol. This is supported by experiments that demonstrated the ability of three species of locust gut bacteria (including P. agglomerans) to produce guaiacol and phenol directly from axenic faecal pellets in vitro. Microbial production of guaiacol was not a universal attribute. Guaiacol was not produced by Serratia marcescens (Enterobacteriaceae), a locust pathogen, or by locust gut enteroccocal species (Dillon, Vennard and Charnley, unpublished). A role for bacteria derived aromatics in other locust species is likely since guaiacol, and phenol were the main compounds detected from three species of locusts and their faecal pellets with guaiacol being the major product in each case (Fuzeau-Braesch et al, 1988). Veratrole, which was detected in previous studies, was not detected. Differences in the profiles of phenolic volatiles might be attributable to variations in the species composition of the gut microbiota. The fact that some of these aromatic compounds are microbially derived might account for variations in the results obtained from previous studies - the gut microbiota of lab-reared locusts will vary widely in both population size and diversity depending on the diet and rearing conditions. Bacterial fermentation continues in the faecal pellet after being voided from the insect. Continuation of aromatic volatile production by bacteria within the faecal pellets will depend on the availability of precursors and the moisture content of the pellet. Thus the duration of pheromone component release from faecal pellets surrounding locust roosting sites will depend partly on external environmental factors.

Knowledge of the bacterial origin of the aromatic compounds enables us to explain the variation in amounts of compound released from different ages of locusts. Lower quantities of aromatic compounds were produced in young adults in this study confirming the observations of the two previous studies (Fuzeau-Braesch *et al.*, 1988; Torto *et al.*, 1994). The hindgut cuticle is the site of the main bacterial population and during moulting it is renewed and the bacterial population declines (Hunt and Charnley, 1981), young adults will therefore contain a reduced population of bacteria which correlates with the fall in guaiacol and phenol production observed at this stage. Periods of starvation may change the composition and total population of bacteria and this would influence the amount of pheromone produced. The intriguing possibility that changes in the metabolism of the gut microbiota are linked to changes in the pheromonal profile is being investigated.

The precursor for guaiacol synthesis in faecal pellets must either be a component of the plant material or an excretory product of the insect. The former is indicated, as guaiacol production was dependent on the diet; considerably more guaiacol was present when conventional locusts were fed fresh wheat seedlings than the freeze-dried, γ -irradiated grass. Incubation of the locust diet with bacteria resulted in only minor amounts of guaiacol or phenol, indicating that digestion of the plant material in the locust gut is required for production of guaiacol by the bacteria. The most obvious precursor for guaiacol synthesis lignin-derived vanillic acid (4-hydroxy-3-methoxybenzoic acid) which is detected in the faeces of both axenic and conventional locusts (Dillon and Charnley, 1988, 1995). Microbial transformation of vanillic acid to guaiacol is via loss of a carboxyl group by the action of an inducible decarboxylase (Dillon, Vennard and Charnley, unpublished). Consistent with this, we found guaiacol was released by three species of locust gut bacteria from glucose/peptone broth cultures containing vanillic acid. Furthermore faecal pellets from conventionally reared insects fed filter paper impregnated with vanillic acid solution yielded large amounts of guaiacol (Dillon *et al*, 2000).

Locusts possess a locally indigenous microbiota composed of species commonly encountered in their environment, in particular the phylloplane biota on food plants (Hunt and Charnley, 1981). Guaiacol production by vanillic acid decarboxylation is an attribute of some plant and soil saprophytes (Crawford and Olson, 1978) which will be ingested with the food plant, so locust faecal pellets will always contain guaiacol though the bacterial species producing it may differ. The flexibility in the association

between the locust and its microbial partners was predicted by Jones (1984) who suggested that insects should evolve mechanisms to minimize the adverse consequences of mutualist loss by reduced reliance on single microbial species.

Bacteria colonizing the insect plant food may be adapted to deal with aromatic compounds and these plant-inhabiting strains may be selectively enriched in the gut environment. Microbial communities adapt through extensive transfer of degradative genes. Although we know that transconjugation between bacterial strains occurs in insect guts (eg.Watanabe *et al.*, 1998), the extent to which this may occur within the insect gut community or on the food source prior to ingestion by the insect is unknown.

Behavioural responses to microbial metabolites associated with insect frass have been reported for other insect species. *Klebsiella* oxytoca and *Bacillus* spp. produce the volatile alkyl disulphides present in the faecal pellets of the leek moth (*Acrolepiopsis* assectella; Thibout et al, 1995) which serve as kairomones to attract the parasitoid *Diadromus pulchellus* to the moth host. These also appear to result from the action of the bacterial enzymes on plant precursor molecules. It is intriguing to note that guaiacol was implicated as a kairomone for another parasitoid *Microplitis demolitor*; though the origin of the compound in the faeces of the soybean looper host (*Pseudoplusia includens*; Ramachandran et al, 1991) was not determined.

CONCLUSIONS,

The gut microbiota is regarded as a valuable metabolic resource for insects on sub -optimal diets but apart from this, most relationships between insects and their microbiota remain undefined. Studies with gnotobiotic locusts suggest that the microbiota confers previously unexpected benefits for the insect host. Microbial transformation of plant secondary compounds in an insect gut and adaptation by the host to use the resulting common metabolites are unlikely to be processes unique to locusts since seven other Orthopterans also have antimicrobial phenolics in their gut fluid. These findings have potentially wide implications for our appreciation of insect-microbe-plant tritrophic interactions.

The importance of colonization resistance of the gut microbiota in other animals is well documented though progress in establishing the mechanisms involved are hampered by the overwhelming complexity of the gut microbiota. Unequivocal demonstration of cooperative effects of the gut microbiota requires the use of rigorous quantitative microbiological methods using *in vivo* models and this has also restricted the work on insects. Insects are often used to establish principles which are common to all animals; perhaps the most famous being Pasteurs' demonstration of disease transmission using silkworm larvae as a model system. In view of the relatively simple microbiota of insects such as locusts, they can be used to establish the principles of colonization resistance which will be of relevance to work on colonization resistance in other animals. Furthermore, there is much interest in the role of the human gut microbiota in carcinogen metabolism and the production of naturally occurring compounds which may prevent tumour formation. One putative suppressor of tumour formation is also a bacteria- derived compound found in the locust gut.

The studies with locusts provide evidence for a *moderately* mutualistic association between the locust and its microbiota. The bacterial community of the locust gut is adapted to metabolize plant allelochemicals into antimicrobial compounds with increased activity against allochthonous microbes and provision of pheromonal compounds. This dual benefit for the insect suggests a closer degree of integration between the locust and its microbial community than was previously suspected. Surprisingly, this has not resulted in the development of an obligately mutualistic association; instead the locust has minimized the consequences of mutualist loss by not relying on a single microbial species.

NEURAL DEVELOPMENT DURING EMBRYONIC AND METAMORPHIC DEVELOPMENT IN INSECTS

L. P. Tolbert, ARL Division of Neurobiology, Univ. of Arizona, P.O. Box 210077, Tucson, AZ 85721-0077, USA, e-mail tolbert@neurobio. arizona.edu.

INTRODUCTION

Why study the development of insect nervous systems? Beyond satisfying sheer curiosity, knowledge of insect neural development holds the hope of revealing novel and specific paths for biologically sensitive intervention to protect or to control specific populations of insects. Furthermore, for developmental biologists, insects offer a rich source of material. The development of the nervous system in insects follows different paths, depending on the life history of the species, yet many of the cellular and molecular mechanisms underlying neural development appear to be common across disparate insect species, and even common between insects and mammals (see Arendt & Nubler-Jung 1999). Individual species variations confer particular experimental advantages to the investigator using insects. For all of these reasons, recent years have seen a huge research effort to understand neural development in insects.

Unable to review all of insect nervous system development in a one-hour presentation, I will provide a very selective review. I will focus on the growing understanding of the importance and nature of cellular interactions in insect neural development. The nervous systems of certain insects have been excellent systems in which to study these interactions. *Drosophila melanogaster*, a superb organism for genetic studies, has been used to great advantage to reveal the cellular and molecular bases for developmental influences in the peripheral and central nervous systems. Large holometabolous insects, such as the hawkmoth *Manduca sexta*, have different advantages; for instance, developing sensory and central neural structures are readily accessible throughout a major postembryonic wave of development (during the metamorphosis of the larva to the adult), when the animal is large and hardy, readily amenable to surgical manipulations. *Manduca*, besides being useful for cellular studies, also has been especially useful for studies of the molecular bases of hormone action, a special type of long-range cellular interaction, in neural development (Levine et al. 1995).

Insect nervous systems develop along widely differing timetables, depending on the life stages of the species. In this review, I will provide background on embryonic development and metamorphosis of the nervous system, but will focus mostly on intercellular interactions that play key roles no matter what the timetable, no matter what the extent of postembryonic reorganization, of the developing nervous system. I will go into most depth on intercellular interactions during development of the antennal system in *Manduca*.

EMBRYONIC DEVELOPMENT

Investigation of the development of the nervous system during embryonic development in insects has a long history and has been reviewed many times. The central nervous system, or CNS, arises from the ventral ectoderm of the embryo (Bate 1976, Doe & Goodman 1985). Regularly spaced cells in the ventral ectoderm enlarge and bud off, into the interior of the embryo, in clusters that form the primordia of the ganglia and brain. These cells then undergo a stereotyped set of mitotic divisions to produce neurons; the lineage of many of the uniquely identified neurons in the grasshopper and in *Drosophila*, is known completely, and is invariant from individual to individual. Soon after neurons are born, they begin to extend axons along specific paths toward their targets (see Bastiani et al. 1985). Once they reach their targets, they form synapses, and the specific neural substrates for behavior are elaborated.

METAMORPHIC ADULT DEVELOPMENT

After hatching, the nervous system continues to change. In species that do not undergo metamorphosis, the changes are likely to be subtle, mostly in response to input, falling under the rubric of "experience-dependent plasticity."

In hemimetabolous insects, such as grasshoppers and crickets, each molt involves the production of new sensory neurons, which then must send axons into the CNS to carry their input. This continuous addition of new sensory neurons and the challenge of integrating them into the animal's neural circuitry has been studied extensively in the cercal system of the cricket (Murphey 1985). In grasshoppers, Arbas (1983), among others, showed regressive as well as progressive changes.

In holometabolous insects, the larval nervous system produced during embryogenesis is much more dramatically altered during metamorphosis to produce an adult nervous system that includes some components of the larval system and some entirely new components (Levine et al. 1995). The overall shape of the CNS is modified, under the control of the *Broad complex* genes in *Drosophila* (Restifo et al. 1995). Best understood in *Manduca*, some of the larval circuitry undergoes extensive reorganization, involving regression and subsequent new growth of dendrites and axons. This reorganization occurs under the control of the ecdysteroid hormones (Truman 1996, Weeks & Levine 1990).

In addition to reorganization of larval structures, new cells and circuits are added to the adult nervous system to accommodate adult-specific functions. Imaginal disks give rise to new appendages, with new sensory neurons and with new muscles to be innervated by motor neurons in the CNS. New neurons are born in the CNS and either become incorporated into existing circuitry, or make new neural centers (e.g., Sorensen et al. 1991). The visual and antennal systems have been studied in most detail. I will focus on the antennal system, below.

INTERCELLULAR INTERACTIONS IMPORTANT IN NEURAL DEVELOPMENT

How do only certain ectodermal cells acquire a neuronal fate? How do new neurons acquire a specific identity? How are neural circuits formed and modified? As in the developing nervous systems of all species with complex nervous systems that have been studied, molecular details are still sparse, but interactions between cells are being understood to be critical for normal development in insect nervous systems. Here, I will discuss some of the major types of interactions, and provide examples of work addressing the underlying mechanisms for the intercellular influences. The experiments cited will come from studies of insects with many different life patterns, in part to make the point that mechanisms appear to be broadly similar.

In the part of the ventral ectoderm made competent to give rise to nervous system by the action of "proneural" genes, lateral inhibition determines which cells will become nervous system and which will remain in the ectoderm. Interactions between the products of the "neurogenic" genes *Notch* and *Delta* have been shown to be involved in this lateral inhibition and are being studied in detail (Anderson & Jan 1997).

Once cells have delaminated from the ectoderm, they acquire specific fates; that is to say, they become specified to give rise to specific sets of cells (see Jan & Jan 1994, Skeath 1999). That some of this specification is accomplished via cell-cell interactions was revealed elegantly by, who used laser ablation methods to kill neuronal precursors in grasshopper embryos, to see whether new cells would replace their progeny. Whether the intercellular interactions trigger "master" regulatory genes that control large sets of genes encoding cellular properties, or whether smaller sets of genes are turned on individually is not known. Recent studies, however, have identified genes that specify unique cell fates in *Drosophila* (Doe & Skeath 1996).

After neurons have adopted a specific fate, they begin to express their cell-specific characteristics. Most noticeable among these is the trajectory of the axon and choice of synaptic target. Axon extension is very complex and involves recognition of and reaction to many dozens of molecules in the environment.

Growing axons, tipped by actively exploring growth cones, may respond to molecules deposited by other cells into the extracellular space, and to molecules on the surfaces of other cells, as well as to soluble molecules released by other cells (Auld 1999, Garcia-Alonso 1999, Van Vactor & Lorenz 1999). Glial cells play special roles in the guidance of early axons (Klambt et al. 1999). Work in *Drosophila* (e.g., Harrelson & Goodman 1988) has led to a comprehensive understanding of families of cell-surface molecules that play roles across phyla.

Development of synapses has been shown to involve two-way interactions between pre- and postsynaptic elements. The developing neuromuscular junction has been used to great advantage in this area (Keshishian et al. 1996), in large part because pre- and postsynaptic partners can be identified at the level of the individual cell.

THE ANTENNAL SYSTEM AS A MODEL SYSTEM FOR STUDIES OF NEURON-GLIA INTERACTIONS

The developing antennal, or olfactory, system offers excellent opportunities for the exploration of intercellular interactions during neural development. Studies in several laboratories have shown the antennal (olfactory) system of the moth *Manduca sexta*, in particular, to be an advantageous system for detailed study of the interactions among neurons and between neurons and glial cells that lead to the creation of olfactory synaptic glomeruli, which are common to both vertebrate and invertebrate species, and, more recently, of the neuron-glia interactions important in axon guidance.

This system is useful for developmental studies for a number of reasons. Olfactory receptor neurons (ORNs) and their postsynaptic targets arise independently during postembryonic development, and are located at some physical distance from each other, allowing the two populations of neurons to be manipulated independently with ease (Schneiderman et al. 1986). The antennal (olfactory) nerve is long from the earliest stages, and is convenient for imaging. Within the CNS, neurons and glial cells are born at different times, so that interference with glial proliferation does not affect neuronal proliferation (Oland et al. 1988). Although the number of cells involved is generally much smaller, cellular organization of the primary olfactory center in *Manduca* is strikingly similar to that of vertebrate olfactory bulbs (Boeckh et al. 1990, Hildebrand & Shepherd 1997), in that it is organized into discrete glomeruli that contain the synapses of olfactory receptors and their target neurons.

CELLULAR ORGANIZATION OF THE MATURE ANTENNAL SYSTEM IN MANDUCA SEXTA:

The ORNs have their cell bodies in 2cm-long paired antennae, and their axons project via the antennal nerve to the brain. In addition to other ORNs, male antennae have ORNs specialized to detect the female's sex pheromone (Kaissling et al. 1989).

The 330,000 axons (Oland & Tolbert 1988) of the ORNs of each antenna terminate in about 64 glomeruli of the ipsilateral antennal lobe of the brain (Rospars & Hildebrand 1992). In the male, the axons of the ORNs responsive to female sex pheromone describe a separate dorsal "macroglomerular complex" (Christensen & Hildebrand 1987). The "ordinary" glomeruli present in both sexes are arrayed in roughly a single layer around a coarse central neuropil. Antennal-lobe neurons branch in the glomeruli, and one major class of neuron, the projection neurons, project an axon out of the antennal lobe to higher centers in the protocerebrum. All glomeruli are surrounded by glial-cell borders (Tolbert et al. 1983; Oland & Tolbert 1987; Rössler et al. 1998).

DEVELOPMENT OF THE ANTENNAL SYSTEM:

The ORNs of the antennae and their targets, the antennal lobes, arise during metamorphosis. The antennae arise from imaginal disks that evert and begin to develop at the onset of metamorphosis. ORNs are born during stages 1 and 2 of the 18 stages (each roughly one day long) of metamorphic adult development

(Sanes & Hildebrand 1976). Almost immediately they extend axons, which begin to reach the brain at stage 3. ORN axons continue to grow into the brain from ever more distal antennal segments until about stage 9. The antennal lobe develops essentially *de novo* during metamorphosis (Kent 1985) from 5 neuroblasts that divide throughout larval life to produce the three clusters of neurons of the adult antennal lobe (Sorensen et al. 1991). By stage 2 of metamorphic development, neurons of the antennal lobe are postmitotic; they extend neurites into a small neuropil which is ensheathed by a continuous border of glial cells. As the first ORN axons begin to arrive, they pierce the glial border and encircle the neuropil, just beneath the layer of glia, before terminating in a fringe (Oland & Tolbert 1987; Oland et al. 1990). From late stage 5 through stage 6, ORN terminals elaborate and segregate into nodular "protoglomeruli", which become enveloped by glial cell bodies and processes. The neurites of antennal-lobe neurons reach outward to overlap with the axon terminals (Oland et al. 1990, Malun et al. 1994), and synapses are formed in large numbers (Tolbert 1989).

INFLUENCE OF ORN AXONS ON DEVELOPMENT:

Hildebrand et al. (1979) observed that if antennal ORN axons are prevented from innervating the antennal lobe during development in *Manduca*, the resulting lobe lacks glomeruli. We found that, without ORN input, development is abnormal beginning as soon as antennal axons would normally have begun to reach the brain (Oland & Tolbert 1987). Glial cells remain restricted to a rim surrounding the neuropil, and that neuropil is composed of neurites of antennal-lobe neurons that branch diffusely, rather than in glomerular tufts (Oland et al. 1990).

Even more intriguingly, Schneiderman et al. (1986) and, more recently, Rössler et al. (1999) used antennal transplantation to show that the male-specific ORN axons of male antennae have the ability to induce a macroglomerular complex in a genetically female host antennal lobe. The axons from the transplanted male antenna induce some female antennal-lobe neurons to send a neurite branch into a macroglomerular complex, and these neurons now respond to female sex pheromone, clearly indicating a strong influence of antennal axons on development of target neurons.

NEURON-GLIA INTERACTIONS IN GLOMERULUS DEVELOPMENT:

Taking advantage of the fact that glia proliferate later than neurons in the antennal system, we reduced the number of glial cells, while maintaining apparently normal numbers of both antennal and antennal-lobe neurons, to ask whether glial cells act as intermediaries in developmental interactions between ORN axons and antennal-lobe neurons (Oland et al. 1988, Oland & Tolbert 1988, Baumann et al. 1996). When glial numbers are reduced significantly, ORN axons begin to form protoglomeruli, but the protoglomeruli dissipate before the neurites of antennal-lobe neurons grow out to meet them; the resulting neuropil lacks glomeruli, and closely resembles that of lobes that develop in the absence of ORN axons. On the other hand, the few glial cells that remain undergo the changes in shape and position seen in glia in normal lobes, indicating that they are responding to ORN axon terminals to describe "protoglomeruli" upon entering the antennal lobe (Oland et al. 1990), glial cells are required to stabilize the protoglomerular organization of the axon terminals while the neurites of antennal-lobe neurons grow out to meet the axons.

What are the molecular substrates for this neuron-glia interaction? We (Krull et al. 1994a) found evidence for the existence of tenascin-like molecules on the surfaces of the glial cells in the antennal nerve in the antennal-lobe neuropil during ORN axon ingrowth and glomerulus formation. Tenascin in other systems can inhibit the growth of axons, so, in a second set of experiments (Krull et al. 1994b), we tested the responses of antennal-lobe neurons to purified mouse CNS tenascin as a substrate for neurite outgrowth in culture and found that many antennal-lobe neurons avoided growing on the purified tenascin. These findings taken together support the idea that tenascin-like molecules on glial cells might constrain the growth of the neurites of certain antennal-lobe neurons in the developing glomeruli, although further work in this area is needed.
NEURON-GLIA INTERACTIONS IN SORTING AND TARGETING OF ORN AXONS:

In ongoing studies of the molecular mechanisms by which ORN axons find the appropriate target glomeruli, we have discovered that glial cells play a key role in sending ORN axons to the correct target glomeruli. We have found that a subset of the ORN axons in *Manduca* strongly expresses molecules likely to be identical to, or closely related to, the *Manduca* form of fasciclin II during the period of glomerulus development. Fasciclin II, a member of the immunoglobulin superfamily (Harrelson & Goodman 1988), is a well documented cell adhesion molecule, known to play roles in guidance of axons in the developing grasshopper (e.g., Bastiani et al. 1987) and in *Drosophila* (Grenningloh et al. 1991). In situ hybridization and immunocytochemical experiments indicate that scattered ORNs in the antenna of *Manduca* express fas II (Higgins et al. 1998). Serial reconstructions reveal that fas II-expressing ORN axons terminate in a reproducible subset of glomeruli. The fas II-positive axons are scattered singly or in small bundles throughout the nerve until they reach a glia-rich zone, at the entrance to the antennal lobe, where axons abruptly change their trajectory and sort into glomerulus-specific, fas II-positive or -negative bundles (Rössler et al. 1999).

This finding led us to ask whether ingrowing ORN axons must interact with the cluster of glial cells that they encounter at the entrance to the antennal lobe in order to be able to sort into glomerulus-specific fascicles. Using the same paradigm as used previously to reduce the number of glomerulus-associated glial cells, we reduced the number of glial cells in the glia-rich axon sorting zone, and found that fas II-positive axons no longer sorted into fascicles based on their expression of fas II or terminated in the appropriate part of the antennal lobe (Rössler et al. 1999). Thus, glial cells appear to be essential to the sorting of ORN axons into bundles destined to terminate in specific glomeruli, just as they are essential to the stabilization of forming glomeruli.

CONCLUSIONS

A great deal is known about the development of the insect nervous system. In recent years, the critical importance of intercellular interactions has been recognized, and the molecular underpinnings of these interactions are being elucidated. Because neural development across disparate species involves solving many of the same problems, many cellular and molecular mechanisms being characterized in insects are being found to be very similar to those underlying nervous system development in other invertebrates and invertebrates. Thus studies in other species can inform us about likely mechanisms in insects, and studies in insects will continue to play an important role in helping to elucidate development in less accessible mammalian systems.

INSECT-PARASITOID INTERACTIONS

M.P. HASSELL

LXII

Department of Biology, Imperial College at Silwood Park, Ascot, Berks SL5 7PY, UK.

For much of this Century, insect ecologists have questioned what determines the abundance and patterns of fluctuation of insect populations. This talk deals with one of the major factors affecting the dynamics of insects - parasitism by insect parasitoids and attempts to review how our understanding of the dynamics of host-parasitoid interactions has advanced over the past 20 years or so. Parasitoids are amongst the most abundant of all animals, comprising some 10% or more of all metazoan species. They have been popular subjects for ecological study for a variety of reasons. First, their importance in biological pest control progra mes has stimulated a large amount of empirical and theoretical work seeking to identify and quantify the attributes that enhance the effectiveness of parasitoids as pest control agents. Second, the study of host-parasitoid population dynamics has greatly benefited from the way that parasitoids make ideal subjects for the development of relatively simple population models. This is mainly because there is only one stage, the adult females, that search for hosts, and because the act of finding a host is then normally followed by oviposition. The success in finding and attacking hosts therefore closely defines parasitoid reproduction. Consequently host-parasitoid models can have a much simpler structure than corresponding predator-prey models in which all predator stages may attack prey with different effectiveness, and reproduction is less closely defined by prey consumption. This close link between parasitoid searching behaviour and reproduction has also made parasitoids a popular group amongst insect behavioural ecologists and those seeking to reveal how features of individual behaviour can affect population dynamics. Finally, many species of parasitoids and their hosts can readily be cultured in the laboratory, and this has greatly increased the amount of empirical information on parasitoids under controlled conditions. There are thus several published time series for host-parasitoid interactions obtained from laboratory microcosms, and many laboratory studies have explored the ways that various factors affect parasitoid efficiency. One product of the long tradition of studying the population dynamics of insects has been the number of long-term field studies that have accrued, most of which show conspicuous fluctuations in population size, but without any longterm trends in average abundances. The mechanisms for persistence in such examples, however detailed the study, have tended to remain elusive. In particular, there has often been no clear indication that density dependence is operating, whether caused by natural enemies or other factors, and ecologists have long disagreed over the implications of this. People have argued over definitions, over whether or not density dependence is needed for population persistence, over the frequency with which density dependence occurs in natural systems and over the best ways to detect density dependence and identify regulated populations. This talk reviews some familiar basic models for the dynamics of host-parasitoid interactions. These have been refined in many ways: (1) by including such factors as host density dependence, generalist natural enemies and density dependent parasitoid sex ratios, (2) by exploring the effects of age-structure on hest-parasitoid interactions formulated in continuous time and therefore with overlapping generations, (3) by examining how parasitoids may affect the dynamics of multispecies systems, and (4) by determining how spatial patchiness and other forms of heterogeneity at a wide range of scales, from local populations to metapopulations, may affect population dynamics.

INSECTS FOR STUDYING FUNDAMENTAL PROBLEMS IN BIOLOGY

<u>M. Locke</u>, Department of Zoology, University of Western Ontario, London, Ontario, Canada, N6A 5B7, e-mail mlocke@juliam.uwo.ca

The organism - Insect or Cell - directs me to problems, questions that need to be answered - segmental gradients in the epidermis, the nature of the cuticulin envelope that bounds all cuticles, organelle specific sequences of autophagy in the fat body, tracheal systems that look as though they might be lungs, ferritin that has a different distribution from that in vertebrate cells, cuticle secretion that serves as a model for directed transport. I have opened boxes of problems that I shall never be able to empty. This lecture tells you about them in the hope that they may interest you enough to research them further. For example: When a biologist looks at an organism he is immediately struck by the regularity of its proportions. How this growth is coordinated in different parts to create a sensible design is a much neglected problem. The mechanism by which coordination is brought about can be shown in the adaptive growth of the tracheal system. Tracheal systems are branched tubes that allow air to diffuse from the spiracles to terminal tracheoles in the tissues. Variable growth of the terminations is reflected in growth of the main branches to keep the cross-sectional area of the diffusion pathway constant at different levels of branching. This implies that information on how much to grow is transported cell-to-cell from the terminations to the main trunks, a conclusion that has been confirmed by surgical experiments. Experiments on other tissues, such as the fat body, also suggest that cell-to-cell communication for coordinated growth may be a general phenomenon. Insect biology is dominated by the properties of the cuticle, the most neglected aspect of which is the study of the cuticulin envelope. The cuticulin envelope, like the corresponding structure in bacteria, defines a compartment external to the plasma membrane. In bacteria, the compartment is involved with transport and protection, in insects it is the space within which the rest of the cuticle is deposited. Current experiments explore the nature of the cuticulin envelope. In conclusion, in honour of V.B.Wigglesworth, I remind you of his views on administration. He thought that the prime purpose of science administrators should be to encourage research. "Anyone who has tried both, knows that administration is immeasurably easier than research" he said. Scientists know this. They also know that all of the wealth and wellbeing of modern man depends on it. How then does it come about that modern man is, for the most part, scientifically illiterate. Coverage of science is miniscule in the National Newspapers of the world and the coverage itself is often scientifically illiterate. Does it matter if most of the population, including those who think of themselves as the elite of society politicians, lawyers, business executives, managers - are scientifically illiterate? It matters because these illiterates have hijacked decision making processes that affect all of us. Think of the crew of the spaceship challenger. They were sent aloft to explode because managers overruled scientists on a simple matter of the safety of the O rings sealing the fuel supply lines. The cult of management, the dictatorship of the manageriate, governed by the bottom line, is dangerous to all of us and to the world at large. These scientific illiterates have also hijacked the flow of money for their own remuneration. Research skills are much rarer than management skills. Scientists are highly selected, first from High School to get into University Science programs, then to do Graduate and Postdoctoral work, and for the very best, if they are lucky as well as able, a scientific career. Compare the money earned by that highly select group called scientists with that paid out to business executives. Nobel Prizewinners earn a fraction of that which thousands of top business executives award to themselves. This is more than an injustice, it is a most serious problem. Human survival depends on science and scientists. Unless the very best brains are recruited into science, unless these top brains have the resources to be fully employed, and unless they have a greater role in decisions arising from the implementation of their findings, those implications that affect humanity, the human species will not survive.

WHITEFLIES REVISITED

Į.

D. Gerling, Department of Zoology, Tel Aviv Univ., Ramat Aviv 69978 Israel Fax- 972 3 6407830 voice 6408611, e-mail <u>DANGR@post.tau.ac.il</u>.

Scientific advances are continually being made. Every scientist knows this and likes to "revisit", in order to share the excitement of new findings with his colleagues. But why have whiteflies been chosen as the group to be revisited? The eternal race for increased fitness [the ability to leave more viable and reproductively effective progeny relative to the abilities of other individuals or populations - (Price 1996)] has led to the emergence of new and better-adapted forms of life. Once detected, it is of special interest to learn in what way such forms stand out and how their traits contribute to greater fitness. Whiteflies, or Alevrodidae, have been known and studied for over 250 years. The research conducted reflects the changes in their economic status and advances in biological theory and scientific methodology. During the last 100 years, two whitefly species, the greenhouse whitefly [Trialuerodes vaporariorum] and the tobacco or sweetpotato whitefly [Bemisia tabaci] seemed to differ from other economic species in defying attempts at classical biological control and have become economic pests of worldwide proportions. During the past 15 years, B. tabaci has caused damages sometimes reaching \$500 million or more per year (Perring et al 1993). Concomitantly, B. tabaci races and biotypes were found. The most prominent one, biotype 'B', showed increased fitness in relation to the former 'A' biotype. It eventually replaced it in extensive regions, and has been described as a separate species: B. argentifolii. The increase in fitness of biotype 'B' and its greater economic importance, have been accompanied by a rise from about 830 publications since Gennadius' description of B. tabaci in 1889 through 1985, to about 3150 from 1985 till 1998. Thus, our body of information, which once concentrated upon whitefly taxonomy and behavior, has been supplemented with studies on whitefly control, host plant relationships, physiology, molecular biology, natural enemies and tritrophic interactions. Therefore, the new biological and physiological information recently uncovered in whiteflies warrants revisiting. Gerling (1990) and Byrne and Bellows (1991) reviewed many of the findings concerning whiteflies in general, whereas Gerling and Mayer (1996) and Henneberry et al (1998) discussed Bemisia. Relying on this fact, I shall only present here some results of recent research that contribute to our understanding of fitness-enhancing strategies: whitefly relations with competitors and natural enemies, the physiology of whiteflies in relation to their environment and the emergence of *Bemisia* as a major pest.

TRITROPHIC RELATIONSHIPS

Whiteflies (Aleyrodidae, Homoptera) have winged, free-flying adults. Their eggs are inserted into the leaf tissue by means of a pedicel. The hatching crawler settles in the proximity of the oviposition site following a search for a suitable location into which to insert its mouthparts and reach the phloem veins from which its feeds. All four nymphal instars, following the settling of the crawler, spend their life in the same location, reinserting their mouthparts into the leaf tissue following each molt. The fourth instar is usually short and transforms into a so-called pupal stage during which the scale-like nympn transforms into the winged adult that emerges through a slit in the dorsum of its shed exoskeleton.

Whiteflies have arrhenotokous reproduction. Unfertilized eggs produce males. Sex ratios are often close to 1, but may be biased towards either sex. Dispersal is through adult flight leading to landing on new host plants. Being small, whiteflies depend upon air currents for transportation. They often fly only short distances, but marked adults have been found seven kilometers from their point of origin (Byrne 1999).

The leaves upon which whitefly nymphs live are also a substrate for other phytophagous insects, the whiteflies' competitors, as well as the roaming grounds of predators and parasitoids, the whiteflies' natural enemies. Additionally, whitefly feeding removes nutrients from the plant and induces biochemical reactions that are unique to injured plants (Inbar et al 1999a,b). It is interesting to examine if and how defense of whitefly nymphs against natural enemies and antagonism *vis a vis* competitors materialized, considering that the only mobile stages of the whiteflies are the adults and crawlers.

Interspecific territoriality in whiteflies can materialize directly, morphologically and/or physiologically, or indirectly through the plant. Morphological features with possible territorial functions in whiteflies include: a powdery wax produced by the adults, and often also covering their places of residence and oviposition upon the leaf; and waxy spines and/or protrusions on the immatures. The quantities of both of these, and the numbers or size of the latter may vary among different species and conditions. In addition, whitefly nymphs may be transparent, white, brown or black.

Such features indicate considerable expenditure in extra-corporal structures (e.g. Guershon 1997), whose cost-benefit relationship should be examined in direct association with all three trophic levels. Few such studies have been performed, but they nevertheless indicate a consistent trend in their functional morphology.

Ovipositing females of the ash whitefly, Siphoninus phillyreae, deposit a typical circle of wax. When developing on Crataegus aronia this wax prevents another homopterous leaf feeder, the tingid Stephanitis pyri, from approaching the area of whitefly development, leaving clear-green regions surrounding the latter. Experimental evidence for direct defense against natural enemies was produced by Guershon and Gerling (1994). The exuviae of the nymphs of Aleyrodes singularis, developing on Lactuca serriola, remain on the nymphs and are piled on top of one another. In addition, the mother female, following oviposition, remains upon the patch on which her progeny develop, frequently shaking powdery wax from her wings to create a permanent waxy cover that prevents parasitoid females, except those of Encarsia inaron, from walking on or mounting these nymphs.

Exclusion experiments in the field showed that even *E. inaron* was able to parasitize fewer hosts in the presence of wax than in its absence. The case of *A. singularis* is of particular interest since it implies parental care by the female. This is further supported by observations that the female physically attacked parasitoids and predators that visited the patch.

Spiny protrusions, in varying quantities, have long been known to exist on whitefly nymphs (Mound 1963). By creating artificial tomentosity on smooth leaves, Guershon (1997) has experimentally shown that the nymphs show individual variability in the propensity to become spiny (or smooth). He also showed that nymphs upon tomentose leaves possess more spines than those on smoother leaves with spineless nymphs found on glabrous leaves. An adaptive explanation for this relationship comes from studies on foraging behavior by adults of the coccinellid predator *Delphastus catalinae*. On tomentose leaves, they prefer to attack spineless vs. spiny nymphs. Associative learning enhanced this trait, making it more explicit in experienced beetles.

In addition to the dorsal spines, many whitefly species secrete a waxy fringe around their margins and waxy filaments over most of their body or parts of it. These waxy "ornaments" may become very elaborate, creating a maze of wax on and around the insect. In some species, like *Aleurodicus dispersus* and *Lecanoidues floccossimus*, the wax covers large sections of the leaf, and has been observed hampering parasitoid movements. Moreover, the parasitoid *Encarsia hispida* that successfully attacks *A. dispersus* on which the wax does not encircle the whole nymph, is unable to reach and parastize *L. floccossimus*, in which the wax ring surrounds the nymph completely (E. Hernandez-Suarez personal communication). Since parasitoids of the genus *Eretmocerus* must reach the margins of their host nymph in order to insert the ovipositor under its margins, it is tempting to speculate upon the defensive values of the "fringe extension" in preventing parasitoid attacks. Unfortunately, no experimental evidence has been forwarded to support or refute this or other hypotheses. Neither has an explanation been forwarded to the fact that many of the whitefly nymphs exhibit the most elaborate protrusions only during the pupal stage, whereas the younger nymphs, which are the targets of parasitoid attack, are hardly ornate. Thus, significance of whitefly investment in wax and structural modifications, and their relationship with fitness, are only starting to unravel.

Insect-plant interactions were shown to induce the production of putative protective proteins in the plants, such as chitinases, peroxidases and lysozymes. The magnitude of induction for each defensive protein varies among insect species and different plant species. Inbar and co-workers (Inbar et al 1999a) showed that adult feeding, oviposition and larval survival were reduced by 26.5%, 47.7%, and 30.7% respectively in the leafminer *Liriomyza trifolii* feeding on plants infested by *B. tabaci*. However, *B. tabaci* remained unaffected by changes in plants caused through feeding of *B. tabaci*, *Helicoverpa zea*, or *L. trifolii*. Additional experiments (Inbar et al 1999b) examined feeding of the looper *Trichoplusia ni* on collard leaves infested with whitefly nymphs vs. uninfested ones. Development of their larvae was 20.8% slower and relative growth rate was reduced by 18% on whitefly infested vs. control leaves. Young larvae were also found more often on the nymph-free adaxial (top) side of the leaf than on the underside on which the nymphs were present. Finally, field survival to pupation was only 4% for larvae feeding on whitefly-infested plants, vs. 18% on whitefly free plants. These results may indicate that the feeding mechanisms of *B. tabaci* avoid contact with the induced plant defensive chemicals. However, since the whitefly induces formation of products that adversely affect its competitors, its immunity can be seen as a mechanism conferring competitive advantage in utilizing food resources, and possibly increasing its fitness.

WHITEFLY PHYSIOLOGY AND BEHAVIOR

Studies of *B. tabaci*, and other whitefly species that feed on annuals, have concentrated upon features that enable them to survive and multiply in their ever-varying environment. The main constraints in such environments are: constant changes in plant suitability, a need to shift from one, wilting, host plant species to another several times a year, and the selective pressures imposed by human agricultural practices. The great increase in whitefly populations and ranges, attesting to their successful adaptation, have led to studies elucidating some of the physiological and behavioral mechanisms underlying whitefly biology.

Physiological changes in the developing whiteflies, that are detectable both morphometrically (Byrne and Houck 1990) and in the egg loads and levels of vitellogenins, (Isaacs and Byrne 1998), indicate that whiteflies can "read" the worsening host plant quality and choose a different metabolic pathway during their immature development. Presumably the emerging adults, now with different wing dimensions, less commitment to egg production and less of an egg load, will make better migrants with better chances of arriving at a suitable host on which to establish further generations.

Host plant choice also poses intriguing dilemmas. Bernays (1999a) argued that polyphagous insects, like *B. tabaci*, face difficulties in choosing host plants that stem from shortcomings in their sensory and nervous systems. The difficulties are expressed as changes in behavior of the landing adult and in the relative number of eggs laid on different host plants when choice vs. no choice replicates are compared (Bernays 1999b). These behavioral patterns indicate better success when attacking an agricultural crop (a monoculture) than a mixed natural stand of plants.

Being weak flyers, whiteflies are dependent on air currents. They may have little influence on their direction of movement, and cannot be precise in the choice of their landing site. There is thus little active choice prior to contact with the plant, after which the insect may remain on the plant or desert it for another (Gerling and Lindenbaum 1991). The phase between landing and feeding cannot be completed before the whitefly has adapted to the new host plant that is often heterospecific with the previous one. Behavioral aspects of this phase, in which new plant features have to be adapted to, have been dealt with by several workers (van Lenteren and Noldus 1990) and I shall not discuss them here. However, recent work has also shown the need for, and the existence of enzymatic adaptability, without which polyphagous plant feeding insects would face difficulties.

Each plant species mobilizes specific types of sugars in the phloem. Cotton plants mobilize sucrose, while cucurbits mobilize galactose-containing sugars such as raffinose, or stachyose. Whiteflies, being phloem feeders, need to break down these different sugars in order to utilize them as well as to dispose of excess sugars by changing them into other oligosaccharides such as trehalulose (Salvucci et al 1997). When migration occurs from squash or melons that use raffinose and stachyose, to cotton that uses sucrose, the insect must also shift its metabolic pathway, using different enzymes for sugar breakdown. By moving whitefly adults from cotton to squash plants and examining honeydew production, it was possible to show that after as little as three hours, they were able to utilize the new sugars for nutrition (Salvucci and Gerling, personal observations).

The outdoor distribution of Bemisia includes mainly countries with desert climates in which temperatures throughout the summer can exceed 40°C. Adaptation to such conditions, and especially protection of soluble proteins from heat-induced aggregation and inactivation, is vital. In whiteflies, the mechanisms for coping are not associated with evaporative cooling, due to their minute size, which renders them too vulnerable to desiccation. Alternative methods include remaining on the lower leaf surface, which under dry weather conditions may evaporate water and thus lower ambient temperatures near the leaf (Lu et al 1997). Whiteflies also synthesize heat-shock proteins (Hsp) in response to heat stress (Salvucci 2000). In addition, Salvucci and coworkers (Salvucci et al 1999, Wolfe et al 1998) have shown that *Bemisia* accumulate the polyhydric alcohol sorbitol, when exposed to temperatures in excess of about 30°C. Recently, Salvucci (2000) has shown that when whiteflies were conditioned at 40°C, they showed greater heat-tolerance than did unconditioned individuals that were kept at 25°C. Relying on the findings of Wolfe et al (1998) that sorbitol levels increased 15-27-fold (to about 0.5M) in heat-stressed whiteflies, he argued that sorbitol accumulation protects whiteflies during heat stress in a similar manner shown for trehalulose protection of yeasts. Since sorbitol levels can only be raised when the insect is actively feeding from the plant, the mechanism of heat resistance begins when the whiteflies are on the plant and is affected by a combination of their location (underneath the leaves), Hsp and raised levels of sorbitol. The latter is mainly active when the whiteflies are feeding on healthy, non-stressed plants, whereas Hsp gain importance when the plants are in poor health. It remains to be examined if loading with sorbitol prior to migration helps whiteflies to resist the high temperatures that may prevail en route to the new host plants.

THE BEMISIA COMPLEX

From its first description, *B. tabaci* has been reputed to reach high populations (Gennadius 1889). Following reports in the 1920-1930s from India and Israel (Husain and Trehan 1933, Sachs 1994), it later appeared as a pest of vegetables and cotton in numerous places in the Old World including the Sudan and Egypt. Between 1970 and 1980 unexplained increases in whitefly populations were reported [Turkey about 1974, Israel 1976/7 (Sachs 1994) and the Sudan about 1979 (Dittrich et al 1990)]. The extensive cotton fields produced millions of whitefly, which, especially following cotton defoliation, moved to other field crops and vegetables. Massive insecticide applications followed, with the inevitable result of resistance build-up and a general failure to cope with the increasing whitefly problems. Dittrich et al (1990) attributed part of the problem to hormoligosis, i.e. the ability of insecticide-resistant *B. tabaci* individuals to increase their oviposition rates several folds when under insecticidal stress. Since then *B. tabaci* has been recorded, sometimes as a very severe pest, in most locations of the Old World in which climatic conditions permit its existence.

In the Western Hemisphere, *B. tabaci* was first reported in 1894, but aside from being a vector of cotton leaf crumple, it was rarely of economic importance prior to 1975 (Henneberry et al 1998). From the mid-1980s on, it started to increase its host plant range and to cause new physiological disorders. Concurrently, unusually high populations developed in California and Arizona and suspicions arose as to the identity of the *Bemisia* species or variety at hand. Several years of study (Henneberry et al 1998) have resulted in the description of a second species, *B. argentifolii*. The validity of the specific status given to the so-called "type B" *B. tabaci* on the basis of mating incompatibility studies and morphological characterization as well as on molecular examination (Bellows et al 1994), is still unsettled, although its distinctive characteristics are well recognized (De Barro 2000, Henneberry et al 1998).

During the last 10 years the range of *B. tabaci* has continued to spread, making it a serious pest in vegetables and field crops in many previously uninfested, South American and Far Eastern countries (Hilje, 1998, Sumalde and Salinas 1999). Thus, Gennadius' prediction that this insect species has the potential of becoming a very damaging pest has fully materialized.

At present, studies on *B. tabaci* bifurcate. On the one hand, the appearance of host-associated races, new biotypes and possibly new species indicates active changes in the process of speciation. Therefore, with its ca. 100 year known history, it offers an interesting subject for the study of possible short-term evolutionary changes. On the other hand, it is one of the most damaging pests known, and prevention of present and future damage is of paramount interest in the agricultural world.

The changes in the taxonomic status of *B. tabaci* might have resulted from recent mutations, selection on existing types, or both. Whatever the case, we could have expected multiple biotypes and strains to exist since its morphological variation has long been recognized (e.g. Mound 1963), resulting in over 10 synonyms of *B. tabaci* presently known (Henneberry et al 1998).

Principal factors contributing to the rapid process of specialization, and possibly speciation, are also recognizable:

1. The extensive geographic and host-plant ranges can lead to allopatric development of differences. For example, the "non-B" biotypes found in Spain (De Barro et al, 2000), may have developed in isolated conditions in relation to the ubiquitous 'A' or other biotypes that were or are typical to the Mediterranean region. Sympatric strain developments in *B. tabaci* that are plant-associated have been reported by Legg (1996). Whiteflies from cotton and sweetpotato did not colonize or survive on cassava, while the

Plenary Lectures

reciprocal arrangement, with the whitefly from cassava on cotton, showed limited colonization of the cotton. However, their adults, emerging from cotton, retained the ability to colonize cassava, confirming the genetic basis for this discrimination.

2. Genetic factors, including: a. The extensive whitefly populations forming isolated subgroups that could have led to segregation. b. The nature of whitefly populations, rising to extremely high numbers and then declining to few individuals due to the absence of suitable host plants, inclement weather, or insecticidal treatments, suggesting a "flush-crash cycle" mechanism (Carson 1968). Thus genetic drift following a bottleneck could change the genetic structure of the population and enable natural selection to act on the new genomic compositions. c. The arrhenotokous haplodiploid sex determination mechanism favors rapid evolution since the deleterious recessives are rapidly selected out of the population in the halploid males (Price 1996).

3. Human activity, driving the process of specialization further. We supply large quantities of uniform, stable food sources and apply insecticidal pressures. These, in turn, lead to the formation of very large whitefly populations, resistance buildup, and to processes like hormoligosis generating, again, large populations that differ somewhat from the parental ones.

4. Finally, new technologies, especially those employing molecular genetic methods (e.g. PCR) enhance our recognition of genetic specialization by enabling us to differentiate among strains that were previously indistinguishable.

It may be worth speculating on the interface between changes occurring to *B. tabaci* and its status as an agricultural pest, i.e. "what are we to expect, and what can we do about it"?

Except for the transmission of viral diseases, the history of *B. tabaci*-associated problems usually repeats itself. Extreme population outbreaks cause extensive damage that even the most frequent and sophisticated insecticide and management techniques fail to control. A few years later the problem abates somewhat, resulting in a more stable, controllable condition that, in contrast with the outbreak phase, is open to IPM technology. This process is reminiscent of the developments that take place following establishment of an invading species. An explosive stage, in which the invader can take advantage of its novel capacity to exploit untamed local resources, is followed by a more balanced stage, in which local resistance, including natural enemies, host plant defenses and climatic constraints materialize. The new population level reached is typical of the local conditions under which it has developed. If we relate to the *B. tabaci* biotypes and strains as invaders, we should expect that, following the outbreak phase, it will stabilize in different crops and conditions at different levels, depending upon climate, host plant availability and suitability, and pest management practices

This reasoning leads to the following practical conclusions:

1. We can expect severe, widespread and hardly controllable outbreaks in the first few years following invasions. These usually cannot be handled by the growers alone and must be dealt with at the state or national level in cooperation with the growers. At this phase a different approach must be taken towards the initial "invasive stage outbreaks" vs. the later "stable stage outbreaks" (Gerling, 1996).

2. It is critical that management, including employment of natural enemies, be implemented as soon as viable. This is especially important since the chances for resistance build-up already at the "invasive stage outbreaks" are substantial, and the resistant populations will be carried over to the "stable stage outbreaks" hampering IPM attempts in the future.

3. The mere discovery and description of new biotypes has little value unless the relationship to functional traits is elucidated as a lever for better biological, ecological and agricultural understanding, leading to better management.

ENTOMOLOGY FOR THE THIRD MILLENNIUM -SCIENTIFIC AND TECHNOLOGICAL CHALLENGES

Manfred Kern, Aventis CropScience, Industrial Park Höchst, K 607, D-65926 Frankfurt/Main, Germany Fax: ++49 (0)69 305 7342, E-mail: manfred.kern@aventis.com

Address:

Introduction

You are all familiar with the rather odd question reporters always ask players immediately after the game before leaving the field: "How did you see the game?" The only sensible answer, of course, would be: "Quite well, I was taking part." What the player while still struggling for breath - is expected to give is a preliminary analysis of the course of the game. Although I am not a sportsman, and this has not been a game, the situation I find myself in here is rather similar.

At the breathless end of what was for me personally a great entomological and educational experience, I can only give a provisional analysis: I am still trying to order the impressions made on me by the contributions to this XXI International Congress of Entomology here in Brazil at Foz do Iguassu.

As a scientist in the area of applied entomology, working in the industry for the crop production company Aventis CropScience, I trust you will believe me when I say that it is a very great honour and an extraordinary challenge to be invited here, to outline the hemimetabolic and holometabolic developments in insect science, and the visions, future tasks, missions and "entomological utopia" of the twenty-first century. This is not a simple task.

What better way to do this than try to "think" or "behave" like an insect? Just like the insects, I will now try:

- to communicate with you,
- to sting and bite you, though certainly not to kill you or paralyse you,
- to get on your nerves, but also to amuse and entertain you,
- to fascinate you and set you buzzing with ideas, and, if you like, to help you develop insect wings for a flying start into the new millennium.

World famous entomologists

All scientific entomological knowledge has grown out of the painstaking work of generations past and present.

There is no need for me here to draw up a list of all eminent entomologists separately - all the Fabres, von Frischs, Buthenands, Uvaroys, Nabokovs, Dethiers, Osamus, Wigglesworths, Gilberts, Wilsons, Nüsslein-Volhards and the rest.

Let it be sufficient to express our gratitude that they approached insects in the right way, and had the ability and wisdom to grasp the essentials about insects in a rapidly changing world and to impart them to us.

I think this is the right time and place to thank all those entomologists from whom we received our basic knowledge, and to honour them with a round of applause.

May I ask you all to stand? ---- Thank you very much!

An applied entomologist

Entomologically speaking, my own "egg phase" started with the study of "Brain ageing in insects - insects as model organisms to prolong life span"; insect brain structure and functions, entomo-neurophysiology, and biochemistry of insects was my profession. During my "hemi-/holometabolic development" I worked in the field of pest control, looking for new selective insecticides, analysing new modes and mechanisms of action, contributing to the field of entomo-neuropharmacology, analysing mechanisms of selectivity and pesticide resistance, working with insect pathogen fungi, and discovering synergisms of genetically engineered plants and insecticides.

During the time I devoted myself to basic and applied research in IPM and ICM, I was able to learn more about a wide range of very different agricultural production methods in almost fifty countries, from wheat, rice, soybean, tea and vegetables to coffee and cacao.

The aim of my work was sustainable dematerialisation, enhancement and optimisation of agricultural production.

During all these years I have watched, analysed and killed a lot of insects, such as tobacco hornworms, *Manduca sexta;* blowflies, *Calliphora erythrocephala*; silkmoths, *Bombyx mori*; honey bces, *Apis mellifera*; coffee berry borers, *Hypothenemus hampei*; tobacco budworms, *Heliothis virescens*; leaf cutting ants, *Atta sextens*; lace wings, *Chrysopa carnea*; paper wasps, *Polistes erythrocephalus*; cotton boll weevils, *Anthonomus grandis*; Colorado potato beetles, *Leptinotarsa decemlineata*, etc. - all of them highly astonishing and fascinating organisms!

Behind all this work, there is a cardinal imperative which will continue to be valid in the twenty-first century: a bio-ethical examination and evaluation of all tests carried out on insects and of all measures taken to control them.

Entomologists in the twenty-first century will very certainly have to develop bio-ethical standards! They will be called upon to find ways of applying the entomological sciences for improving the quality of life, especially in the context of the human right to sufficient food.

World food security and insects

In fact, the quality of life is the focal point we have to face when we talk about the role of insects, the safeguarding the world's food supplies. Today, during the hour or so taken up by the closing lecture of the XXIst ICE, the world population will have increased by another 7,000 people.

There is no escaping the fact that "food and safeguarding of food supplies" is a topic which will continue to increase in importance. The number of conferences held on the subject has increased threefold since 1994, with 400 to 500 per year and the tendency pointing upwards. The central question is: "How can we feed the future world population sustainably and in keeping with human dignity?"

Let us take a look at the factors "requirements" and "consumption" up to 2025 (2050). Round about 1850 the number of people on this planet was approximately 1 billion, and during 1999 the number reached 6 billion. Mean estimates indicate that by 2025 the world population will have risen to more than 8 billion. However, this numerical increase is not the main problem for future world food supplies and the safeguarding of these supplies; a much greater impact will be had by rapid economic growth in the key regions of our planet. This economic development will very quickly alter world eating habits and increase total food consumption - first of all regionally, and then throughout the world.

A look at the increases in calorie consumption will reveal significant regional differences. Consumption today in the Western world is around 3,400 kilocalories per head and day. The increase here over the next 25 years is hardly worth mentioning: 3,470. At the same time the average global calorie consumption rate will increase from 2,700 to 3,000. Here is where the great challenge lies. To make this clear, let us take Asia as a whole - China included - where the calorie consumption will rise from 2,400 kilocalories per head and day to 2,880 by the year 2025. This means that about 50 percent of the world population is moving over from low calorie consumption to a more nutritious dietary level, though still not up to Western standards.

And if we now look at the food requirements and food production of the world as a whole, we will find that we have a slight "surplus". The word "surplus" suggests that we already have more than enough. But this is not so: at the moment only 0.26 percent more food is being produced than is actually consumed. And this without even allowing for the fact that we are still a long way from eliminating the hunger of 0.84 to 1.2 billion people in the world today.

Our first priority must be to create the technical basis for producing as much calorie and energy-rich food as is needed throughout the world. We must bear in mind that over the next thirty to fifty years world food requirements will more than double, and this will make it necessary to double - and even treble - agricultural production and supplies. At the same time, we will have to compensate for reduced farmland areas, water shortages and the switch from plant-based to meat-based diets.

In the next thirty years we will have to produce more food worldwide than over the whole of the last 10,000 years. And we will have to do all this in a sustainable and environmentally compatible way. "Meeting the needs of the present without compromising the ability of future generations to meet their own needs" is our guideline for sustainable development written in the Brundtland commission report in 1987.

The need for food creates a relationship between human beings and the environment, and insects are here the key organisms. Insects can survive very well without us, but we - like most other terrestrial organisms - would be lost without them.

In the USA, for example, the annual value of pollination by honey bees has been estimated at 6.7 billion dollars. When a mite plague spread among bee colonies in America at the end of the nineties, agricultural yields went down immediately. This is just one example of how we hardly notice insects in everyday life, and only start to realise the role they play when they are disappearing or have already disappeared.

On the other hand, it must not be forgotten that the principal occupation of an insect, especially of a caterpillar, is eating. Anything else it does is connected with its metamorphosis, is subservient to the function of procuring food. Most species feed on plants and live in the open, but some tunnel into the leaves, into the fruit, or into the stem or wood. Other species feed on seeds, stored grain, and cereal preparations.

Yudelman et al. (1998) have reviewed the estimated annual losses from pests on 50% of the crop area world wide, especially in rice, wheat, barley, maize, potatoes, soybeans, cotton, and coffe. Pre-harvest losses were due to insects (15%), pathogens (13%), weeds (14%) and additionally 10% by post harvest losses. Without pest control the overall world wide losses from pests were as high as 50%.

Entomologists in the twenty-first century will be under an obligation to answer the following questions: "What must we do, what must we try to achieve, what actions must we take, and what constructive changes must we make in order to keep a sound balance between world food security and a functioning environment?"

For this reason I would like to draw your attention to the Rio Conference of 1992 on Sustainable Development, Agenda 21, Chapter 16, on the subject of biotechnology. Chapter 16 expressly propagates gene technology. Although it refers only to biotechnology, the wording in this context is invariably used in the sense of gene technology. "Biotechnology is the integration of the new technologies emerging from modern biotechnology with the well established approaches of traditional biotechnology.

Biotechnology, an emerging knowledge-intensive field, is a set of enabling techniques for bringing about specific man-made changes in deoxyribonucleic acid (DNA), or genetic material, in plants, animals and microbial systems, leading to useful products and technologies."

In view of the tasks confronting a sustainable future agriculture, genetic engineering combined with improvements in conventional production technologies will make a decisive contribution to the production of more food and raw materials on a sustainable basis and on already available farming areas. Basic and applied entomology has a special obligation to meet these challenges and find appropriate solutions.

Climate change, pests and beneficials, biodiversity

Climate change will have significant implications for the regional flora and fauna, with insects as poikilothermic organisms being amongst the first species to respond to change.

The present geographic propagation of pests is substantially limited by temperature. Insect populations at present confined to the tropics will most likely spread towards middle latitudes when the atmosphere warms up. A significant northward move in Europe at an average rate of 20 - 50 km/year is estimated by Kozar, F. (1997). Warmer climates generally offer better possibilities of wintering and lead to a higher density of population, earlier presence of populations and an increased risk of invasion by migratory insects. Higher atmospheric CO₂ concentrations increase the carbon assimilation of plants and modify the carbon distribution pattern, and qualitatively and quantitatively the secondary plant ingredients. The increase in bound carbon in a plant causes a reduction of the nitrogen concentration. The result is that nitrogen may become more and more a limiting factor for the development of insects. In economically important species, this will finally lead to an increased uptake of biomass. Considerable yield reductions due to increased damage by insects loom up in agriculture.

Quite different reactions to the impending climatic change are to be expected in view of the biological and physiological/biochemical diversity of the pests and the complex relationships within the systems "crop plant – pest – beneficial". The following effects are most likely to occur in pests and beneficials, independent of the host, due to an increasing climatic change:

1. Various changes in the geographic propagation of pests and beneficials

- 2. More rapid development and an increased number of generations
- 3. Prolongation of the development season
- 4. Modification of the interaction "plant noxious organism beneficial".

Insect-dependent plant pollination will also change as a result of climatic changes and thus also the productivity of plants. Climatic changes do not only have effects on local and regional food chains, but even on complete food systems. Such changes will affect the biodiversity of some regions.

Important fields of work and tasks of entomology in the twenty-first century may be derived from these briefly outlined interrelated topics:

An important part of the work of entomologists will be to analyse the habits of plants, pests and beneficials and their interactions in various agricultural ecosystems, paying attention to factors such as CO_2 , CH_4 , N_2O , O_3 , temperature, and effects on biogeography and biodiversity.

Biodiversity and insects

"The preservation of biodiversity is a common concern for mankind" (Convention on Biological Diversity, Rio de Janeiro, 1992).

The Rio de Janeiro Convention on Biological Diversity was a milestone on the road to sustainable conservation of the earth's genetic resources. The preservation of biodiversity is an essential prerequisite for the future development of the earth as a viable habitat. It is therefore an objective worth pursuing in its own right. New insights into processes and structures, and genes of animals and plants, will also help us to find new ways of combating disease, safeguarding the food supply of the world's growing population and protecting the environment. The preservation and sustainable utilisation of the diversity of species is of vital importance for the interests of all mankind, for the countries which supply these resources and, last but not least, for the health and food industries.

Let me give you an example to illustrate the importance of preservation: One single Peruvian peasant who cuts down rain forest to feed his family and then moves on from one patch to the next as soon as the nutrients in the soil have been used up, will destroy trees and insects of more species than are native to the whole of Europe. And he will go on felling trees as long as he cannot earn his living in any other way.

"Biodiversity can be rescued from the grindstone of poverty only if we can find new potential uses for already cleared land and for the remaining intact areas. We must look for new methods to make better use of the yield potential of natural habitats - without involving their destruction - and to encourage the invisible hand of the free market economy to grow a green thumb. The search has already started" said by E.O. Wilson (1997). Protection of global biodiversity areas, conservation of biodiversity on arable land and safeguarding of the biodiversity potential of crop plant species are key areas of biodiversity, sustainable agriculture, sustainable development and, ultimately, of a sustainable socioeconomy.

By 2015, pests and diseases will be controlled largely by genetic methods (Delphi '98). Within the next couple of years entomologists will have to prove that the widespread application of biotechnology has no significant adverse effects on the preservation of genetic diversity or biodiversity in the agricultural sector. This is one of the key responsibilities of entomologists in future.

Nobody today can possibly say what a particular beetle might have been useful for if it still existed today. Simply the fact that it survived over a very long period of time made it something special - after all, 99 percent of all other species had already become extinct before it.

During the process of evolution, many forms of life - some breathtaking, some very unobtrusive - have developed and survived into our own times. As Gleich et al. (2000) have demanded, we should never sacrifice any of them except under sheer force of circumstances. They are our vital capital for the future, for an intact environment and the foundation of its dynamism.

Parasites and pathogens - the plagues of the future

In future more than half of the world's population will be living closely packed together in mega-cities of 10 to 25 million people, and since human parasites and their vector organisms have by no means reached the end of their evolution, we have to assume that future generations will be confronted with massive onslaughts of parasites and pathogens, both old and new, with ever more finely-tuned molecular methods for overcoming immune barriers and control methods.

Half of the world's population lives under the threat of insect-borne diseases.

At the present time more than 12 million human beings are afflicted by leishmaniasis, according to estimates of the World Health Organisation, and more than 350 million people live in risk areas. The number of new infections is about 2 million per year, tendency rising.

Vectors such as mosquitoes and ticks transmit diseases to hundreds of millions of human beings, and the number of mortalities associated with these infections exceeds 1 million each year and perhaps as many as 2.5 million. But malaria control, for example, is not a profitable market, which is why very few financial resources are available for research in this field.

Advances in biotechnology, including mapping the genome of the malaria parasite, point to a possible malaria vaccine. But it will need a private-public cooperation to take the right course.

Nanotechnology and insects

In the early days of entomology scientists observed insects under natural conditions, collected them, described them, named them and classified them. Later on, entomologists started to learn more about insects by analysing the interior of insects, i.e. they studied the organisms in vivo. In the century which has now just ended they learned to examine them in the test tube, i.e. in vitro. In future they will investigate insects with the aid of the computer, in silicio, so to speak.

Scientists will systematically analyse natural functional principles in order to exploit them commercially. Material specialists and chemists, architects and automobile constructors will be looking into nature's toolbox. And they will do this because insects show what can be achieved given a good power source, sophisticated controls, superlative materials and 350 million years of evolution.

The "nano era" of the twenty-first century will also revolutionise, or evolutionise, entomology. Biochips will be expressed in insects, and with the aid of nanotechnologies, i.e. nanoelectronics, nanomechanics, nanobiology, nanomanufacturing, nanocontrol and nanomicrology, it will be possible to construct mechanical insectoids, hybrid cockroach robots and ant robots. Crawling robots and "intelligent spare parts" which will make life easier for handicapped people (controllable "running" plates and cups).

At the same time as we are advancing our knowledge of the macro-world, we are also engaging in unremitting exploration of the micro-world. After undergoing the "catalysis" of modern science and technology, certain notions that used to be looked on as wild tales are now confronting mankind "as if coming to life". Some of man's fantasies are to manufacture extremely small-scale electrical machinery that can only be seen under a microscope, an "intelligence chip" that could be transplanted into the brain of an insect, or a "remote controlled submarine".

We will have the responsibility of ensuring that all these things do not become a knife "cutting both ways" and threatening social stability. "Microscale electromechanical insects" or "modified insects" should never be used as nanotechnology weapons"!

Entomology/Gen(e)tomology

Another challenge lies in the creation of genetechnology-based entomology. In fact, entomology in the twenty-first century will bear the title "Gen(e)tomology". The large number of highly diversified insect species, the successful evolution of insects, their enormous adaptive potential, their many different survival strategies, their immensely efficient communication systems, and their highly organised society formation will become key fields for molecular biology and gene technology in the future. Transgenic strains of arthropod vectors will become commonplace. We will also be in a position to create and produce new insect species.

Just imagine the scope of possibilities: one thousand grams of DNA (dissolved in one cubic metre) would have a larger storage capacity than all computers which have ever been built, or about 100 billion times the storage capacity of our brain. Thirty grams of DNA work one hundred thousand times faster than the fastest computers we know today (Kaku, 1998).

The genetic code of life is a gigantic biological manuscript that we have scarcely yet begun to examine or decode.

Plenary Lectures

"Drosophila - completely decoded" was the great headline at the beginning of the year 2000. This means that we now know the 13,601 genes of each separate cell and also those for the development from egg to adult fruit-fly.

Let me describe the great amount of work that still lies ahead: Molecular biologists will be responsible for the process of gene and genome cloning, sequencing and the expression of the genome. Entomologists will be needed in the field of expression, for instance to express DNA (chips) (transcriptones), and to analyse the consequences of a treatment or a stress on gene expression. Furthermore, they will analyse the proteins (proteomics) and various metabolites (metabolomes) in an insect cell (which will be the basis for any patents), and last but not least carry out functional analyses of gene networks (phenomics or better 'physiomics'). An important goal will be to determine the function of a gene, *in silicio*, in *vitro* and *in vivo*.

What will we have to establish?

1. Genetic maps, for identifying and localising traits on the chromosomes.

2. Cytological maps, for visualising chromosomes and bands corresponding

to traits and for localising genes on the DNA.

3. *Physical maps*, describing the complete nucleotide sequences.

Genomic research will enable us to identify and validate new targets for insecticides, and to determine the mode of action of active ingredients. It will also place us in a position to identify new genes and gene functions to enable us to discover and validate new traits for seed improvements.

With the aid of gene technology, we will obtain insects which are able to produce drugs, probiotics and essential products.

At the beginning of the next century a diverse range of novel molecular DNA markers will be available for entomological investigations. Both DNA and protein markers have revolutionized the biological as well as the entomological sciences; they have enhanced many fields of study, especially ecology, taxonomy, population biology, insecticide resistance and pest control. A review article is given by Loxdale, H.D. and Lushai, G. (1998).

End of 1999 Wimmer, E., Berghammer, A. and Klingler, M. in Germany succeeded for the first time in developing a universal marker gene that was to function in all insect species. Demonstrated in the fruit fly and yellow mealworm beetle as examples, the eyes of transgenic animals fluoresce green due to the introduction of this marker gene. The universal suitability of this marker gene is based on the fact that it is activated by a regulatory mechanism, which has been generally expressed throughout the animal kingdom. An exciting new field has been opened.

In this case also, it may be stated that insects remain an endless source of both theoretical and applied interest in the field of molecular markers.

Entomology - key science of the twenty-first century

Let us, like the insects, direct our eyes forwards and try to gain an overall panorama of the future.

If biology, as many people believe, becomes the "key science" of the twenty-first century, entomology will fulfil a pioneer function and occupy a top position. It is important to get this over clearly to the public as a whole.

Holistically trained and holistically thinking entomologists will be in a position to furnish the knowledge necessary for solving tomorrow's problems and for achieving a sustainable healthy environment.

But at this point I must draw your attention to a very important area of future entomological research: "Endangered Species: Doctoral Students in Systematic Entomology". By 2017, as Howell Daly wrote in 1995, there will be hardly any doctoral students carrying out studies in insect systematics in the United States of America and Canada, and there will also be hardly any insect systematists. This development is very disturbing and must be stopped, particularly since in the new century insect systematics will be decisive for cataloguing and promoting biodiversity.

Entomologists will no longer be "dreamy egocentric individualists" or specialists in the "left legs of cockroaches", but will be indispensable, sought after and, I would proudly add, fully recognised men and women.

It will be our responsibility to point out suitable ways for young people. Our decisive contribution must be to devote special attention to long-term financial support mechanisms to allow basic science to continue growing in an international environment marked by sharp competition and the call for immediate results.

Some entomologists are of the opinion that the Internet will completely replace scientific journals. It is true that the Internet has advantages of which almost everyone is aware and it certainly helps to "democratise" information. All the same, I am convinced that even in the future peer reviewed journals will continue to be of vital importance for entomology. They will do much to minimise or prevent the publication of frivolous or false research results, scientific misinterpretations and faulty ecological and economic decisions which may have worldwide consequences.

We all know that science is knowledge which is stored, multiplied and passed on; that an entomologist who is unable to give an account of his scientific work to a 15-year-old pupil is an impostor, and that the words of Krass and Landois as early as 1895 will continue to remain valid in the twenty-first century: "A scientist is doing his job properly only if he pursues his particular line of study in depth, and at the same time contributes to the spread of scientific knowledge throughout the population." In this spirit, we, as entomologists, must not shrink from using well-made insect comics or even science fiction - such as LEXX, the "super insect" - as a vehicle.

Plenary Lectures

"Serendipity" and "mavericks" in entomology

We must admit that rationality in scientific research is not everything. We should make full use of the opportunities opened to us by random discoveries. This will increasingly become an attribute of entomologists in the twenty-first century.

Therefore we should always welcome creative unconventional thinkers, or "mavericks", who notice what others overlook, who perceive, absorb and wonder, who ask questions and reflect, who question the status quo, break with familiar habits and take a sceptical look at things, who venture, risk and act, who foresee, search and discover, and who have a feeling for "how everything works".

It will be our task to collect all information available, in the natural world, in the laboratory, in experiments and via the Internet. If we ultimately succeed in bringing about new qualities and future solutions, it will be thanks to our ability to regain information by reconstructions and model calculations, and by re-combining information. We must enter into a new symbiosis between modern technologies and nature.

We entomologists will need an optimistic holistic vision of what the future can be, and we must develop holistic sciences. We will continue to extend the boundaries of our knowledge at an ever-growing rate. Our motto should be: "Venture courageously to the uttermost limit of necessity". No better time to start than now, at the beginning of the new millennium. And finally, quite apart from the scientific challenges for entomology in the coming century, let us never lose our eye for the beauty of insects and of the world in which these creatures - and we ourselves - live. Now that this XXIst ICE here in Fos do Iguassu is about to close, let us take a look together at the picture "Niña del Campo" of the Spanish artist Guillermo Silva Santamaria. Its fascinating profusion of colour, its striking lightness and its youthful carefreeness are things well worth taking back home with us for the coming millennium.

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[0001] PHYTOSEIIDS AS MANIPULATORS OF SEX: *WOLBACHIA*, PARAHAPLOIDY AND GENOMIC IMPRINTING

<u>M. A. Hoy</u>, Dept. of Entomology and Nemaiology, University of Florida, P.O. Box 110620, Gainesville, FL 32611-0620, USA

Populations of the predatory mite *Metaseiulus* (= *Typhlodromus* or *Galendromus*) occidentalis Nesbitt (Acari: Phytoseiidae) exhibit partial reproductive incompatibility. This has been confirmed to be due to the presence of *Wolbachia*, a microbial endosymbiont that is transmitted transovarially. *Wolbachia* has been proposed as a potential drive mechanism for inserting genes into populations because *Wolbachia*-infected females can produce progeny when mated with infected or unifected individuals. The incompatible crosses (unifected females mated with infected individuals. The incompatible crosses (unifected females) produce fewer eggs than normal, shriveled eggs, and a highly male-biased sex ratio. This phenotype is due to the unusual genetic system (parahaploidy, but sometimes called pseudoarthenotoky) of *M. occidentalis*. *M. occidentalis* females can produce progenent as diploids. Male embryos lose haif their chromosomes during embryonic development as are eliminated are paternal in origin. The loss of the paternal chromosome set must be due to some form of genomic imprinting, but the nature of this has not been resolved.

Index terms: Metascinlus occidentalis, Phytoselidae, Wolbachia, genomic imprinting

[0003] HOST IMMUNE RESPONSE TO SARCOPTES SCABLEL AND INDUCED IMMUNITY

L.G. Arlian & <u>M.S. Morgan</u>, Dept. of Biol. Sciences, Wright St. Univ., Dayton, OH, 45435 USA.

Sarcoptes scabiei mites burrow in the epidermis of mammalian hosts and induce both a humoral (1h2) and cell-mediated (1h1) immune response in the infested host. A previous infestation or immunization with extracts of house dust mites induces protective immunity in a majority of hosts. Hosts that exhibit protective immunity exhibit stronger Th1 and weaker Th2 responses than hosts that do not exhibit resistance. The dominant cells in the dermal infiltrate during a protective immune response are neutrophils and mononuclear cells which appear coincidentally with the appearance of many Langerhans cells (LCs) in the epidermis. Monoclonal antibody studies of canine scables skin biopsies show that the mononuclear cells contain a large representation of CD4+ cells. This population of CD4+ cells consisted of both T-helper cells and neutrophils and the large increase in their density during challenge infestations suggests they play a key role in the successful immune response that results in resistance to subsequent scables infestations. Neutrophils may function as antibodydependent cytotoxic cells to kill mites or disrupt their reproduction. The high prevalence of LCs in the epidermis suggests they play a key role in the initiation of the immune reaction and antigen presentation. Some naive T-cells (CD45RA+) and cytotoxic T-lymphocytes (CD8+) also infiltrate scabietic lesions but no B-lymphocytes (CD21+) were found in the dermal Keratinocytes may be a major source of IL-1 that stimulates the infiluates. immune/inflammatory reaction since we have found that keratinocytes up-regulate secretion of these cytokines in response to scables mites. Likewise, production of IL-6 and IL-8 by fibroblasts was up-regulated in response to products from scabies mites. These cytokines stimulate the release of IL-1 by keratinocytes co-stimulated by scabies mites Index terms: scables mites, resistance, humoral response, cell-mediated, cytokine studies

[0002] COLD RECEPTORS ON THE BODY SURFACE OF THE TROPICAL BONTTICK AMBLYOMMA VARIEGATUM

P. M. Guerin, A. Widmer, M. Vlimant & P.A. Dichl, Institute of Zoology, University of Neuchâtel, Rue Emile-Argand 11, 2007 Neuchâtel, Switzerland, E-mail patrick.guerin@zool.unine.ch.

Ticks make use of thermal cues in addition to other sensory modalities for survival. Amblyomma variegatum possesses warm and cold receptors in each of two long poreless sensilla at the tip of each of the foreleg tarsi. These appendages are employed by ticks while searching for a host. Now we have discovered cold recentors scattered over the body surface of A. variegatum. Ultrastructure investigations reveal that all of these sensilla have a terminal-pore structure and contain a tubular body in addition to five receptor cells. The cell we suspect to be the cold receptor is much bigger than the others and possesses two ciliary bodies giving rise to two outer dendritic segments. These dendritic segments are invaginated proximally and then branch extensively within two sets of sensilla. The first set is comprised of 20 sensilla that are 10µ long and concentrated bilaterally on a non-sclerotized section of cuticle on either side of the basis capitulum. The second set of 8-10 slightly longer sensilla occurs around each eye. The other 100-120 terminal-pore sensilla containing cold receptors are much longer than the others and are scattered over the rest of the body. The latter sensilla are characterised by the fact that the outer dendritic segments of the big receptor cell are neither invaginated nor branched. Electrophysiological responses from these cold receptors were recorded using an airflow switching device that delivered different T° shifts to the preparation. The responses of these receptors show the highest gain to small drops of temperature, still clearly responding to a ΔT° of 0.02°C. Evidence from behavioural tests will be provided to show how these receptors contribute to survival of A. variegatum.

Index terms: Amblyomma, thermoreception, cold receptor, behaviour, sensory physiology

[0004] ECDYSTEROID SYNTHESIS AND ACTION IN THE IXODID TICKS

L.H. Chen, L. O. Lumas, P. C. Turner & H. H. Rees, School of Biological Sciences, University of Liverpool, Life Sciences Building, Crown Street, Liverpool, L69 7ZB, UK

Ecdysteroids (moulting hormones) were initially characterised in insects and are involved in the regulation of moulting and metamorphosis as well as reproduction. Similarly, ecdysteroids in ticks have been suggested to function in the regulation of moulting, salivary gland degeneration, pheromone production, and aspects of reproduction. It has been demonstrated that epidermal tissue of the soft tick, Ornithodoros parkeri, was capable of synthesising ecdysteroids. We have identified that the integument of the adult ixodid tick, Amblyomma hebraeum was able to synthesise ecdystercids in vitro. The synthesis was stimulated by a neuropeptide hormone originated from synganglian tissue (central nervous system) with possible involvment of a cAMP second messenger system, analogous to the known prothoracicotropic hormone-prothoracic gland endocrine axis of insects. In insects, ecdysteroids act in target tissues by binding to their receptor (EcR), thereby forming a functional receptor complex. This complex is a heterodimer of two proteins, EcR and ultraspiracle (USP), which in turn, binds to the upstream regulatory elements of the early target genes and regulates their expression. The products of the early genes subsequently function as transcription factors that can activate many late genes, which are believed to relate to the regulation of many of the above mentioned physiological processes. EcR and USP are members of the nuclear hormone receptor superfamily. These proteins have common structural features and some domains, such as the DNA-binding domain and ligand-binding domain, are highly conserved. Using an RT-PCR method employing degenerate primers designed on the basis of these highly conserved domains, we have cloned cDNAs for EcR and USP from the female ixodid tick, Amblyomma hebraeum. With these cDNAs as probes, we analysed tissue distribution and developmental profiles of the receptors in relation to the changes in the ecdysteroid titres. This has opened up a way for us to characterise molecular mechanisms of ecdysteroid action in this species of tick.

Index terms: Ticks, Amblyomma hebracum, ecdysteroid, hormone, receptor

Session 01 – ACAROLOGY

[0005] A NOVEL ANTI-INFLAMMATORY FACTOR IN THE SALIVA OF THE LONE STAR TICK AMBLYOMMA AMERICANUM

A.S. Bowman¹, J.S. Tucker² & <u>I.R. Sauer</u>², ¹Dept of Zoology, Univ. of Aberdeen, Tillydrone Ave, Aberdeen AB24 3TZ, SCOTLAND, E-mail a.bowman@abdn.ac.uk; ²Dept of Entomology and Plant Pathology, Oklahoma State University, Stillwater, OK 74078, USA.

Ticks remain attached to naïve hosts for unusually long periods without eliciting a host immune or inflammatory response capable of rejection. Factors in tick saliva facilitate the tick's vectorial ability by dampening the host immune response, thus, allowing ticks to remain attached for extended periods and allowing pathogens to be introduced into an immunocompromised environment. We have identified an activity in tick saliva that inactivates the pro-inflammatory lipid mediator platelet-activating factor (PAF). In mammals, PAF is deactivated by the enzyme PAF-acetyl hydrolase (PAF-AH) that cleaves the acetyl group from the sn-2 position resulting in the biologically inactive lyso-PAF. An homolgous activity (tPAF-AH) was detected in the saliva of seven ixodid tick species from four genera. The specific activity in Amblyomma americanton saliva is ca. 2000x that detected in sheep plasma and is present throughout the feeding cycle. (PAF-AH is Ca2+, EDTA, dithiothreitol and 5'5'-dithbis(2-nitrobenzoic acid) insensitive, thus, more akin to secreted mammalian PAF-AH than the intracellular form. The tPAF-AH was inhibited by PMSF and pbromophenacylbromide indicating the involvement of a serine and histidine residue in the catalytic mechanism. The tPAF-AH is heat-stable up to 85°C and maintains 75% maximum activity over the pH range 4.5 - 11. Isolation of the tPAF-AH yielded an active fraction of 125kDa on both FPLC size exclusion column and native gels. The band dissociated upon boiling to form a band ca. 57kDa. Amongst the many actions of PAF is its ability to cause platelet and neutrophil aggregation and the recruitment and degranulation of monocytes, neutrophils, cosinophils and basophils. The tick's ability to deactivate locally formed PAF in the feeding lesion would appear vital to the successful completion of a bloodmeal and may also play a role in pathogen transmission.

Index terms: platelet-activating acetyl hydrolase, PAF, lipid mediator, Amblyomma americanum

[0006] PROSTAGLANDINS IN TICK SALIVARY GLAND PHYSIOLOGY

<u>LR. Sauer</u>¹ & A.S. Bowman², ¹Dept. of Entomology and Plant Pathology, Oklahoma Sta. University, Stillwater, OK, 74078, USA, E-mail jrs4864@okstate.edu; ²Dept. of Zoology, Univ. of Aberdeen, Aberdeen AB24 2TZ, Scotland, UK.

Tick salivary glands and saliva contain extremely high levels of prostaglandin E_2 (PGE₂) and PGF_{2a} which are likely important in tick feeding. Data also demonstrate that PGE₂ functions as a local hormone in ixodid tick salivary gland physiology. A PGE₂-specific receptor was identified in the salivary gland plasma membrane that exhibits a single, high affinity PGE₂ binding site, is saturable, reversible, specific for PGE₂ and is coupled to a cholera toxinsensitive guanine nucleotide regulatory protein. PGE₂ directly activates phospholipase C and stimulates inositol triphosphate (IP₃) formation in dispersed salivary gland acini and stimulates an efflux of Ca²⁺ from pre-labeled salivary glands. Functionally, PGE₂ stimulates release of salivary gland anticoagulant protein in preference to PGF_{2a} or the thromboxane nalog U-46619 in accordance with their respective binding affinities for the PGE₂ receptor. I'MB-8, an antagonist of intracellular IP₃ receptors inhibits PGE₂ stimulated secretion of salivary gland protein in a dose-dependent manner, suggesting that PKC is a regulator of Ca²⁺ dependent exocytosis. The results support the hypothesis that PGE₂ stimulates secretion of ick salivary gland protein via a phosphoinositide signaling pathway, mobilization of ntracellular Ca²⁺ and activation of PKC.

ndex terms: exocytosis, protein kinase C, calcium

[0007] GENETIC SIGNATURES OF DISPERSION

M. Navaias, Inst. Nat. Res. Agronomique, Centre de Biol. et Gestion des Populations, Lab. de Modélisation et Biol. Evol., 488, rue Croix de Lavit, 34090 Montpellier, France, E-mail navajas@ensam.inra.fr.

Dispersal is an important parameter that often escapes direct observation in natural populations. It is however of paramount importance to properly account for this parameter in order to understand species evolution and adaptation. Population genetics theory predicts that variations of neutral allele frequencies in space can provide a reliable indirect measure of the amount of genetic exchange, and thus of individual migration inside a species. Predictions of levels of dispersal can be made based on the biology of a species, that can then be tested in the field using these indirect methods. Based on examples from the literature, I review several features (residence status, natural vs. agricultural, host range, etc.) of phytophagous arthropods having an influence on population genetic structure. The different methods commonly used to quantify genetic variation and infer gene flow at different scales are presented. Taking as an example the cosmopolitan spider mite Tetrancyhus urticae I show how different genetic markers and sampling schemes can reveal the genetic structure and allow inference of individual dispersal at different geographic and temporal scales. Combined results on mitochondrial COI and nuclear ITS ribosomal DNA sequences of a worldwide sample of T. urticae show a great homogeneity of the species, associated with relatively recent range expansion events. However, on a fine geographic scale and using nuclear gene allele frequency variations, a strong pattern of isolation by distance over relatively short distances is obvious. These results are not contradictory, but rather concern different temporal scales in the evolution of the species.

index terms: gene flow, genetic markers, genetic structure, tetrancyhus urticae

[0008] DISPERSAL AND SPREAD OF EXOTIC PHYTOSEHDS IN AFRICA

J. S. Yaninek¹ & R. Hanna², ¹USDA Coop. State Res. Ed. Ext. Service, 1400 Independence Ave., Washington D.C. 20250-2220, USA E-mail syaninek@reeusda.gov; ²Intern. Inst. Trop. Agr., PHMD, IITA Benin Station, 08 B.P 0932, Cotonou, Benin, E-mail rhanna@cgiar.org.

The establishment of three exotic phytoseiid predators of the cassava green mite, Mononychellus tanajoa (Acari: Tetranychidae), in Africa provided a unique opportunity to evaluate the dispersal and spread of deliberately released natural enemies. *Neoseiulus idueus* was released in 1989. established in one site each in Benin and Kenya, never spread beyond a 50 m radius from the release fields. Typhlodromalus manihoti, also released in 1989, has been recovered in 145 field sites in Benin, Burundi, Ghana, and Nigeria. T. manihoti dispersed at a rate of 3.3 km per year covering an area estimated at 4,300 km2 after 7 years in West Africa. Typhlodromalus aripo was first released in October 1993 in Benin, West Africa and subsequently recovered from more than 1000 field sites in 19 countries through 1998. It spread at a rate of 12.5 km in the first season, and up to 200 km per season thereafter to cover an estimated 900,000 km2 in 4 years. All three species use herbivore-induced infochemicals to locate prey patches and persist as long as sufficient prey are available. However, N. idaeus require prey for both development and reproduction, and disperses away from cassava in search of new prey patches as M. tanajoa densities decline. Both Typhlodromalus predators are capable of exploiting a range of prey and non-prey diets including plant-provided exudates for juvenile development and increased longevity during periods of prey scarcity, but eventually require prey for optimum reproduction. This increased predator persistence helps suppress colonizing and incipient pest populations, yet maintain a "stream" of dispersers in search of M. tanajoa prey for oviposition. These results revealed a relationship between prey exploitation strategy, ability to use indirect host plant defenses, propensity to disperse, and the rate of spread that should warrant additional attention by the biological control community.

Index terms: Mononychellus tanajoa, exotic phytoseiids, dispersal, spread.

[0009] PREDATOR DISPERSAL AND PREY-EXPLOITATION STRATEGIES

B. Pels & M. W. Sabelis, Inst. for Biodiversity and Ecosystem Dynamics, Univ. of Amsterdam, Kruislaan 320, P.O. Box 94084, 1090 GB Amsterdam, The Netherlands, Email pels@bio.uva.nl.

We studied the impact of dispersal of predators on local predator-prey dynamics in systems that are characterised by overexploitation of prey. Based on a caricature, two types of dispersal strategies can be distinguished: the Killer-strategy in which predators do not disperse from patches with prey, and the Milker-strategy in which continuously part of the predators leave, even when the patch still contains many prey. Once all prey have been eliminated, both Milkers and Killers are expected to disperse instantaneously. Theory predicts that Killers are selected for, when local predator populations are started by multiple founders, whereas Milkers are selected for when the number of founders is sufficiently low. To test which of these dispersal strategies occur in wild populations of predatory arthropods, we carried out replicated experiments on local dynamics and dispersal in a system consisting of bean leaves, herbivorous mites (Tetranychus urticae) and various field-collected strains of predatory nuites (Phytoseiulus persimilis). We found that the predatory mites indeed tend to drive local prey populations to extinction. We also observed consistent differences in dispersal behaviour of two predator strains that were measured in detail. In one strain predators did not disperse until after extermination of the local prey population, but in the other the adult females started to disperse earlier, *i.e.* when there were still prev available. In agreement with theory, the earlier predator dispersal was associated with a longer interaction period, a larger prey population and a larger production of dispersing, adult female predators. Finally, it was observed that not all predatory mites leave instantaneously once prey have been eliminated. Dispersal occurred over a period of 10 days since all prey were eliminated (Pels and Sabelis 1999). Follow-up experiments showed that, in absence of prey, a part of the juvenile predators turn to cannibalism whereas other juveniles disperse. The dispersers probably avoid being eaten by larger conspecifics, whereas the cannibals continue to feed and may mature and mate before they leave the arena. Since P. persimilis reproduces by pseudo-arthenotoky (i.e., males and females develop from fertilised eggs), dispersing juvenile females first have to find a mate before they can start laying eggs. We hypothesise that dispersal after prey elimination is part of a size-dependent cannibalism and mate-finding game.

Index terms: Phytoseiulus persimilis, predator-prey interaction, cannibalism.

[0010] DISPERSAL OF AN EMERGING INFECTIOUS AGENT: POTENTIAL ROLE OF MITES

M. A. Houck, Dept. Biol. Sci., Texas Tech University, Lubbock, TX 97409-3131, USA, Email MAHOUCK@ttu.edu.

Hantavirus pulmonary syndrome is an often-fatal disease, thought to be transmitted exclusively by rodents. Previously, no arthropod vector had been implicated. We report the first evidence of Bayou hantavirus-specific RNA from chiggers and a tick collected from wild-caught rodents and from a free-living predatory stage in the chigger life cycle. While the tick host was hantavirus-positive, the chigger hosts were hantavirus-negative, suggesting that chigger infection was trans-stadially transmitted. The recovery of hantavirus-specific RNA from a free-living stage in the chigger life cycle indicates that mites may contribute to the long-term ecological persistence of the virus. I hypothesis that rodent-todent transmission is through aerosol routes while rodent-human cycling occurs through the agent of arthropod vectoring. Index terms: hantavirus, coevolution

[0011] THE ROLE OF HERBIVORE-INDUCED PLANT VOLATILES IN DISPERSAL AND FORAGING OF PHYTOSEIID PREDATORY MITES

M. W. Sabelis, Sect. Pop Biol., Univ. of Amsterdam, Kruislaan 320, 1098 SM Amsterdam, The Netherlands, E-mail sabelis@bio.uva.nl.

Herbivory is known to induce the production of volatiles in the plant. These signals are thought to betray herbivores to their predators, which are then attracted or arrested near the plant under attack. Evidence for involvement of herbivore-induced plant volatiles in predator recruitment is largely based on experiments with olfactometers designed to demonstrate a response to odors, not to elucidate the behavioral mechanisms used to locate the source. Since the mechanisms underlying orientation may well operate at a spatial scale beyond that considered in the lab, experiments are required to unravel the tactic and kinetic responses in carefully designed laboratory experiments at a larger scale and to assess the responses under more realistic (greenhouse, field) conditions. We discuss experiments showing the role of odor-conditioned anemotaxis, tactic/kinetic responses to odor gradients, odor-conditioned landing and take-off responses, as well as the role of hunger, associative learning and innate responses in predatory mites.

Index terms: behaviour, foraging, infochemicals, phytoseiid mites, predators, tritrophic interactions

[0012] EVOLUTION OF PARASITISM IN THE ASTIGMATA: THE ROLE OF PHORESY

M. A. Houck, Dept. Biol. Sci., Texas Tech University, Lubbock, TX 97409-3131, USA, Email MAHOUCK@ttu.edu.

Astigmatid mites specialize in the ecological exploitation of ephemeral habitats. Successful navigation among these temporary habitats is through cultivation of associations with other organisms (=phoresy). Phoresy plays a proximate ecological role in the dispersal of astigmatid mites among habitats that are temporally and spacially limited. Not all life stages in the astigmatid life cycle are capable of phoresy however. A heteromorphic deutonymph (=hypopus) arose early in the evolution of the Astigmata (plesiomorphic) and radiated among astigmatid lineages. Only the astigmatid deutonymph is morphologically equipped for phoretic dispersal. Since successful dispersal, during times of ecological stress, depends on the navigational success of the deutonymphal stage alone, this imposes key selective forces on the deutonymph to coevolve with specific phoretic hosts having shared ecological requirements. As will be developed, phoresy has the ultimate potential of providing a transitional mechanism for providing a free-living ancestral disperser a means to assume a parasitic (or mutualistic) role, within an evolutionary time scale. Parasitic (or mutualistic) interactions mitigate the historical pressures to disperse among temporary habitats and provide a more integrated and stable alternative for persistence within an ecological and evolutionary community. This presentation summarizes eighteen years of research on the exploration of a biological model organism (Hemisarcontes corremani) to illuminate the required steps of transition from an independent life-style to a parasitic life style in the Astigmata, through the application of a phoretic intermediate. Data and inference from several sources will be integrated to argue this point: biochemical, behavioral, and morphological.

Index terms: Astigmata, coevolution, Hemisarcoptes

[0013] PHYLOGEOGRAPHY OF RHOMBOGNATHINE MITES

H. Abé, College of Bioresource Sciences, Nihon Univ., 1866 Kameino, Fujisawa, Kanagawa, 252-8510 Japan, E-mail: acari@brs.nihon-u.ac.jp.

The Rhombognathinae, a subfamily of marine mite family Halacaridae, consists of four genera: Isobactrus, Rhombognathus, Rhombognathides, and Metarhomoo-gnathus. A morphology-based phylogenetic analysis implied that Rhombognathus was the earliest derived genus, and thereafter Isobactrus, Rhombognathides, and Metarhombognathus were derived successively. Rhombognathus and Isobactrus have cosmopolitan distribution, whereas Rhombognathides and Metarhombognathus have limited trans-Atlantic distribution In these mites, long distance dispersion across the deep oceans is hardly probable, because they are benthic animals inhabiting the coastal area in the oceans and do not have the floating stage in the ontogenetic development. Therefore, it is expected to explain their worldwide distributional patterns with reference to the continental drift. Each rhombognathine lineage was assigned on an area cladogram of the six major continents by the Drooks parsimony method. In the reconstructed area cladogram, the continents of Eurasia and North America constituted a sister-group and the common stem that indicates Laurasia bore the lineages of Rhombognathides, Metarhombognathus and the most recent common ancestor of both genera. The basal stem of the area cladogram, which represents the super-continent Pangaea, held the lineages of Rhombognathus, Isobactrus, the most recent common ancestor of both genera, and the common ancestor of the subfamily. This geological event can be traced to the late Palaeozoic Era of about 220 to 280 myr ago. Taking a branching process of a lineage into consideration, several evolutionary scenarios underlying the phylogeny and geographical distribution of rhombognathine mites will be outlined on the basis of the historical legacy of interactions among their ancestors and habitation.

Index terms: Acari, evolution, Halacaridae, continental drift, vicariance.

[0015] DAMAGE CHARACTERIZATION OF *OLIGONYCHUS YOTHERSI* (ACARI: TETRANICHIDAE) TO ERVA-MATE (*ILEX PARAGUARIENSIS*) (AQUIFOLIACEAE)

The mites are very important pests in many culture. In the last years these arthropods have been frequently observed in Brazil and Argentine associated to reduction on the production of leaves of the erva mate. However, there are few studies about these pests. This observation were carried out in a erva mate commercial plantation, near to the Campus of Unioeste at Cascavel, State of Paraná, Brazil. The observation began at September of 1999, after the budding. It was observed that the mite distribution was heterogeneous on the area. The damaged plants showed new leaves with small purple punctuation on the dorsal face that were concentrated on the central nervure and mainly near by the basal region of the leaves. The punctuation growing larger forming necrotic areas. After some days the damage leaves became wrinkled with the border turning down. It was observed some depression on surface of leaves with a grate number of the mites in all life stages, besides exuviae and most webs. The mites affected the leaves development and the most infested ones (15 to 20 mites/leave) were smaller than non infested or less infested leaves which at the time drops off. There were a direct relation to the damage and the production because in the most infested and damage plants were 90 to 100% of premature defoliation with reduction of weigh of biomass.

[0014] BASES FOR AN ACARICIDE RESISTANCE MANAGEMENT PROGRAM OF *BREVIPALPUS PHOENICIS* (ACARI: TENUIPALPIDAE) TO THE ACARICIDE DICOFOL IN BRAZILIAN CITRUS

E. B. Alves, C. Omoto & C. R. Franco, Depto. de Entomologia, Fitopatologia e Zoologia Agrícola. Escola Superior de Agricultura "Luiz de Queiroz", Univ. de São Paulo, Av Pádua Dias 11, 13418-900, Piracicaba, SP, Brasil, E-mail ebalves@carpa.ciagri.usp.br.

The phytophagous mite Brevipalpus phoenicis is one of the most serious citrus pest in Brazil, because it transmits citrus leprosis virus. Failures to control this mite, especially with the acaricide dicofol have been reported. Because of constant selection pressure with acaricides, the evolution of resistance in B. phoenicis could be one of the major factors affecting the efficacy of this product. Basic information for the implementation of a resistance management program of *B. phoenicis* to the dicofol was collected in this study. A residual bioassay technique was used to characterize the responses of susceptible (S) and resistant (R) strains of B. phoenicis to dicofol. The estimated LC50s for the S and R strains were 7.44 µg of dicofol / mL of distilled water [ppm (A.I.)] (95% CI 6.74 - 8.23) and 422.45 ppm (A.I.) (95% CI 369.41 - 482.80), respectively. The resistance ratio derived from LC₅₀₅ was about 57-fold. Based on this difference, discriminating concentrations between 32 and 100 ppm (A.I.) were defined for monitoring dicofol-resistant mites. Then, fitness cost associated with dicofol resistance in B. phoenicis was evaluated under laboratory conditions. Initially, we conducted cage studies to evaluate the dynamics of resistance in populations of B. phoenicis with 20, 50 and 80% of dicofol-resistant mites. The frequencies of resistance were estimated monthly in a 6-month period with a discriminating concentration residual bioassay of 32 ppm (A.I.). The resistance revealed to be unstable; that is, the frequency of dicofol-resistant mites declines significantly in the absence of selection pressure. Life-history studies of S and R strains were evaluated. No difference in the egg-adult developmental time was detected between strains. However, significant differences were found in the longevity and fecundity of mites. The mean longevity of S and R strains were 31.4 and 21.7 days, respectively. The fecundity of R strains was about 51.5% of the S strain. And lastly, studies of cross-resistance relationships between dicofol and other acaricides recommended in citrus were evaluated in B. phoenicis to find alternative products for managing dicofol-resistant mites. S and R strains were tested against fenbutatin oxide, propargite, fenpyroximate and bromopropilate. Dicofol-resistant B. phoenicis showed positive cross-resistance to bromopropilate and negative cross-resistance to fenpyroximate. No cross-resistance was detected between dicofol and the acaricides fenbutatin oxide and propargite.

Index terms: fitness cost, cross-resistance, chemical control

[0016] EFFECT OF NUTRIENTS ON THE FLAT MITE, *BREVIPALPUS PHOENICIS* (ACARI:TENUIPALPIDAE) AND ON COFFEE RING SPOT VIRUS TRANSMISSION IN THE COFFEE (*COFFEA ARABICA*) CULTURE

R.C. de Andrade & O. Nakano, Escola Superior de Agricultura "Luiz de Queiroz" ESALQ - USP - Piracicaba - SP - Brazil, Postal Box 09. Zip code 13418-900 e-mail reandrad@carpa.ciagri.usp.br

The flat mite has caused damages in coffee plant because it transmits a virus that causes leaf and fruit falls. A trial was carried out with the variety Red Catuai to check the influence of coffee plant nutrients on spider mite and, consequently on the disease, in July, 1999. The experimental design was completely randomized block, with 5 replications. The treatments were: 1- control; 2- Boron (Boric Acid); 3- Sulphur (Kumulus-S); 4- Zinc (Zinc Chloride); 5-Boron plus Sulphur; 6- Boron plus Zinc; 7- Sulphur plus Zinc; 8- Boron plus Sulphur plus Zinc; 9- Liming. The plots were shaped by 7 plants being used the 3 central plants for evaluation and they were spaced 0,80 m and the rows were spaced 4 m apart. The fertilization was based on soil analysis. The evaluations were realized on 10 leaves/plant and the number of leaves with injured , injuries per leaf and flat mite vere counted. The results allowed to conclude: a) there were fewer occurrence of the symtoms at the treated with Sulphur plus Zinc and with only Zinc; b) the smallest spider mite number happened in the treatments with Sulphur.

Index terms: virouse, boron, zinc, sulphur,

[0017] HOUSE DUST MITE (DERMATOPHAGOIDES PTERONYSSINUS) MORTALITY IN OCCUPIED BEDS AND HEATED AND UNHEATED CARPET

<u>J.R.H. Andrews</u>¹, M. Cunningham², A. Pike¹, S. Wood¹ & M. Hearfield², ¹ School of Biological Sciences, Victoria University of Wellington, PO Box 600, Wellington New Zcaland, E-mail john.andrews@vuw.ac.nz; ² Building Research Association of New Zcaland, Private Bag 50908, Porirua, New Zealand.

Psychrometric measurements from occupied beds suggested that unfavourable temperature and humidity conditions for mites may occur in some parts of the bed, leading to some mortality or a stimulus to escape to more favourable areas. Temperature and humidity conditions recorded from the bed were simulated in a programmable incubator and the effects on mite mortality noted. Although the temperature and humidity in the upper layers of the bed appeared unfavourable, according to steady state literature data, experimental simulations conducted over 72 -hour and 7 day periods showed little or significant decline in mite numbers, compared with controls. This suggests that mites can survive unfavourable cyclic periods, although variable conditions elsewhere in the bed would offer a more amendable haven if required. Psychrometric measurements taken from another significant dust mite habitat, curpet, showed that mottality under normal conditions was not significantly different from ideal steady state controls, but carpet beated to 50°C for one hour and two hour periods showed significant reductions in mite numbers. The implications for control are discussed. Index terms: *Dermatophagoides pteronyssinus*, beds, cappets, mortality

[0018] LIFE HISTORY PARAMETERS AND FUNCTIONAL RESPONSE PHYTOSEIULUS PERSIMILIS ON TETRANYCHUS URTICAE

¹<u>M. H. Radii</u>, ²J. Landeros & ¹A. E. Flores, ¹Autonomus University of Nuevo Leon, AP. 391. San Nicolas, Nuevo Leon, 66450, México, E mail mbadii@ccr.dsi.uanl.mx; ² Autonomus Agricultural University of Narro, Saltillo, Coahuila, México.

Life history of and life table parameters for Phytoseiulus persimils Athias-Henriot (Phytoseiidae) on different stages of the two-spotted spider mite, Tetranychus urticar on excised pieces of bean leaves located on circular acrylic discs (3 cm diameter) were studied under laboratory conditions of 28 \pm 2° C, 60 \pm 8% RH and 12:12 L:D Photoperiod. Data for life history and life table analyses were generated on the basis of a cohort of 37 females resulting from 100 eggs placed individually on study arenas. The methodoloy of Birch was used to generate the growth and longevity parameters. The following parameters were obtained in this study. The raw reproductive rate (RRR) of 42.59 dauthers per female per generation in the absence of any mortality, the net reproductive rate (Ro) of 41.12 dauthers per female per generation, the finite rate of increase (I) of 1.51 dauthers per female per day, an aproximate rate of increase (re) of 0.44 dauthers per female instantly and an intrinsic rate of natural increase (rm) of 0.41. Some longevity parameters were also produced as follows: a duration of cohort (T_c) of 8.41 days, a generatin time (T_g) of 9.10 days and a doubling time (T2) of 1.70 days. The functional response of the the gravid female predator on increasing densities of different stages of its prey was anlyzed under similar conditions of life history test based on Holling's disk equation. Different densities of 1, 2, 4, 8, 16, 32, 64 and 100 eggs and larval stages were used individually as pery items, in the case of proto and deutonyphs, densities of 1, 2, 4, 8, 16, 32 and 64 and for prey females densities of 1, 2, 4 and 8 individuals per arena were utilized for this study. Each density was repeated 15 times. The instantaneous rate of discovery (a) and handling time (Th) of this predator on different life stage of the prey were estimated using the model of Woolf Transformation, at the end of 2, 4, 6, 8, 10, 12 and 24 hours. The functional response of P. persimilis on immature stages of T. urticae was of type II, while in the case of the femle prey a linear line was obtained. There was no significant difference between the observed and expected functional response on any and all stages of the prey. The prey stages most severely attacked by the female predator were egg with a mean of 52.37, larva with an average of 63.07 (the highest) followed by the nymphal stages with a mean of 32-7 and finally the stage least attacked by the predator was the prey female with an average of 6.93 individuals per day.

[0019] FUNCTIONAL RESPONSE OF *PHYTOSEIULUS PERSIMILIS* ON *TETRANYCHUS URTICAE* ON THREE DIFFERENT ROSE VARIETIES

¹<u>M. H. Badii</u>, ²J. Lauderos & ¹A. E. Flores, ¹Autonomus University of Nuevo Leon, AP, 391. San Nicolas, Nuevo Leon, 66450, México, E mail mbadii@ccr.dsi.uanl.mx; ² Autonomus Agricultural University of Narro, Saltillo, Coahuila, México.

The two-spotted spider mite, Tetranychus urticae Koch (Tetranychidae) is the principal pest of the agricultural crops in the glasshouse. Mexico is the second major exporting country of roses in Latin America. The control of the two-spotted spider mite in the glasshouse has become quite difficult due to the development of resistance of this mite pest to the chemical pesticides, the destruction of natural enemies and the phytotoxicity caused by some of these synthetic compounds. A valid alternative to the unintelligent and unilateral use of miticides for the control of the two-spotted spider mite is the employment and sound utilization of biological control agentes. Phytoseiulus persimilis Athias-henriot (Phytoseiidae) has been tried with excellent results as the regulating agent against the population of this mite pests. Therefore, a study was designed to test the functional response capability of this predaceous nuite species on increasing densities of its prey, the two-spotted spider nuite. In the northeastern region of Mexico, there are basically three varities of the rose, namely, Royalty, Starlite and Parco which are exported to the foreign countries. In experiments under laboratory conditions i.e., 28 ± 2°C, 60 ± 10 % RH and a 24 hr. L period regim, The functional responses of the gravid femañes of P. persimilis were investigated. Only egg stages of T, urticae were used as previtem. To test the functional response, the egg stage of the prev were placed on the exsciezed pieces of different varieties of rose at increasing densities of 1. 2, 4, 8, 16, 32, 64 and 100. Each density was replicated 15 times. The number of the eggs attacked by the predator were counted at the end of 2, 4, 6, 8, 10, 12 and 24 hours. The Woolf transformation model was used to generate the functional response parameters, i.e., the instataneous rate of discovery or attack coefficient ('a), and handling time (Th) for each of six exposure periods. The parameters, then were used in the model of Holling in order to generate the expected number of prey items attacked by the predaceous mite species. The functional response curve was of type II, according to holling, for all cases. The highest values of the attack coefficient were obtained for the predator at the end of 4 hr expousre time for all three rose varities. In the case of handling time, the highest values were also obtained at the end of 4 hr time period for the two varieties of Royalty and Starlite, however, for the Pareo variety the maximum value was generated at the end of 6 hr epocure period. Comparing all around functional responses, there were no difference between the expected and observed functional response curves, furtheremore, the values of the attack coefficient as well as handling time were basically the same for all three rose varities.

[0020] FUNCTIONAL RESPONSE OF THE PREDACEOUS, *EUSEIUS IIIBISCI* ON IMMATURE STAGES OF TWO-SPOTTED SPIDER MITE, *TETRANYCHUS URTICA*E

M. H. Badii¹, E. Hcrnández² & A. E. Flores¹, ¹Autonomous University of Nuevo Leon, AP. 391, San Nicolas, Nuevo Leon, 66450, Mexico, E-mail mbadii@ccr.dsi.uanl.mx; ²Programa Moscamed, SAGAR-CONASAG. AP. 368, Tapachula, Chiapas, 30700, Mexico.

Strawberry is the most important cash crop in the central region of Mexico. The two-spotted spidet mite, *Tetranychus articae* Koch is the most relevant economic pest and in fact the key pest of starwberry in the "Bajia Region", central valley of Mexico. Strawberry farmets have relied mainly on synthetic organic miticides to control this mite pest species, and this pactice has significantly increased the cost of the production of this crop in Mexico. Since strawberry is basically cultivated for exportation and due to the strict standards of pesticides residue guidelines set by the the importing countries, there is an urgent need to mange this nuite pest by alternative methods such as biological control. Eusius hibisci (Chant) is the most common predaceous mite species associated with the tow-spotted spider mite, on strawberry in the central region of Mexico. Although the species belonging to the genus of Euseius basically posess type III life history style, i.e., general pollen feeders, some studies have suggested their important role in the biological control of the spider mites. Therefore, the objective of this research was to determine the predaceous capacity of this predator on the prey species by means of the functional response, to the varying densities of eggs, larvae and protonymphs of the two-spotted spider mite as well as the combination of the larval stage of this prey and the pollen of Ligustrum ovalifolium Hassk. In order to verify the consistency of the results and for omparative puposes, several functional response models were used. The functional response on all stages tested was type II. The functional response parameters , i.e., The instantaneous rate of disacovery or attack coefficient ('a) and handling time (Th) for this predator species attacking different immature stages of the two-spotted spider mite were estimated by means of Holling's disk model, Rogers' equation, Livdahl and Stiven's model and non-linear regression cueve. The highest value of 'a and the lowest value of Th were obtained for the predator feeding on egg stage, while the contrery results were obtained when protonymphs were offered as food. Using the Jack-Knife method, the mean values for the papameters of functional response were generated and compared among all the functional response models. There were no significant differences among the mean values for each paramteres among four models, However, there was a marked tendency to overestimate the parameters with Rogers' model. The results indicated a relative tendency to consume higher number of prey egg stage followed by the laraval and finally the nymphal stage. Using pollen simultaneously with prey laraval stage as food, decreased the consumption of the latter stage by as much as 20%.

[0021] ASSESSMENT OF PUBLIC HYGIENE INSECTOACARICIDES IN RUSSIA

E.I. Bakanova, S.A. Roslavtseva & N.Yu. Bakanova, Research Institute of Desinfectology, 117246, Nauchny proezd, 18 Moscow, Russian Federation, *Moscow State Lomonosov University, faculty of Economics, Moscow, Russian Federation, e-mail: elena_bakanova@mail.ru.

Synanthropic crawling and flying insects, mites and ticks represent one of most important problems, since they can contaminate food with bacteria, transmit diseases and cause human allergies. During the past eight years there was an increase in applying of different insectoacaricides to control synanthropic pest species in Russia. All the means were analysed by three criterias: formulations, methods of applications and target organisms. The major formulations are containerized aerosols, water based ready-to-use insecticides, wettable powder, soluble powder, tablets and granules, emulsion, micro-, suspoemulsion concentrates, flow formulations, microcapsulated formulations, chalks, gels, bait stations, sticky traps, vaporizer mosquito liquid, electric heaters with mates, creams, lotions, shampoos etc. The largest market shares belongs to the following formulations - containerized aerosols (22,5 %), powders (9,1 %), bait stations (6,6%), emulsion concentrates (5,6%), electric heaters with mates (5,1%), chalks (4,9%). Leading methods of application are liquid sprays. For the last two years an interest to microcapsulated formulations raised. There are trends to the growth of low helth and environmental risk assessment means to pest control. It's different kinds of baits and sticky traps. Most the producing means controlled the following important pests of public hygiene: common houseflies, german and oriental cockroaches, ants, mosquitoes, bedbugs, fleas, head- and bodylice, mites and ticks. During the same two years there was decreasing of the amount of pediculicides but repellents and acaricides were increasing. Ticks Ixodes persulcatus is the main vector of two important tick-borne diseases: tick-borne encephalitis and Lyme borreliosis. It is recommended on the high epidemiological risk recreational areas to make the treatments with "Baytex 40% w.p." (1 kg/ha).

[0023] PLAN OF SAMPLING OF *DICHOPELMUS NOTUS* (ACARI, ERIOPHYIDAE) IN PARAGUAY-TEA ORCHARDS

L. A. Chiaradia^U & J. V. Neto², ^UCPPP/Epagri, Box 791, CEP 89801-970, Chapecó, SC, BR, E-mail: chiaradi@epagri.rct-sc.br; ^UUNOESC, Box 747, CEP 89800-000, Chapecó, SC, BR, E-mail: jvn@unoesc.rct-sc.br

This research had the objective of proposing a sampling plan for the mite Dichopelmus notus (Acari, Eriophyidae) in paraguay-tea (Ilex paraguariensis) orchards, a plant used to industrialize tea and other drinks. This pest causes shoot death and tan leaves with posterior fall. The following factors of the behavior of the mite in the orchards were considered: three tree heigth (upper, medium and lower) and two canopy depth (internal and external). These factors were analyzed through the model of blocks in factorial structure. The samples were taken biweekly from February to May of 1999 in orchards with eight years old conducted in an arrangement of 2,5 x 4,0 m between the trees. The orchard was located in Chapecó West of Santa Catarina, Brazil. The experimental unit was constituted by one tree. Each date 18 leaves were collected from ten trees, being six leaves per height and three per depth. The mites counting were carried out in the Laboratory of CPPP/Epagri with esterioscopic microscopic with fourty magnificence. The effects of heigh and depth were considered fixed, while blocks (trees) and leaves were taken as aleatory to obtain the mathematical hopes of the medium squares. Starting from the experimental model was obtained the stimactor of the variance of the general mean and of the components of the variances associated with aleatory effects. Determination of the number of trees (k) and the number of leaves (l) recommended for sampling was observed by the combination among k and l that turned minimum the variance of the mean. Results suggest that for rational estimation of the number of mites in paraguaytea orchard with a standard error until 10%, it is necessary to sample three leaves from 110 trees, from lower and medium parts of the trees. Idex terms: paraguay-tea, tan mite, sampling.

[0022] BIOLOGY OF *TETRANYCHUS DESERTORUM* (ACARI: TETRANYCHIDAE) ON PAPAYA TREE AND ITS OCCURRENCE IN PROTECTED ENVIRONMENT

T. M. M. G. Castro^t & M. R. Vieira¹, ¹Dept. Of Biology, Unesp. P. O. Box 31, 15385-000, Ilha Solteira, Sp, Brazil, e-mail marineid@bio.feis.unesp.br.

The occurrence of Tetranychus desertorum in papaya tree was researched on Improved Sunrise Solo Line 72/12 and Baixinho de Santa Amália varieties, in three situations: natural environment and two screened with mesh of 2 x 2 mm and 2 x 1 mm, providing a incidence of solar radiation reduction of 30% and 40% respectively. In this assay, the species only occurred in screened, with upper populations that mesh 2 x 2 mm on Improved Sunrise Solo variety. The biology of this tetranychid on the two varieties, was carried out in Petri plates using leaves discs with 2,5 cm diameter, on a moisten cotton layer with destilated water. The plates were kept to 25.4 ± 0.32 °C, relative humidity of $70.8 \pm 0.84\%$ and 10 hours photophase. In this condition, the duration of the period from egg to adults for female was 8.2 ± 0.27 days on Improved Sunrise Solo and $8,0 \pm 0,05$ days on Baixinho de Santa Amália, which the female depositing 55,0 \pm 6,54 eggs in 14,25 days (4,1 \pm 0,45 eggs/day) and 54,7 \pm 4,12 eggs in 17,0 \pm 1,51 days $(3,6 \pm 0,34 \text{ eggs/day})$, respectively. On Improved Sunrise Solo variety, the life table of fertility's parameters were: intrinsic rate of increase (rm) of 0.23, finite rate of increase of 1,26 individual per female per day, mean generation time (T) of 16,37 days and net reproductive rate (Ro) of 43,39, while on Baixinho de Santa Amália the values were 0,21, 1,23 individual per female per day, 16,88 days and 37,55, respectively. Index terms: screened, varieties, life table of fertility, net reproductive rate.

[0024] FLUCTUATION OF *BREVIPALPUS PHOENICIS* (ACARI, TENUIPALPIDAE) IN CITRIC ORCHARD IN CHAPECÓ, SC

L. A. Chiaradia ^u, L. C. de Souza^v & José Maria Milanez^u, ^uCPPP/Epagri, Box 791, CEP 89801-970, Chapecó, SC, BR, E-mails: chiaradi@epagri.ret-sc.br and milanez@epagri.rct-sc.br; ^uStudent of Agronomy Course, UNOESC, Chapecó, SC, BR.

Brazil is the biggest Citrus productor in the world with annual production around 20,000,000 ton. The mite Brevipalpus phoenicis transmit the leprosys citrus disease, a virous that causes damage in the sugar oranges trees, and requires permanent pest control that increase the production cost and environmental problems. To study the fluctuation of this pest and its interference with environmental factors one experiment was conducted in an orchard located in Chapecó, West of Santa Catarina, Brazil. This study started in August 1997 and his datas is until July 1998 (however this research will continue for more two years). With six years old trees variety 'Valence' on Poncirus trifoliata conducted with 4.0 x 6.0 m between trees, had 2,5 m heigth. The samples were taken biweekly with "sweeping" method that consisted of the all fruit bark observation, mainly fruits with "scab" disease, remainder fruits and early fruit, looking three fruits from twenty trees. When with no fruits, shoots and leaves with insertion at terminal portion by sixty branches of canopy internal were sampled. The samples were made in the orchard using lens with ten magnificence and one squar centimeter by fixed camp. The preliminary results showed that B. phoenicis ocurred during all period with large infestation from September to December. The monthly rain total and air humidity had few interference on the mite fluctuation. The total monthly maximum temperature mean (U3) was the factor with more interference on the pest infestation and the analysis correlation accused value of 0,72, with 0,007 significance level and resulted in the equation $\hat{U} = -42,28 + 3,73 U_3$ with linear regression analysis.

Index terms: Citrus, leprosys mite, fluctuation, environmental interference

[0025] IGG BINDING SITES IN THE SALIVARY GLANDS AND CEMENT CONE OF AN IXODID TICK

L. B. Coons & M. Rothschild, Dept. of Microbiology & Molecular Cell Sciences, Life Science Bldg. Univ. of Memphis, Memphis TN 38152 USA.

IgG binds to the secretory granules of a, d, e and g type cells in *Dermacentor variabilis* salivary glands. The a, d, and e type secretory granules occur in fed and unfed ticks of both sexes; but g type secretory granules occur only in fed males. Previous studies have shown that e type granules are shed into basolateral spaces that are contiguous with the hemocoel. The contents of these granules may be involved in binding host IgG in the hemocoel. IgG also binds to the cement cone that surrounds the tick's mouthparts during feeding. Previous studies have shown that the cement cone and both d and e type secretory granules have similar immunoreactive polypeptides, indicating that these granules may contribute a component of the cement cone. In f cells, host IgG undergoes transcytosis into the saliva . We suggest that this IgG binds to sites in the cement cone where it acts to shield the parasite from the host's immune system during feeding.

Index terms: Dermacentor variabilis, Ixodidae, Host IgG

[0027] EAR MITES OF GOATS IN BRAZIL

J. L. H. Faccini, Depto. Parasitologia Animal, Univ. Federal Rural do Rio de Janeiro. Seropédica, RJ, 23890-000, Brasil, E-mail faccini@ufrrj.br.

An overview of the relationship between ear mites and goats in Brazil is presented. Two species have been diagnosed: Psoroptes cuniculi and Raillietia caprae. Both are cosmopolitan but data gathered in Brazil and elsewhere suggest that the first species is much more common than the second. Diagnosis of mite infestation has been carried out either by swabbing or flushing the ear canals of hosts. The latter is the better method as it allows quantification of the intensity of infestation. Mixed infestations may occur. Prevalence and intensity of infestations in both species of mites appear to be independent of age and sex of the host. Surveys, carried out in northeastern, southeastern and western Brazil, have shown that average herd prevalence of *P. cuniculi* ranged from 73%, 76% and 89%, respectively, whereas intensity of infestation ranged from 71-1237, 76-229 and 259-934 mites/goat, respectively. In southcastern Brazil, prevalence and intensity of infestation of R. caprae ranged from 31-100% and 2-27 mites per goat, respectively. Breeds of goats such as Saanen, Toggenburg, Anglonubian, Alpine and Moxotó (native) appear to be highly susceptible to infestation with R. caprae, but further research is needed to confirm such data. Population structure of each species is quite different. In P.cuniculi all stages of the life cycle are found in the ear canals whereas in R. caprae nymphs are absent. It is suggested that part of the life cycle of R. caprae occurs in the environment. The pathogenesis of parasitism has not been fully clarified, but one may infer, based on morphology of the chelicerae of both species, that otitis is caused by invasion and colonization of mite-feeding lesions by common bacteria which live in the ear canals of goats. Clinical parasitosis is rare, although typical lesions of otitis are frequently found during necropsy of parasitized goats. From the epidemiological point of view, these animals are an important source of intra and interherd mite transmission. Transmission of both species to sheep pastured together with goats might occur under certain circumstances, so that sheep may also be a source of mite transmission. A strong association, between R. caprae and pathogenic mycoplasmas for goats has been observed under natural conditions in southeastern Brazil.

[0026] STUDIES ON INFECTION MECHANISMS OF THE FUNGI BEAUVERIA BASSIANA AND METARIHIZIUM ANISOPLIAE ON HYPOTHENEMUS HAMPEH USING FLUORESCENCE MICROSCOPY AND SCANNING ELECTRON MICROSCOPY

<u>F. Delgado¹</u>, P.E. Vélez¹, E. M. Giraldo¹ & Y. López¹, ¹Disciplina de Entomología. Centro Nacional de Investigaciones de Café (Cenicafé).Chinchina, Caldas, Colombia. E-mail fefdelb@cafedecolombia.com Fax: 0968-506630. A.A 2427.Manizales. Caldas. Colombia.

Among the several pests that attack coffee crop (Coffea arabica), the most serious for colombian coffee growers is the coffee berry borer (Hypothenemus hampei). So far the use of entomopathogenic fungi B. bassiana and M. anisopliae are considered to control this insect pest of economic importance. We have studied infection mechanisms of both B. bassiana and M. anisopliae on adults of H. hampei and cuticle fragments by light fluorescence microscopy and scanning electron microscopy (SEM). The infection seems to involve the following events: (1) adherence of the spores to the cuticle (2) germination of spores and growth of the mycelium on cuticle surface (3) penetration of germinative tubes into the cuticle (4) extensive lateral development of hyphae followed by strong degradation of the cuticle layers. Labelling with Calcofluor White suggests that cuticle penetration and colonization mechanisms by both B. bassiana and M. anisopliae are closely related to enzymatic hydrolisis and mechanical pressure. Germinative tubes of B. bassiana and M. anisopliae can penetrate at any place of the H. hampei cuticle, although the most frequently penetration site is the insect abdomen close to the adherence site of the spores. A fissure is produced on the cuticle surface after penetration of the germinative tube into the insect. These observations bring further insights into the infection mechanisms of both fungi on H. hampei and on the localization of fungal spores and their penetration site on the insect cuticle. Spores localization, germination, mycelium growth and development of these fungi were observed from 48 h to 12 days after inoculation on growing media containing fragments of H. hampei cuticle using fluorescence microscopy and SEM.

Index terms: Entomopathogenic fungi, Coffee berry borer, conidial attachment, microscopy

[0028] THE FOOD WEBS OF ARTHROPOD COMMUNITIES IN *NEPENTHES* PITCHERS: WHERE DO HISTIOSTOMATID MITES FIT IN?

N. J. Fashing, Dept. of Biology, P. O. Box 8795, College of William & Mary, Williamsburg, VA23187-8795, USA, E-mail Norman.Fashing@wm.edu.

Many terrestrial plant species possess morphological attributes that collect and retain water, and these bodies of water often house communities of arthropods. Termed "phytotelmata". they have been lauded as excellent subjects for testing community theory since they are natural microcosms that are easily manipulated, provide for replication and contain relatively few species. In this regard, the fluid-filled pitchers of Nepenthes make excellent subjects and have received a great deal of attention in recent years. The trophic relationships of insect inhabitants are relatively well known, but those of the mite inhabitants remain largely uninvestigated. Although individually small, mites attain high population levels in pitchers and are important competitors of larger inhabitants. An understanding of the trophic relationships of mite inhabitants is therefore essential to an understanding of community dynamics. Three species of histiostomatid mites inhabit Nepenthes pitchers in northern Queensland, Australia, and studies emphasizing functional morphology of mouthparts via scanning electron microscopy reveal differences in feeding behaviors. Typically, histiostomatid mites possess non-chelate, flattened, serrated chelicerae, as well as a very long, flagella-like, terminal seta on each pedipalp. The long pedipalpal setae beat in a manner that creates a vortex in the fluid medium, thereby drawing small particulate matter and microorganisms toward the mouth where they are raked in by alternate protraction and retraction of the chelicerae. Zwickia (near) guentheri has typical mouthparts and utilizes this mode of feeding. Zwickia (near) nepenthesiana has short rather than long pedipalpal setae, and its chelicerae are stout and blade-like rather than serrated. It is not adapted for filtering particulate matter and microbes from the fluid and probably feeds by cutting (slicing) pieces of tissue from decaying insects. While Cruetzeria sp. has rake-like chelicerae, it lacks long pedipalpal setae. This genus is unique among astigmatic mites in that it is adapted for swimming. Rather than using the action of long pedipalpal setae to draw small particulate matter and microbes to the mouth region, members of this genus rapidly swim at an angle to the substrate keeping it in contact with their chelicerae. The chelicerae act as "brushes" to stir up small particulate detritus and microbes from the surface of decaying insects. The "suspended" matter is then funneled into the mouth by the forward movement. Cruetzeria sp. and Z. (near) guentheri gather microbes and small particulate detritus from the fluid, thereby competing with mosquito larvae. Z. (near) nepenthesiana, however, feeds directly on decaying insects and competes with sarcophagid, phorid and ceratopogonid larvae. Index terms: Zwickia, Cruetzeria, Acari, functional morphology, mouthparts

[0029] SETAL POLYMORPHISM WITHIN AND BETWEEN STASES IN AN ALGOPHAGID MITE INHABITANT OF WATER-FILLED TREEHOLES

N. J. Fashing, Dept. of Biology, P. O. Box 8795, College of William & Mary, Williamsburg, VA23187-8795, USA, E-mail Norman.Fashing@wm.edu.

A manuscript is now in press describing a new genus of Aigophagidae, members of which are obligate inhabitants of water-filled treeholes in a semitropical rainforest in Queensland, Australia. One of the two described species exhibits an interesting polymorphism in regard to the morphology of dorsal setae. In non-dispersing (= homeomorphic) inumature instars as well as adults, setae se, c3, and c2 are similar in that they are hair-like, however the morphologies of all other dorsal setae vary between stases with none being hair-like in immatures Larvae even exhibit intra-stase variation, with some individuals having stout setae with relatively long biserrations, others having long, bipectinate setae, and yet others with a setal morphology in between. Non-larval stases exhibit only slight intra-stase variation for any given seta. As setae are compared between immature instars, a progression is observed from the long, bipectinate and/or bushy setae of the larvae to the shorter, biserrate and lanceolate setae of the tritonymphs. In adults, setae si, c1, c2, c3, cp, d1, d2, and e1 become short and hair-like, Those few adult setae that retain a biserrate condition with short barbs (f2, h_1,h_2,ps_1 and $ps_2),$ are much shorter relative to body length than in early immature instars. It is postulated that the longer, bipectinate and/or biserrate dorsal setae of the immatures function as a deterrent to predators. The algophagid mites share the treeholes with predatory arrhenurid and ascid mites, as well as with predatory tanypodine midge larvae and the predatory tadpoles of a frog. Although such setal morphology could potentially offer protection to adult as well as immature instars, it would also have a negative effect during copulation. Males of algophagid species are approximately the same size as females and mount dorsally during copulation, facing in the same direction as the female, and overlapping her to a great extent. If enlarged, bipectinate dorsal setae were present, they would undoubtedly hold the male away from the female and interfere with copulation. This seems a logical explanation for the transition from the relatively long, stout, bipectinate setae of larvae to the primarily short, weak, hair-like setae of adults. It is interesting that the second species of algophagid found in the treeholes retains greatly enlarged pectinate setae in adults as well as homeomorphic nymphs, however, it has evolved a different strategy to prevent interference during copulation. The enlarged dorsal setae are lost early in the adult stage through abscission

Index terms: Algophagidae, Acari, copulation, Australia

[0030] SPACIAL AND TEMPORAL DISTRIBUTION OF CALACARUS HEVEAE ON RUBBER TREES IN BRAZIL

N. J. FERLA¹, O. BONATO² G. J. MORAES DE¹, H. J. SCOMPARIN³, C. C. FRANCHECHI¹, ¹Esalq, Depto. De Fitopatologia, Entomologia E Zoologia Agrícola, C. P. 11, 13418-900, Piracaba, São Paulo, Brazil; ²ird (Ex-Orstorn), França; ²embrapa Meio Ambiente, C.P. 69, 13820-000, Jaguariúna, São Paulo, Brazil; ³ Plantações E. Michellin, C.P. 80, 78700-090, Itiquira, Mato Grosso, Brazil; ⁴ Triânguto Agro-Industrial, C.P. 42, 78250-000, Pontes E Lacerda, Mato Grosso, Brazil: E-Mail Ferla@Carpa.Ciagri.Usp.Br

Three eriophyid species (Acari: Eriophyidae) are found on rubber trees in Brazil: Calacarus heveae, Phyllocoptruta seringueirae and Shevtchenkella petiolula. The former is the most important, for rusting the leaves and causing premature leaf drop. The objective of this work was to analyze the distribution of C. heveae on the plant, selecting the most representative sampling stratum and studying the dynamics of the mite population during one growing season. The study was conducted at Itiquira and Pontes e Lacerda, in the State of Mato Grosso. The most susceptible clones were selected for study in each site, PB 260 (10 years old) in the former and IAN 873 (12 year old) in the latter. Ten trees were randomly selected in each field, at least 20 m from field margins. No chemical treatments were done in those areas during the time the study was conducted. The trees were divided into 3 strata: basal, medium and apical. From September 1998 to August 1999, monthly samples consisting of 3 leaves from each stratum of each of the pre-selected plants were collected, taking them to the laboratory for examination. Mite density was analyzed with ANOVA and proportions of mites was analyzed with Friedman's test. In both sites, the proportions of infested leaves in the different strata were statistically similar. At Itiquira, the average mite density in the basal stratum was significantly higher or lower than that at other strata in only 4 sampling dates. At Pontes e Lacerda, this parameter was not significantly different between strata. At Itiquira, the proportion of mites in the basa! stratum was significantly higher or lower than that in the median stratum in 5 sampling dates; it was higher than that in the apical stratum in one sampling date and lower in another sampling date. At Pontes e Lacerda significant differences were found in just one sampling date, when the proportion of mites at the apical stratum was significantly lower than that on other strata. The amplitude of the proportions of infested leaves and of the number of mites per leaf was lower in the medium stratum, indicating that this should be the stratum selected for samplings of populations of C. hevene. The peak of the population of C. hevene occurred in December at both sampling sites, but in Itiquira it was cousiderably higher.

Index terms: Calacarus heveae, rubber tree, Hevea brasiliensis, populational dynamic

[0031] MODEL FOR OPTIMISATION OF THE WORKRATE OF AIRBLAST SPRAYERS ON CONTROL OF *BREVIPALPUS PHOENICIS*

M. C. Ferreira^{2,3} & T. Matuo^{2,3}, ²Dept. Fitossanidade, Univ. Estadual Paulista-Campus de Jaboticabal, ³E-mail: mdacosta@fcav.unesp.br; ⁴E-mail: matuo@fcav.unesp.br. Project supported by FAPESP.

Cost of pest control is responsible for one third of the total production cost of citrus in Brazil. This high cost is due mainly to citrus leprosis mite (Brevipalpus phoenicis, Geijskes 1939) that usually is lodged in sites difficult to be reached by the spray. This demands traditionally very high rates for spraying. Therefore is very important to improve the working capacity of the sprayers in order to reduce costs. Studies regarding to operational capacity of these types of sprayers are scarce. The aim of this study was to conduct field measurements and establish the validity of a mathematical model and apply it in simulation studies determining systems for optimisation of the operational capacity of airblast sprayers for citrus minimising the production costs. Comparing estimated figures with data observed in the field it was verified that the model is valid, presenting correlation coefficient ranging from 0.83 to 0.99. Using the simulation model it was verified the feasibilityin increasing the performance of the sprayer reducing costs. We concluded that proposed simulation model is valid and is suited to conduct simulations that afford reduction in production costs through changes in operational attitudes as well as changes in he sprayers. A software named FiSiCoM was developed that allows to compare situations such as reduction in spray volumes and changes in the other application parameters. The use of simulations can show the best situation for economically carry out the spray operations in minimum time. Nevertheless the information that leads to a better way to spray are very scarce, for example, the basic knowledge in reducing spray volume maintaining the same efficacy. This is certainly a research field that is needing more efforts in order to allow more rational procedures in pesticide application, lowering costs as well as reducing environmental impacts.

Index terms: simulations, spray technology, sprayer, pest control, citrus mite

[0032] MODEL FOR REDUCTION OF THE COSTS AND ENVIRONMENTAL IMPACTS ON THE CONTROL OF *BREVIPALPUS PHOENICIS*

M. C. Ferreira^{2,3} & T. Matuo^{2,3}, ²Dept. Fitossanidade, Univ. Estadual Paulista-Campus de Jaboticabal, ³E-mail: mdacosta@fcav.unesp.br; ⁴E-mail: matuo@fcav.unesp.br. Project supported by FAPESP.

More than 50% of mitecides used in Brazil is for the control of citrus leprosis mite (Brevipalpus phoenicis, Geijskes 1939). Excessive spray volume carrying large amounts of chemicals is responsible for such figure. Traditionally very high spray volumes, sometimes higher than 10,000 L/ha, is used due to the difficulty in reaching mites located in the inner part of the canopy and in chinks offruits and branches. This fact causes undesirable wastage of resources and environmental impact. In the present study a simulation was performed using the mathematical model in order to estimate the economy reached using an improved filling procedure and a lower spray rates. In the filling procedure using transfer of already prepared spray solution are included the costs of an auxiliary crew (one tank car driver and one assistant) and costs of the tank car. Conventional spraying for mite control spraying to only one side of the machine using 19 L of spray solution per tree in 8 x 4 m planting scheme considering the yield of 35.7 t/ha reaches the operational cost of US\$ 30.56/ha not considering the costs of the chemicals. In the other hand, considering the improved filling procedure using transfer of already prepared spray solution and applying 12 L per tree in 7 x 3.5 m planting scheme and considering the same 35.7 t/ha the application cost will be US\$ 10.28/ha, i.e. one third of the conventional spraying. Improved filling procedure combined with lower spray rates provide saving in resources, mainly water, as well as less contamination leading to create mere stable and sustainable agri-ecosystem. Thus, research on reduction of spray volume to more effective pest control as well as improved operational capacity of sprayers are very important factors in Brazilian citriculture.

Index terms: simulations, citrus leprosis mite, sprayer, spraying, pest control

[0033] KETOENOLE: A NEW CHEMICAL GROUP TO THE MITES CONTROL IN THE CITRUS CULTURE

A. C. P. Florim¹ & <u>O. Nakano¹</u>, ¹Dept. of Entomology, Fitopatology and Agricultural Zoology, Univ. of São Paulo - ESALQ/USP, Av. Pádua Dias 11, P. O. Box 9, Piracicaba, São Paulo, Brazil.

The citrus culture is usually aimed by several pests, which can cause beyond repair damages when found in favorable conditions to its development. Among the dangerous and frequent pests, it's possible to remark the mites action, that also becames resistent to the conventional acaricides. Meaning to avoid the promotion of this resistance evolution it's recommended to manage the pest varying the acaricide group. Meanwhile, even though we find several acaricides available, most of them belongs to the same chemical group, making it harder to create a rotary scheme of different groups. So we can say that the emergence of this new group, the Ketoenole, represented by BAJ 2740, formulated at 240SC, is providing another option to the acaricide management. This acaricide acts over all the mite development stages, and also acts as an ovicide. It presents low oral and dermal toxicity, is not aggressive to the eyes and skin and, when on the soil or in the aquatic system, degrades quickly. Depending on the time it's been applied, presents low effect over other predators mites, is non toxic to the bees and birds, being compatible to the entomophatogenic fungus and beneficial insect, and besides has not presented any crossing resistance to the world comercialized products. The BAJ 2740 was tested in the field conditions over Brevipalpus phoenicis, Phyllocoptruta oleivora and Panonychus citri populations, in different dosages (10;15 and 20 ml/100L H_2O). It's been verified that any dosage used was very efficient to control the concerning mites. The evaluations were realized from the third up to the 75th day after application (DAA), depending on the mite species. The evaluation consisted of counting the mites found on ten alcatory fruits per parcel with 40 fruits/treatment. Those are the results: B phoenicis, high efficiency from the 15th DAA up to the 75th DAA; P oleivora, over 90% efficient from the third DAA up to the 45th DAA; and P citri, over 90 % efficient from at third DAA and 100% efficient after the 15th DAA.

Key words: Ketoenole, acaricide, citrus.

[0034] INTERACTION OF TICK SALIVA WITH THE HOST IMMUNE MECHANISMS AND ITS SIGNIFICANCE FOR PATHOGEN TRANSMISSION

N. Fuchsberger¹, P.Kocáková¹, V.Hajnická², M. Slovák³, M. Labuda³ & P.A. Nuttall⁴, ¹Inst. Virology, Slovak Acad. Sci., 842–45 Bratislava, Slovakia, E-mail virufuxo@savba.k; ² Institute of Preventive and Clinical Medicine, Limbova 14, 83301 Bratislava, Slovakia; ³Institute of Zoology, Slovak Academy of Sciences, Dubravska 9, 84306 Bratislava, Slovakia; ⁴ CEH Institute of Virology and Environmental Microbiology, Oxford, OXI 3SR United Kingdom

Ticks are of great medical and veterinary importance not only as haematophagous ectoparasites infesting humans and domestic animals, but also as vectors of a wide variety of pathogenic organisms. Ixodid ticks are obligate blood-feeders in all their life stages. In contrast to other haematophagous parasites, the contact between an ixodid tick and its host lasts for days or even weeks. During the prolonged feeding period, the salivary glands increases in protein content. Feeding provokes host haemostatic, inflammatory and immune responses. Therefore, ticks counterattack with anti-haemostatic, anti-inflammatory and immunomodulatory substances. We demonstrate the differences in protein patterns of different tick species (Ixodes ricinus, Haemaphysalis inermis, Dermacentor reticulatus, Rhipicephalus appendiculatus, Amblyomma variegatum), differences in patterns at different stages of feeding, differences between sexes and collaboration of both sexes during feeding. The salivary glands are also the primary means for transmission of tickborne pathogens. Such pathogens exploit the immunomodulatory activities of tick saliva. This phenomenon is known as Saliva activated transmission (SAT). We demonstrate the promotion of virus growth by tick SGE in an animal-free system. We demonstrate the interaction of tick SGE with host immune mechanisms namely with the interferon system, with natural killer cells, and with chemotaxis. We demonstrate the interaction of tick saliva with the host cytokine network at the levels of both production and action.

[0035] MITE POPULATIONS IN RELATION TO CYDIA POMONELLA CONTROL IN THE ALTO VALLE DE RÍO NEGRO Y NEUQUÉN (ARGENTINA)

 $\underline{\rm H.}$ Giganti, G. Dapoto & M. Bondoni, Fac. C. Agrarias - U.N.C. , C.C. 85–8303 Cinco Saltos (R.N.) Argentina. E-mail: hgiganti@uncoma.edu.ar.

Apple tree is the most important crop in Alto Valle de Río Negro y Neuquén, and *Cydia* pomonella (L.) is the key pest. The chemical control determine different changes in other species those wich reach population densities above economic damage threshold. Four plots were observed for to look about the evolution of Tetranychidae (Acarina) with different *C* pomonella control modes manage as follow: from 1994/95 to 1996/97: a) neglected, 1994/95 to 1997/98: b) recently implanted, for organic crop, c) with regional usual chemical treatments and in 1997/98: d) pheromone disruption. Since october to march once a week, 40 leaves were taken out of 10 trees in each plot, from wich the nites were extracted by Berlese method. Results show that plots a), b) and d) increase populations more that plot c) at the end of spring and begining of summer, but they do not reach economic damage threshold. The peaks of phytophagous, mainly *Panonychus ulmi* Koch, are controlled by predators and a narrow phytophagous/predator relation is obtained until the end of cycle. In plot c) graphics do not show trends and in spite of the pesticide pressure it has a small but prudent population of *Neoseiulus californicus* (Mc Gregor), the main predator.

Index term: Tetranychidae, Phytoseiidae, Cydia pomonella control, apple tree, Argentina.

[0036] EFFECTS OF CILLORPYRIFOS AND TEFLUTHRIN ON LUMBRICUS TERRESTRIS

<u>R. Giménez</u>, **A. B. Della Penna & E. Odello**, Cátedra de Terapéutica Vegetal, Facultad de Agronomía, Univ. de Buenos Aires. Av. San Martín 4453, (1417) Buenos Aires, Argentina, E-mail: rgimenez@agro.uba.ar

This essay was carried out in order to evaluate the ecotoxicity of the insecticides Chlorpyrifos and Tefluthrin on the earthworm Lumbricus terrestris L., using the Daniel funnel test, following the guidelines of the International Organization of Biological Control (IOBC). This is a laboratory test to measure side effects of pesticides on L terrestris. The earthworms were collected from a soil free of pesticides from the Ap horizon at the Faculty of Agronomy field. It was placed in recipients with sterilized soil, under fully dark and 12°C conditions by 5 days, and was fed with dried clover leaves. Only juveniles earthworms were used: then those with a live biomass higher than 1,5 g / individual and without clitelum were used, and putted into the experimental unity (Daniel funnel's) with ten dried leaves of Trifolium repens L. over the soil surface. The treatments sprayed in the surface of the funnels were: To= standard, with water; T1= negative standard, with 30 mg/l chloroacetamid solution (L; 97,37%); T2= Chlorpyrifos (EC; 48%) 5 liters/ha and, T3 = Tefluthrin (EC; 5%) 2 liters/ha. A hand spray were use, with drops of 150 micrometers and covering a surface of 70 drops/cm². The experimental design was a DCA with 10 replications. During the 15 days of exposition the following variables were analyzed: weight variation, the individual activity measured by the withdrawn leaves; and mortality of earthworms. ANOVA and Tukey test were used for the statistic analysis. The increase of weight of the earthworms was similar in all the treatments. The activity, measure as the dairy number of leaves withdrawn, showed that there were no significant differences between the treatments. The L. terrestris survival was affected only by Chloroacetamid, drug used like negative standard, in that case it showed that the 80% of the individuals dead during the 15 days of exposition.

Index terms: insecticides, side effects, non-target, ecotoxicology, earthworms

[0037] LIFE TABLES OF THE RED MITE, *EOTETRANYCHUS LEWISI* (ACARI: TETRANYCHIDAE)

M. P. González-Castillo¹, M. T. Valverde² & T. M. Pérez³, 1.- Instituto Politécnico Nacional, CIIDIR, U. Dgo, A. P. 112, Vicente Guerrero, Dgo, C.P. 34890, México, Becario de la COFAA-IPN. E-mail: marypgoca@hotmail.com. 2.- Lab. Esp. de Ecol., Fac. de Ciencias. UNAM. Cd. Univ. C.P. 04510, México, D.F. 3.- Lab. de Acarol. Int de Biol. UNAM. A. P. 70-153, C.P. 04510, México, D.F.

The red mite, Eotetranychus lewisi shows a worldwide distribution and may live on a number of host plants, including the peach tree. This mite may colonize the leaves of peach trees causing severe damage to the peach production in several regions of México. Mite populations in Zacatecas and Durango, México occur from march to september each year. The aim of this study was to describe the life cycle of E. Lewisi and to build a life table for a population of this mite kept under controlled conditions in order to evaluate demographic variables such as stage-specific mortality and fertility, and analyze its potential for population growth. The work was carried out at the Entomology laboratory of CHDIR-IPN, in the Mexican State of Durango during 1997. Mites were kept at a temperature of 27 ± 2 °C, a relative humidity of 70 \pm 10 % and a 12:12 hr photoperiod. Starting with eggs that were followed closely, the life cycle of E. Lewisi was described including the duration of each stage and the total longevity of males and females. Stage-specific mortality was recorded and fertility was measured; this allowed us to build a life table from which population growth estimates were calculated, in particular, net reproductive rate (Ro), intrinsic rate of population increase (r_m) , generation time (T) and finite rate of increase (λ) . Female were able to oviposite from the 18th day after emergence; each female produced an average of 22 eggs. According to the fertility and survival records of our life table, E. Lewisi may produce a 4-fold population increase each generation. The generation time, which may be interpreted as the average time elapsed between the birth of parents and the birth of their offspring, was 12.54 days. The intrinsic rate of population increase (rm) was 0.114 and the finite rate of population growth (λ) was 1.12. The moment of highest population growth was when females were between 23 and 25 days old, which coincided with the moment of highest oviposition decreased after day 26. The potential for population increase of E. Lewisi is high. This may contribute to the fact that it is usually considered a pest. Yet, it is important to study the demographic behavior of this mite under natural conditions since, for instance, mortality factors in the field must be much stronger than under controlled conditions. In any case, this study has allowed us to address fundamental aspects of the biology of E. Lewisi both from the point of view of its life cycle and its demographic potential. Key words: damage, peach tree, population.

[0038] EFFECTS OF CASSAVA CULTIVAR ON ABUNDANCE OF EXOTIC PHYTOSEIID MITES IN AFRICA

R. Hanna¹, D. Ojo¹, J. S. Yaninek², M. Toko¹, D. Gnauvossou¹ & A. Onzo¹, ¹Intern. Inst. of Trop. Agric., PHMD, IITA-Benin Station, 08 B.P. 0932, Cotonou, Benin, E-mail r.hanna@cgiar.org; ²USDA Coop. State Res. Ed. Ext. Service, 1400 Independence Ave., Washington D.C. 20250-2220, USA, E-mail syaninek@rceusda.gov.

The establishment of the exotic phytoseiid mite Typhlodromalus aripo on cassava in Africa has generally provided excellent biological control of cassava green mite Mononychellus tanajoa, and has resulted in substantial increases in cassava yields. Typhlodromalus aripo inhabits the apex of cassava shoots during much of day and forages on cassava leaves during the evening and night hours. Cassava provides shelter, prey as well as non-prey food such as exudates for the maintenance of T. aripo populations. In field surveys throughout the areas where T. aripo has been established, we have observed at times large differences in T. aripo abundance among cassava cultivars that differed in the level of shoot apex 'hairiness'. In an initial attempt to understand the relationship between cassava cultivars and T. aripo, we set up a common experiment with 6 cassava cultivars, 3 with 'hairy' apices and 3 with 'glabrous' apices. Mite abundance and several cassava apex characteristics were evaluated on 4 occasions over a 12-months period. Abundance of both M. tanajoa and phytoseiid predators varied considerably between sampling periods, as expected, and among cultivars. 'Hairy' cultivars had significantly higher hair density and hair length on the midrib, vein, and venule of immature leaf tissue in the cassava shoot apex. Mononychellus tanajoa densities were higher during the dry season on 'glabrous' compared with 'hairy' cultivars. Moreover, T. aripo abundance was positively correlated with hair density on the midrib, veins and venules of immature leaf tissue in the cassava shoot apex, despite lower abundance of M. tanajoa on the hairy' cultivars. Under the conditions of the experiment, none of the cultivars suffered substantial M. tanajoa damage. The utility of these findings for developing tactics to enhance M. tanajoa biocontrol and in cassava improvement programs will be discussed. Index terms: Mononychellus tanajoa, Typhlodromalus aripo, shoot apex surface

[0039] BIOLOGICAL CONTROL OF *OLIGONYCHUS PERSEAE* (ACARI: TETRANYCHIDAE) ON AVOCADO: EVALUATING THE EFFICACY OF VARYING RELEASE RATES AND RELEASE FREQUENCY OF *NEOSEIULUS CALIFORNICUS* (ACARI: PHYTOSEIIDAE)

M. S. Hoddle, Department of Entomology, Univ. of California, Riverside CA 92521, USA. E-mail: mark.hoddle@ucr.edu.

Three different release rates and timings of the phytoseiid Neoseiulus californicus were evaluated for Oligonychus perseae control on avocado trees in a commercial orchard in southern California, USA. Densities of natural enemies and O. perseae were monitored on trees for 34 weeks that were treated with either one, two, or three releases of 500, 1000, or 2000 N. californicus, or two applications of 5% narrow range (NR) 415 insecticidal oil. Predator releases were made when 50% (release one), 75% (release two), or 95% (release three) of sampled leaves were infested with one or more motile O. perseae. Densities of O. perseae on trees treated with N. californicus or oil were compared to control trees that received no treatments for O. perseae suppression. Release of a minimum of 2000 N. californicus per tree was necessary to significantly reduce O. perseae densities in comparison to control trees. Releasing 1000 N. californicus twice or 2000 N. californicus once provided O. perseae control similar to oil treatments and to trees treated with cumulative releases totaling more than 2000 predators per tree. This result indicated that releases totaling more than 2000 N. californicus per tree did not substantially improve O. perseae control and the cumulative number of predators released per tree is more important than the number of times N. californicus is released for controlling O. perseae. index terms: Persea americana

[0040] THE CAPTURE EFFECT OF PREDACEOUS MITE AMBLYSEIUS ORIENTALIS TO THE RED MITE PANONYCHUS CITRI AT DIFFERENT TEMPERATURES

S. O. Hu, M. Gan & M. H. Li, Dept. of Biological Science and Engineering, Nanchang Univ, Nanchang 330047, Jiangxi, China, E-mail hsqlqlw@public.nc.jx.cn

Panonychus citri is an important injurious mite in citrus orchard, affecting both the quality and quantify of orange trees. Amblyseius orientalis is a effective natural enemy on *P.citri*. The capture effect of *A.orientalis* on the phytophagous mite *P.citri* was dealt with five temperatures with seven density of *P.citri* in the laboratory (Tab 1). The results showed that the function response of *A.orentalis* to *P.citri* all accorded with Holling's II equation at different temperatures. The mathematical model and maximum predation of *A. orentalis* to *P.citri* showed at different temperatures (tab 2).

Index terms: Holling's II equation, mathematical model, maximum predation

[0041] THE CARBOHYDRAZES OF THREE ACAROID MITES (ACARI: ACARIDIDA) – PRELIMINARY RESULTS

<u>J. Hubert</u> & E. Ždárková, Research Inst. of Crop Production, Drnovská 507, Praha 6, 161 06, Czech Republic. E-mail hubert@hb.vurv.cz.

Feeding habits of the most abundant acaroid mites in stored grain in the Czech Republic were assessed by measuring carbohydraze activities in the mites. The enzymatic activities were measured in the whole body homogenates of Acarus siro, Lepidoglyphus destructor and Tyrophagus putrescentiae. The mites were reared on yeast and wheat germs diet in darkness at 25°C. The enzymatic activities against starch, amylopectin, cellulose, cellobiose, saccharose, maltose, lichenan and trehalose were tested by a saccharogenic method, detecting glucose as the reaction product. The S-Test using specific chromolytic substrates (Institute of Chemistry® Bratislava, Slovakia) was used for the amylase and laminarinase assays. The spectrum of digestive enzymes was similar in all studied species. The amylase, isoamylase, maltase, saccharase and laminarinase activities were always detected. The activity splitting cellobiose was detected in L. destructor only. The activities splitting cellulose, lichenan and trehalose were not detected in neither species using the saccharogenic method. The proportions of laminarinase in all observed species and cellobiase in L. destructor were low in comparison to other carbohydrases. Amylase, isoamylase and maltase activities strongly prevailed on saccharase in A. siro and T. putrescentiae. The proportion of saccharolytic activity was higher than maltase and isoamylase on L. destructor, but lower than amylase. The enzymatic equipment of the studied mites indicates that the digestion of storage polysaccharides is more intensive than digestion of the content of fungal cells and plant cell walls. A possible interpretation of the enzymatic equipment for understanding of feeding habits of the studied species is discussed. The work was supported by grant COST OCNA.50. Index terms: Astigmata, digestive enzymes, feeding habits

[0043] THE EFFECT OF STARVATION ON METABOLIC RATE AND MICROANATOMY OF GALUMNA ELIMATA (ACARI: ORIBATIDA)

<u>J. Hubert¹</u> & V. Šustr², ¹Research Inst. of Crop Production, Drnovská 507, Praha 6, 161 06, Czech Republic E-mail hubert@hb.vurv.cz, ²Inst. of Soil Biology, ASCR, Na sádkách 7, České Budějovice, 370 05, Czech Republic.

Starved oribatid mites Galumna elimata were reared in sterilised plastic vials containing moistened zeolite at 25 °C in 12:12 photoperiod. The control group was reared on bark covered by the green bark algae (Desmococcus viridis) under the same conditions. The physiological parameters such as mortality, weight, oxygen consumption and digestive enzyme activity (amylase, trehalase, and cellobiase) were recorded in both groups after 21 days. The microanatomical observation of the digestive tract was done after 21 and 42 days. The weight of starved individuals significantly decreased while the water content in the body tissues increased. The mortality of individuals was significantly higher in starved groups than in the controls. Oxygen consumption of starved mites was lower. The activity of amylasc showed significantly higher variability in feeding individuals than in starved ones. A similar trend was also observed in trehalase and cellobiase activities but the results were not significant. The starved individuals usually had no food in the gut. Mucoid droplets produced from the caeca and salivary glands filled the gut, but some guts were empty without mucoid substances. All parts of the gut (mesenteron, colon and rectum) of control individuals were filled with food boli. These boli contained algal cells. The granulation and thickness of mesenteral cells were reduced after 42 hours. The secretion activity of caecal cells was observed after 21 days of starvation, however the activity was reduced in comparison with control mites. The reproductive organs were also influenced by starvation. The vesiculae seminales were without spermatic cells in starved males. A possible interpretation of starvation under the outdoor conditions is discussed.

Index terms: Cryptostigmata, mites, respiration, amylase, gut

[0042] THE FOOD INTERACTIONS BETWEEN THREE ACAROID MITES (ACARI: ACARIDIDA) AND SOME MICROMYCETES

J. Hubert¹, E. Ždárková¹ & A. Kubátová²¹Research Inst. of Crop Production, Drnovská 507, Praha 6, 161 06, Czech Republic. E-mail hubert@hb.vurv.cz ²Department of Botany, Faculty of Science, Charles University, Benátská 2, Praha 2, 128 01, Czech Republic.

The 8 fungal species used for this study (Mycocladus corymbifer, Eurotium amstelodami, Aspergillus versicolor, A. montevidensis, A. niger, Cladosporium cladosporioides, Alternaria alternata, Penicillium aurantiogriseum) were isolated from stored poppy seed. The micromycetes were offered as food to 3 acaroid mites (Acarus siro, Lepidoglyphus destructor and Tyrophagus putrescentiae). After 3 days of feeding all fungal species were reisolated from both the body surface and the digestive tract of the mites. Some bacteria together with fungi were also isolated. The bacteria occurred on the surface of mites and inside their bodies but were not observed on plates, which were not infested with fungi. Mites consumed the fungal species differently. For instance all tested mites rejected A. niger. Also the voracity of mites differed. T. putrescentiae consumed fungi most intensively and the rate of growth of its population was highest. The microanatomy of the guts of acarid species showed different levels of digestion of the consumed fungi. The results were compared with the enzymatic equipment of the observed species and discussed. The work was supported by grant NAZV Czech Republic, No. EP 9138/99.

Index terms: Astigmata, fungi, feeding, microanatomy, gut.

[0044] THE PREDATORY MITE NEOSEIULUS CALIFORNICUS: ITS POTENTIAL AS A BIOCONTROL AGENT FOR THE FRUIT TREE RED SPIDER MITE PANONYCHUS ULMI

<u>R. L. Jolly</u>, Dept. of Entomology & Plant Pathology, Horticulture Research International, East Malling, Kent, ME19 6BJ, UK, E-mail rebecca.jolly@hri.ac.uk.

The predatory phytoseiid mite, Neoseiulus californicus, is not native to the UK. However, it has been released on several occasions in previous years and has been found on apple, strawberry, blackcurrant and hop where it appears to be overwintering. Previous releases were allowed based on a spurious synonomy with a native species. In fact, the literature on this group is confused. A study of the morphological features, including SEM examination of the chelicerae, has clarified species differences and resolved synonomies. The ability of N. californicus to undergo diapause was determined. It was found that two strains of N. californicus differed in diapause propensity, and it is possible that they may have originated from different parts of the world. Field studies have examined the overwintering potential of N. californicus in artificial refuges. Although less abundant than native species, it appeared to be overwintering as succesfully. There has been no previous study of N. californicus as a biocontrol agent of Panonychus ulmi. An investigation into the effect of prey type on developmental time of the immature stages showed that N. californicus developed as rapidly on P. ulmi as on the two-spotted spider mite Tetranychus urticae. Neoseiulus californicus developed more rapidly than the native predatory phytoseiid Typhlodromus pyri. Index terms: Neoseiulus californicus, Panonychus ulmi, biocontrol, diapause.

[0045] LIFE TABLES OF ACARUS SIRO (ACARI, ACARIDAE) ON SEVEN DIFFERENT DIETS

N. Kilic¹ & S. Toros², ¹ Dept. of Plant Protection, Agric. Faculty, Univ. of Trakya, 59030, Tekirdag, TURKEY, E-mail:tzfbitkikoruma@superonline.com ² Dept. of Plant Protection, Agric. Faculty, Univ. of Ankara, 06100, Ankara, TURKEY.

The grain mite Acarus siro is a common and serious pest of stored food products. In this study, life tables were constructed on selected 7 diets (wheat flour, corn flour, rice flour, wheat starch, corn starch, powdered milk and yeast) for investigating the effects of these materials on the rate of reproduction capacity and population growth of A. siro. The mite were produced separately for every diet in micro-cells at 25 ± 1°C and 75 ± 5 % R.H. The highest Ro and rm values calculated on the yeast diet were 97.59 female/female/life and 0.221 female/female/day. (Table 1). Mean generation time was also the shortest (20.73 days) in this diet. This indicated that the most suitable food among the test materials was yeast. The lowest values of Ro and rm were obtained on rice flour (1.23 female/female/life, 0.005 female/female/day). These data indicated that rice flour was not appropriate food for A. siro. The mite completed its development very slow on rice flour and reached to the adult stage after a mean generation time of 45.52 days. On wheat flour and powdered milk R_0 values were 26.03 and 33.94 female/female/life and r_m values were 0.124 and 0.125 female/female/day, respectively. The rm values of wheat flour and powdered milk were not significantly different from each other which means both of these foods are suitable for A. siro feeding. R. and r. values were obtained low on corn flour, wheat starch and corn starch and these foods were found unsuitable for A. siro because of prolonged generation time and decreased reproduction rate

Index terms: Acarus siro, diet, life table, intrinsic rate of increase

[0047] TETRANYCHUS EVANSI – A NEW CHALLENGE TO SMALL-HOLDER TOMATO GROWERS IN SOUTHERN AFRICA

M. Knapp¹ & S.W.S. Luchen², ¹Int. Centre of Insect Physiology and Ecology (ICIPE), P.O. Box 30772, Nairobi, Kenya, E-mail: mknapp@icipe.org; ²Nat. Irrigation Res. Station, Private Bag S-3, Mazabuka, Zambia.

Tomato growers in southern Africa (Zimbabwe, Mozambique, Namibia, Malawi, Zambia) have experienced increasing problems with red spider mites in the last years. In most countries the species involved were usually misidentified as Tetranychus cinnabarinus or T urticae. Recent identifications of material collected in the region show that T. evansi is causing the problems. T. evansi is specialized on Solanaceae: introduced to southern Africa. probably from South America and expending northwards. Only few natural enemies have been found so far (Phytoseiidae, Anthocoridae, Staphylinidae) and identifications are in progress. Results of surveys conducted in Kenya and Zambia clearly show the impact of different spider mite species on tomato production. In Kenya T. evansi is not yet present and we usually find T. urticae on tomato. Only 1% of the Kenyan farmers considered red spider mites as one of their two most important problems in tomato growing. In Zambia the corresponding figure was 27%. Asked more specifically about most important pest and disease problems, 16% of the Kenyans mentioned red spider mites; the corresponding figure for Zambia was 89%. The current control approach is purely use of chemicals, 42% of the Kenyan farmers and 97% of the Zambian farmers apply pesticides for red spider mite control. Many of these chemicals are highly toxic broad-spectrum insecticides and some of them have only limited activity against mites. In Zambia the most common control agent is monocrotophos (49% of farmers applying pesticides) followed by antitraz (39%), and cypermethrin (10%). In Kenya acaricides are more commonly used. Dicofol is used by 42% of the farmers who apply pesticides, followed by bifenthrin (18%) and cypermethrin (16%). Integrated pest management and classical biological control are discussed as alternative strategies to control T. evansi in southern Africa.

Index terms: Tetranychidae, tomatoes, IPM

[0046] A FAUNISTIC INVESTIGATION ON THE MITE SPECIES OF STORED PRODUCTS IN TEKIRDAG PROVINCE

N. Kilic¹ & S. Toros², ¹ Dept. of Plant Protection, Agric. Faculty, Univ. of Trakya, 59030, Tekirdag, TURKEY, E-mail:tzfbitkikoruma@superonline.com ² Dept. of Plant Protection, Agric. Faculty, Univ. of Ankara, 06100, Ankara, TURKEY

Mites which are pests of stored products damage and taint cereals and attacking the germ thus affecting the viability of grain. 27 different stored products (grain and grain products, rice and its products, sunflower seed, animal feed and its raw material, corn starch, sweepings etc.) were collected from storehouses in Tekirdag province. 536 samples out of 1140 were infested with mites and the average rate of infestation was obtained as 47.02 % in the province. Except corn starch all kind of stored products were found as infested with the mites. Results of survey showed that 13 harmfull mite species from five families belong Astigmata were determined. They included Acarus siro, Tyrophagus putrescentiae, T. similis, Aleuroglyphus ovatus, Rhizoglyphus callae, Suidasia nesbitti, S.medanensis, Glycyphagus domesticus Lepidoglyphus destructor, Blomia freemani, Gohieria fusca, Chortoglyphus arcuatus, Dermatophagoides farinae. Five species from one family belong Prostigmata and three species from two families belong Mesostigmata were regarded as beneficial mites, namely Cheyletus eruditus, C.malaccensis, C. trouessarti, Acaropsis sollers, Eucheyletia taurica, Blattisocius tarsalis, Proctolaelaps pygmaeus and Androlaelaps casalis casalis. S. medanensis, B. freemani and E.taurica were new records for Turkish fauna. Among harmful species A. siro, L. destructor and T. putrescentiae were found as the most common species and their infestation rates were estimated as 68.28 %, 53.17 % and 16.31 %, respectively. However T. similis and R. callae were determined as the most rear species (0.01 % and 0.06 %, respectively). C.eruditus and C.malaccensis were found to be as the most common beneficial species with 55.75 % and 42.26 % infestation rates, respectively whereas E.taurica was the most rare species with 0.01 % infestation rate.

Index terms: stored product mites, harmful species, beneficial species, infestation rate

[0048] INVESTIGATION OF THE MECHANISMS OF ANTI-COMPLEMENT ACTIVITY IN IXODES TICKS

C. H. Lawrie & P. A. Nuttall, NERC Institute of Virology and Environmental Microbiology, Mansfield Road, Oxford, OX1 3SR, U.K., E-mail: charles.lawrie@zoo.ox.ac.uk.

Ticks and tick-borne pathogens are a major drain upon worldwide agricultural resources as well as representing significant veterinary and medical problems. The ability of a tick to feed successfully on a host relies upon the ability of the tick to overcome the inflammatory and immune responses of that host. The complement system plays a central role in the orchestration of these host responses. Anti-complement activity has been described in the salivary glands and saliva of *Ixodes* ticks directed against the alternative pathway of complement. We have investigated the mechanisms of anti-complement activity in the salivary gland extract (SGE) of the European Lyme-disease vector *Ixodes ricinus*. We tested the effect of SGE upon various components of the complement activity in *Ixodes* ticks. Index terms: *Ixodes ricinus*.

Session 01 - ACAROLOGY

[0049] CHECKLIST OF MITES FROM MOSO BAMBOO IN FUJIAN, CHINA

J. Z. Lin¹, Z. Q. Zhang², Y.X. Zhang¹, Q.Y. Liu³ & J. Ji¹, ¹Institute of Plant Protection, Fujian Academy of Agricultural Sciences, Fuzhou, 350013 China; E-mail zyxlj@pub3.fz.fj.cn; ²Landcare Research, Private Bag 92170, Auckland, New Zealand; ³Laboratory of Forest Protection, Fujian Forestry Bureau, Fuzhou 350002, China.

This paper gives a report of 45 species of mites from the moso bamboo (*Phyllostachys pubescens*) in Fujian province, China. They belong to 23 genera in 9 families. Some of the Tetranychidae (e.g. *Aponychus copuzae* Rimando and *Schizotetranychus nanjingensis* Ma et Yuan) and Eriophyidae (e.g. *Aculus bambusae* Kuang), either alone or in mixed populations, cause serious injury to the moso bamboo in Fujian.

Index terms: Acari, pest, natural enemy, bamboo, Phyllostachys pubescens

[0051] MORPHOLOGICAL DIFFERENCES IN AQUATIC AND TERRESTRIAL SUBANTARCTIC ALGOPHAGUS SPECIES (ACARI: ASTIGMATA)

<u>D. J. Marshall¹</u>, B. M. OConnor² & P. J. A. Pugh³. ¹School of Life and Environmental Sciences, Univ. of Durban-Westville, Durban, South Africa; ²Museum of Zoology, Univ. of Michigan, Michigan, U.S.A.; ³British Antarctic Survey, Cambridge, U.K.

The Algophagus mite complex on the sub-Antarctic Prince Edward islands comprises at least five morphologically and ecologically distinct species. Three species (A. antarcticus antarcticus, A. a. laticollaris, and A. semicollaris) occur in inland or supralittoral pools, and two (Algophagus sp. 1 and sp. 2) in water films covering supralittoral beach boulders or in edaphic habitats. Principal morphological differences of the species are, sizes and proportions of the idiosoma and legs. Morphometric analyses of females suggest that the legs, claws and apodemes are functionally related to habitat, showing an aquatic/ terrestrial dichotomy. The aquatic species (A. antarcticus antarcticus, A. a. laticollaris, and A. semicollaris) have proportionally longer legs, spines, and claws, features which are probably important in maintaining an upright position in water and allowing easy passage through filamentous algae. On the hand, the stout legs, relatively close apodemes, and small thick claws of the terrestrial species (Algophagus sp. 1 and 2), seem important for crawling over solid surfaces and through dense soil media. Being comparatively close to the midline in the terrestrial species, apodemes I and II allow, via an increased leg muscle mass, more effective and direct leg muscle action. Additionally, the distal position, enlargement, and extension of setae e and pon leg II in the terrestrial species may contribute to the grip on solid surfaces.

[0050] INTERSPECIFIC PHYSIOLOGICAL DIFFERENTIATION IN MARINE AND TERRESTRIAL *HALOZETES* SPECIES (ACARI, ORIBATIDA)

<u>D. J. Marshall</u>¹, S. L. Chown², R. Mercer² & C. J. Klok², ¹Dept. of Zoology, Univ. of Durban-Westville, Durban, South Africa; ²Depart. of Zoology and Entomology, Univ. of Pretoria, Pretoria, South Africa.

Species of the mite Halozetes at sub-Antarctic Marion Island are either marine or terrestrial (two species of each). We were interested in knowing to what extent the physiology of the marine species differs from that of the terrestrial species, and by implication whether this has a role in habitat separation. Experiments were performed to determine particularly 1) tolerance of exposure to dry air, 2) tolerance of continuous submergence in freshwater and seawater, and 3) lower and upper lethal temperature limits of the mite species H. marinus devilliersi (marine), H. marionensis (marine), H. belgicae (mainly supralittoral but referred to here as terrestrial) and H. fulvus (terrestrial). Some comparative physiological features, such as rate and tolerance of water loss, and tolerance of submergence in freshwater and seawater, suggest a physiological basis for the exclusive marine existence of the marine species, but do not explain the exclusive terrestrial existence of the terrestrial species (particularly that of H. fulvus). For example, the terrestrial species controlled water loss better and survived for longer in dry air than the marine species, but there was no significant difference among the species in their levels of tolerance of freshwater or seawater submergence. Although lethal temperature limits differed between the marine and terrestrial species, generally being lower at the low temperature limits (c. -15 DC) and higher at the upper temperature limits (c. 43 C) in the terrestrial species, temperature limits of all the species showed no correspondence with present-day habitat temperature extremes (for example the seawater temperatures vary between 2 and 8 C). Those aspects of physiology which were similar among the species, or clearly not related to habitat (submergence tolerance, supercooling points, lethal temperature limits), indicate a broad based generic tolerance physiology, which may be important for the persistence of Ilalozetes in adverse and changeable (at least within a geological timeframe) antarctic environments, by offsetting the seemingly limited capacity within the genus for specific adaptation and speciation. Index terms: mites, sub-Antarctic, physiology

0052] THE UNIQUE INSECT BIODIVERSITY OF THE KLAMATH/SISKIYOU MOUNTAIN REGION IN NW USA; CHALLENGES FOR INVENTORY AND CONSERVATION

<u>A. R. Moldenke¹</u>, B. G. Marcot², D. DellaSala³ & N. Rappaport⁴, ¹Dept of Entomology, 2046 Cordley Hall, Oregon State University, Corvallis, OR 97331-2907; ²US Forest Service, 1221 SW Yamhill St., PO Box 3890, Portland, OR 97208-3894; ³World Wildlife Fund, 116 Lithia Way – Suite 7, Ashland, OR 97520; ⁴Forest & Range Experiment Laboratory, USDA Forest Service, Albany, CA. E mail: moldenka@bcc.orst.edu

This region has long been recognized as of extreme significance botanically. Escape from glaciation, diversity of geologic substrates combined with varied relief, and location at the interface of mesic vs. xeric biomes should have rendered this region as unique entomologically as botanically. Though scattered literature supports this hypothesis, a careful documentation of the endemic levels of arthropod biodiversity needs to be undertaken. The World Wildlife Fund, the Forest Service (land owners) and entomologists from Oregon State University are collaborating in a unique attempt to define and protect the ecological processes arthropods participate in, preserve biodiversity hot-spots and premiere taxa, while permitting economic utilization of the forest resources as a sustainable long-term resource. The three most critical management concerns center on ancient-forest stands, riparian habitats and the adequacy of buffers, and unique habitats. Relict ancient taxa representative of the transcontinental forests before mountain orogeny split the continent in two characterize this region (i.e., Tricholepidion gertschi (Thysanura) endemic to CA; Cryptocercus punctulatus (communal Blattaria) amphi-continental distribution). Beta diversity is driven by habitat heterogeneity and recent adaptive radiation (i.e., Amaurobiidae (Araneae)). Additionally, taxa with limited mobility have spawned localized geographic isolates as they recolonized the Pacific Northwest since glaciation (i.e., Pleocominae (Scarabaeidae), Caseyidae (Diplopoda)). Though the vast majority of taxa inhabiting the region is widely distributed geographically, endemicity is likely to be relatively high. With adequate inventory a system of protection can be implemented before this ecosystem is more heavily impaired. Index terms: palacoendemic, adaptive radiation

[0053] PARASITIC AND MUTUALISTIC RELATIONSHIPS BETWEEN ASTIGMATID MITES AND BEES OR WASPS IN JAPAN

K. Okabe¹ & S. Makino², ¹ Kyushu Res. Cent., Forestry & Forest Prod. Res, Inst., 4-11-16 Kurokami, Kumamoto 860-0862, Japan, e-mail kimikook@ffpri-Kys.Affrc.GO.JP; ² Forestry & Forest Prod. Res. Inst. Matsunosato 1 Kukisaki, Ibaraki 305-8687, Japan, e-mail makino@ffpri.affrc.go.jp.

There are some species of mites associate with bees or wasps in Japan. The common relationship is phoresy in which mites depend on hosts for transfer. However, the nature of the relationship between the mites and the hosts is not always clear. We surveyed some astigmatid mites for their association with hosts. Sennertia sp. was only found on adults of the common carpenter bee Xylocopa apendiculata. It is morphologically specialized to attached to the host for phoresy though detailed observations were not made. Kuzinia spp. were commonly found attaching to bumblebees (Bombus spp.) in the field. They sometimes become pests in artificially reared nests. The mites are suspected cleptoparasitc because they probably feed not on the host but on pollen stored by the host. A winterschmidtiid mite was specifically attached to the eumenid wasp Anterhynchium flavomarginatum, which nests in tube-like structures. The immature mite seemed to feed on various fungi and debris in larval host cells whereas the adult female was suspected to suck hemolymph of the larva or pupa. Therefore, we hypothesize that the relationship between the juvenile mite and the host is mutualism or commensalism while the female mite is purely parasitic. Observations on collected nests in different seasons revealed the followings. The number of adult mite females per host cell was one or very rarely two. A large number of deutonymphs aggregated on a prepupal host and overwinter. Once the host pupated, the deutonymphs became active, then quickly moved from pupal skin to the adult body during host eclosion. Seventy percent of wasps associated with the mite were males in Kyushu in 1999. Because the mite can produce progeny only in a nest of the host, those mites finding themselves on the male may transfer to the female, which is the only sex to nest, during mating. The mite should also be adapted to release itself from the female body while the host is engaging in nesting activities.

[0055] OVICIDE ACTION OF BAJ 2740 (SPIRODICLOFEN) AND PEROPAL (AZOCYCLOTIN) 250 WP AND 500 FW ON CITRUS LEPROSIS MITE BREVIPALPUS PHOENICIS

C.A.L. Oliveira¹ & M.L. Oliveira¹, ¹Depart. de Fitossanidade, FCAV/UNESP, Jaboticabal, 14870-000, Brazil, E-mail: amadeu@fcav.unesp.br

The efficiency of the spirodiclofen, azocyclotin and cyhexatin on eggs of Citrus Leprosis Mite was evaluated in a bioassay conducted in the Acarology Laboratory at the FCAV/UNESP, Jaboticabal, SP. The experiment was carried on a controlled-environment room, at 25 C°, 55-60% RH and photophase of 14 hours. Fruits of citrus cv Pêra-Rio were used, presenting 6 cm of diameter on the average, defined by a tanglefoot barrier. From a population of B. phoenicis, 20 females were transferred to each fruit, maintained at a period of 4 days for oviposition. After that period the females were eliminated, and only eggs were left on the fruits, approximately 100 for treatment. The bioassay was in a randomized block design, with 6 treatments in 7 blocks. Each fruit was constituted as an experimental plot. The spary volumes were expressed in g or ml of the product formulated by 100 L of water: BAJ 2740 240 FW at 10 and 15 ml, Peropal 250 WP at 100g and 500 FW at 50 ml; Hokko cyhexatin 500 WP at 50 g and a check. Spraying on the fruits was applied by a tower of Potter, at 2nd per fruit. The percentage of ovicide efficiency of each product was evaluated after 7 and 11 days of the application, based on the percentage of the egg hatching on the check less the percentage of the egg hatching on the treated fruits, divided by the percentage of the egg hatching on the check, times 100. The products evaluated were highly efficient as ovicides in the control of B. phoenicis, presenting the following percentage of efficiency: BAJ 2740 240 FW at 10 and 15 ml, 100% at 7 and 11 days after spray application; Peropal 250 WP and 500 FW, 96.4 and 100% at 7 days and 96.7 and 100% at 11 days; and Hokko cyhexatin 500 WP, 89.7c 90.7 at 7 and 11 days after spray application.

Index terms: Citrus sinensis, chemical control, mitecide, Tenuipalpidae,

[0054] EFFICIENCY OF BAJ 2740 (SPIRODICLOFEN) 240 FW AND PEROPAL (AZOCYCLOTIN) 250 WP AND 500 FW IN THE CONTROL OF CITRUS LEPROSIS MITE IN CITRUS ORCHARD

C.A.L. Oliveira¹ & M. L. Oliveira¹, ¹Dept. de Fitossanidade, FCAV/UNESP, Jaboticabal, 14870-000, Brazil, E-mail: amadeu@fcav.unesp.br

The Brevipalpus phoenicis mite, vector of the virus of the citrus leprosis (CitLV) is one of the major pest in the system phytosanity management in citrus orchards. Aiming to evaluate the mitecides action of BAJ 2740 240 FW and Peropal 250 WP and 500 FW, two field trials were conducted, in 1998 and 1999, respectively located at Olímpia (trial 1) and Bebedouro (trial 2), State of São Paulo, important citrus regions in Brazil. Both experiments were installed in orange orchards cv Pêra-Rio, with 8 and 12 years old. A randomized block design with 4 replications was adopted. Each experimental plot consisted of three citrus tree, considering as useful tree the central one. In trail 1, there has been installed the following treatments, whose spray volumes are expressed in g or ml of the product formulated by 100 L of water: BAJ 2740 240 FW at 20 and 40 ml; Peropal 250 WP at 100 g and a check. In trial 2, there has been tested: BAJ 2740 240 FW at 10, 15 and 20 ml and Peropal 250 WP at 100 g and 500 FW at 50 ml and a check. Spraying was performed in June, 16, 1998 and August, 10, 1999, respectively, to trials 1 and 2, using a spray gun with D6 nozzle, pressure of 300 p.s.i., applying 10 L of spray solution per tree. Population assessment was counted before and after the spray solution applications, 10 fruits from each tree were sampled. The mites were removed from the fruits by means of a mite-brushing machine and counted under a stereoscopic microscope. The results of trial 1 evidenced that, BAJ 2740 240 FW at 20 and 40 ml presented high control efficiency on B. phoenicis, with 100% of reduction of mite population 128 days after spraying, and Peropal 250 WP at 100 g presented efficiency of 98.5%. In trial 2, it was verified, after 72 days of spraying, reductions of 100% for BAJ 2740 at all the dosage rate tested and at 91 days reductions of 99.5, 100 and 100% at dosage rate of 10, 15 and 20 ml, while for Peropal 250 WP and 500 FW were verified reductions of 88.7 and 73.6% at 72 days and 30.3 and 14.6% at 91 days, respectively.

Index terms: Brevipalpus phoenicis, Citrus sinensis, chemical control, mitecide.

[0056] CONTROL OF PHYLLOCOPTRUTA OLEIVORA IN CITRUS WITH SPIRODICLOFEN AND AZOCYCLO'IIN

C.A.L. Oliveira¹ & M.L. Oliveira¹, ¹Depart. de Fitossanidade, FCAV/UNESP, Jaboticabal, 14870-000, Brazil, E-mail: amadeu@fcav.unesp.br

The citrus rust mite is considered one of the major pest in citrus orchard in Brazil, due to the damages that it caused on fruit. Besides the qualitative damages, the mites cause quantitative yield reductions, and their control have been through the use of mitecides, that should be efficient and selective to assist to the necessary requirements for an appropriate management. The present work evaluated the mitecide action of spirodiclofen (BAJ 2740 240 FW) and azocyclotin (Peropal 250 WP and 500 FW) in the control of P. oleivora in citrus orchards. The experiment was carried out in a citrus orchard cv Pêra-Rio, 17 years of age, planted in the spacing of 7 x 6 meters, located in Bebedouro, State of São Paulo. A randomized block statistical design was adopted, with 6 treatments and 4 replications. Each experimental plot consisted of three citrus trees, having been considered as useful, the central one. The spraying volumes were expressed in g or ml of the product formulated by 100L of water: BAJ 2740 240 FW at 10, 15 and 20 ml; Peropal 250 WP at 100g and 500 FW at 50 ml and a check. Spraying was performed in November, 11, 1998 in morning period, at 31.9°C, 61.5% RH and wind speed of 6.4 km/h, using a spray gun with D6 nozzle, pressure of 300 p.s.i., using 2000 L of spray solution/ha. The pH of the water determined by occasion of the application was of 5,8. Population assessment was counted before and after the spraying, it has been collected 15 leaves, which were conditioned in paper sacks and immediately transported to the Acarology Laboratory at the FCAV/UNESP, Jaboticabal, SP, for evaluation. The samples of each plot were submitted to a mite-brushing machine and the mites were counted under a stereoscopic microscope. The results evidenced that BAJ 2740 240 FW at 10, 15 and 20 ml were highly efficient in the control of citrus rust mite *P. oleivora*, presenting reductions of 97.6, 100 and 99.3%, respectively after 40 days of spraying. Peropal 250 WP and 500 FW were inferior to BAJ 2740, presenting reductions of 71.7 and 66.9%. Peropal formulation FW was superior to WP in the control of the P. oleivora.

Index terms: Eriophyidae, chemical control, Citrus sinensis, citrus rust mite.

[0057] MITECIDE ACTION OF SPIRODICLOFEN AND AZOCYCLOTIN ON POLYPHAGOTARSONEMUS LATUS ON CITRUS

C.A.L. Oliveira¹ & M.L. Oliveira¹, ¹Depart. de Fitossanidade, FCAV/UNESP, Jaboticabal, 14870-000, Brazil, E-mail: amadeu@fcav.unesp.br

The broad mite P. latus, is an important pest of many plants cultivated that are attacked specially in their new parts and fruits. Its occurrence on citrus in Brazil, has been more intense on Tahiti lemon, due to its several flowerings during the year, however, it has also been infesting sweet orange orchards. Its damage is more evident on fruits, is characterized by a decoloration or opaqueness, manifested later as silvering of the surface. The aim of this work was to evaluate the mitecide efficiency of spirodiclofen and azocyclotin to control mites in a citrus orchard ev Pêra-Rio, 17 years of age, planted in spacing of 7x6 meters, located at Bebedouro, State of São Paulo. The adopted statistical design was a randomized block with 6 treatments and 4 blocks. Each experimental plot consisted of 3 citrus trees, considering as useful plant, the central one. The treatments, whose spray volumes were expressed in g or ml of the product formulated by 100L of water were: BAJ 2740 240 FW at 10, 15 and 20 ml; Peropal 250 WP at 100 g and 500 FW at 50 ml and a check. Spraying was performed in November of 1998, in the morning period, 32°C, 62% RH and air speed of 6 km/h, using a spray gun with D6 nozzle, pressure of 300 p.s.i., using 10 L of spray solution/plant. The pH of the water used in spraying was 5,8. Population assessment was counted in the field trials, before and after spraying, with a magnifying glass in 10 new fruits, random chosen around the top of the plants. The results showed that BAJ 2740 240 FW at 10, 15 and 20 ml and Peropal 250 WP and 500 FW at 100g and 50ml, respectively, were highly efficient to control P. latus on citrus, presenting 100% of reduction of the mite population at 20 days after spraying, occasion in that was closed the population assessment due to the accentuated decrease in the check treatment.

Index terms: Tarsonemidae, chemical control, Citrus sinensis.

[0059] OCCURRENCE OF LATENT MITE PEST AFTER BIOLOGICAL CONTROL OF DOMINANT SPIDER MITE BY INTRODUCED NATURAL ENEMY AND EFFICIENCY OF INDIGENOUS PHYTOSEILD MITE

<u>Mh. Osakabe,</u> Dept. of Plant Protection, National Agriculture Research Center, 3-1-1 Kannondai, Tsukuba, Ibaraki 305-8666, Japan, E-mail mhosaka@narc.affrc.go.jp.

To control Tetranychus urticae, Phytoseiulus persimilis was released on commercially cultivated strawberries in a plastic greenhouse in western Japan in 1999. This resulted in good control of the mite pest. However, leaves of the strawberry were infested with Eotetranychus asiaticus after harvesting of the fruit (Teramoto, personal conununication) although strawberry had not been known as a host plant of this mite. E. asiaticus did not occur, however, on strawberries in another plastic greenhouse cultivated by the same farmer where P. persimilis was not released. It appeared that the use of P. persimilis as an agent of the biological control of T. urticae actually caused the occurrence of E. asiaticus. The efficiency of P. persimilis to control E. asiaticus was studied in laboratory experiments. Five adult females of E. asiaticus were placed on a detached strawberry leaf (3 cm sq.) and those of T. urticae were done on another detached leaf. After six days, these leaves were linked together by a small piece of filter paper soaked with water, and three adult P. persimilis females were then introduced to each leaf. T. urticae was quickly consumed and eliminated by the predator, which also preyed on E. asiaticus. However, several eggs or individuals of E. asiaticus survived the predation. As P. persimilis reproduced very few eggs and its offspring rarely grew to adults when they fed only on E. asiaticus, the predator was extinct after T. urticae was eradicated. Consequently, the E. asiaticus population again increased on the leaf. It was therefore assumed that the occurrence of E, asiaticus in the above greenhouse resulted from the feeding habits of P. persimilis. In the next experiment, the efficiency of two indigenous phytoseiid mites. Amblyseius californicus and A. womersley were tested using the same procedure. A. californicus exterminated E. asiaticus 24 days after its release, but reproduced very few eggs. The observed control effect was assumed to be due to immigration and attack by this predator that fed on T. urticae and increased. A. womersley, in contrast, preved on and exterminated E. asiaticus as it did on T. urticae. Moreover, this predator reproduced well on the leaves infested by both species of spider mites. Consequently, A. womersley is assumed to be the most efficient natural enemy of E. asiaticus.

Index terms: Eotetranychus asiaticus, Phytoseiulus persimilis, Amblyseius californicus, Amblyseius womersleyi, strawberry

[0058] ACTION OF THIAMETHOXAN ON THE POPULATION DYNAMICS OF THE BROAD MITE *POLYPHAGOTARSONEMUS LATUS* ON COTTON AND ITS SELECTIVITY TO PREDATOR MITE *EUSEIUS CONCORDIS*

C.A.L. Oliveira¹, R.L.B. Fontes¹, A.L. Matioli¹ & M.L. Oliveira¹, ¹Dept. de Fitossanidade, FCAV/UNESP, Jaboticabal, 14870-000, Brazil, E-mail: amadeu@fcav.unesp.br

The broad mite is an important pest of several crops in Brazil, responsible for significant quantitative and qualitative reductions of cotton yield. It has been evaluated, in field conditions, the action of thiamethoxan, that is not a mitecide, on the populacional assessment of broad mite, once, some chemical products applied on the crop causes an increase in mite population. It also has been evaluated, in laboratory, the selectivity of thiamethoxan to E. concordis, because it has been considered the more frequent predaceous mite on cotton crop. The field trail was conducted in a cotton crop or IAC-22, in a experimental area at the FCAV/UNESP, Jaboticabal, SP, Brazil, in 1998. The statistical analyses was performed in a randomized block design with 4 treatments in 6 blocks: thiamethoxan (Cruiser 3 g p.c. /1.0 kg seed); thiamethoxan (Actara WG 25 to 200 g p.c. /ha) and deltametrina (Decis 25 EC at 400 ml p.c./ha) both applied in spraying and a check. Each plot consisted of 6 lines of 15m. After spraying, populacional assessment of broad mite was carried out, and it was sampled two leaves of the top of 10 plants in the central lines of each plot, and the damages caused to the leaves were evaluated through a visual scale of notes that varies from 0 to 3. In laboratory, it was carried on a bioassay to evaluate the selectivity of thiamethoxan (Actara WG 25) to E. concordis for 1, 1/2, 1/4 and 1/16 and 0 of the recommended rate (200g p.c. /ha), 10 times replicated. Spraying was performed using a tower of Potter, applying 2 ml of the spray solution for each Petri dish containing 5 disks of cotton leaves, with 2,5 cm of diameter, on a cotton layer soaked in distilled water. After dryer the disks, it has been realized the transfer of two mites to each leave disk. The mites were fed during the bioassay with pollen of Typha sp. The thiamethoxan in the seed treatment (Cruiser) and sprayed (Actara) and, deltametrina (Decis) didn't cause populacional increases of P. latus on cotton crop. The thiomethoxan presents selective action to the predator mite E. concordis, causing reductions of 15.4, 23.1, 15.4 and 0% considering 24 hours after transferring the mites. Index terms: Tarsonemidae, phytoseiid, Gossypium hirsutum, ressurgence.

[0060] FIELD EVALUATION OF SPIDER MITES (ACARI: TETRANYCHIDAE)

The spider mites Tetranychus spp. are maize pests in some areas of Europe and have the potential to develop high populations that may result in significant yield reductions. Feeding damage is therefore cumulative; mite feeding reduces chlorophyll content of leaves and may interfere with vascular tissue. In 1998, a field survey was conducted, at Baixo Alentejo (Portugal), in order to evaluate abundance and spatial distribution of mites in 3 maize fields. These maize fields were sampled on a weekly basis, from tassel to grain-filling growth stages, when maize is the best host for mites and their densities can increase rapidly. Each field sampling consisted of 3 groups of fifty leaves randomly selected and removed from each third of the plants (lower, middle and upper thirds); the samples, identified with the field, date and the third of plant sampled, were carefully observed at laboratory under a dissecting microscope; the number of mites (females and males) per leaf and the number of infested leaves were recorded. The average rate of plant damage was also determined, for each field under study, and for each plant third, using a 1-10 rating scale: 1= 1-10 % of the leaf area damaged by mite feeding to 10= 91-100 % of the leaf area damaged. Maize growth stage was recorded each week. The abundance and the within-plant distribution of these spider mites were described and the average plant damage rating was determined for each field. Index terms: Tetranychus spp., spider mites, population intensity, damage, maize.

[0061] DAMAGE AND POPULATION DISTRIBUTION OF BREVIPALPUS PHOENICIS ON GUAVA FRUIT, PSIDIUM GUAJAVA

<u>M. J. Quirós-González</u>¹ & N. C. Poleo¹, ¹University of Zulia, Agronomy Faculty, Museum of Arthropods, MALUZ, Núcleo Agropecuario, Maracaibo, Zulia State, Venezuela. E-mail: mquiroz@luz.ve.

Brevipalpus phoenicis is an important pest of guava in Zulia State. Venezuela, This study was conducted to determine the qualitative damage and distribution of B. phoenicis on guava fruit. From February to December 1998, 5 to 10 fruits/15 plants were harvested every 14 days for mite counting and damage observation. The damage and populations start very early with the fruit formation, about 10 days old. Mite Populations fluctuate on the fruit during 140 days of total fruit development. Two separate populations were observed, one at the apical end of the fruit, between the sepals (or remaining flower parts) and at the base of the sepals; while the other population establishes at the base of the fruit. Degree of damage were distinguished using a qualitative scale on each part, it was observed that the highest degree of damage (Grade 3=Severe) is reached first at the apical end of the fruit than at the base of the fruit. The mean number of mites are significantly different between the apical y basal ends. The population of mites at the apical end is always higher, up to 3 times, compared with that of the base of the fruit. B. phoenicis strategically prefers the apical end where the females find refuge at the innerside of the sepals (oldest fruit tissue) to lay the eggs, once the sepals food is depleted they and the future larvae and nymphs move to the concavities and tissues that surround the base of the sepals which is a meristematic kind of tissue. The mite populations that establish at the base become from females that walk from the nearest leaves and twigs and remain there for feeding. Exact location and initial timing for damage of the pest ensure the management success

Index terms: Tetranychoidea, Tenuipalpidae, False Spider Mites, Flat Mites

[0062] LABORATORY STUDIES ON THE LIFE HISTORY, POST-EMBRYONIC SURVIVAL AND OVIPOSITION OF THE PREDACEOUS MITE *CYDNODROMUS* SP. [ACARINA: PHYTOSEIIDAE] ON DIFFERENT KINDS OF FOOD SUBSTANCES

<u>S. Ragusa¹</u>, R. Vargas² & R. Asbach², ¹Istituto di Entomologia Agraria, Viale delle Scienze, 90128 Palermo, Italia. email: ragusa@unipa.it; ²INIA, Centro Experimental de Entomología La Cruz, Casilla 3 La Cruz, Chile. email: rvargas@lacruz.inja.cl

The effect of different kind of foods (pollen and prey) on development of *Cydnodromus* sp was determined in laboratory conditions. Biological parameters of *Cydnodromus* sp varied when different kind of foods were provided. From 50 to 62% of the individuals reached adulthood on *Oxalis* sp. and *Agrostis* sp. Postembryonic development was not successful on *Acacia* sp., *Carpobrotus* sp., *Citrus limon, Convolvulus* sp., *Cynodon* sp., *Pluchea* sp. and *Ricinus* sp. When *Cydnodromus* sp. fed on *T. urticae* and *P. citri* 100% of the inmature stages reached adulthood. The oviposition and longevity were observed on *Oxalis* sp., *Agrostis* sp., T. urticae and *P. citri*. It is discussed the potential use of these results in Integrated Mite Management programes.

Index terms: Phytoseids, Pollens, T. urticae, P. citri.

[0063] HOST RESISTANCE TO INSECTS AND MITES IN ZOYSIA SPP. FOR URBAN LANDSCAPES

J. A. Reinert & M. C. Engelke, Texas A&M Univ. Res. & Ext. Ctr., 17360 Coit Road, Dallas, TX 75252-6599, USA, E-mail j-reinert@tamu.edu.

Various species of Zoysiagrass (Zoysia matrella and Z. japonica) originating in the Orient are in use as durable turfgrass around the world for landscapes. Genetic plant resistance to pests including insects, mites and diseases is an effective, economical and environmentally sound control strategy and should be a major component of every turfgrass management program when resistant cultivars are available. In our program at Texas A&M University, Dallas, TX. USA, many cultivars and genotypes of Zoysia have been evaluated for pest resistance (insects, mites and diseases) and for low cultural input landscape grass. Resistance has been identified to fall armyworm (Spodoptera frugiperda) in the genotypes 'Cavalier' and DALZ8501. Resistance to tropical sod webworm (Herpetogramma phaeopteralis) was identified in Cavalier, DALZ8501, 'El Toro' and 'Korean Common'. Cavalier also expressed high resistance to the differential grasshopper (Melanoplus differentialis) which migrates into landscapes during drought years, and Cavalier and 'Diamond' provided resistance to tawny mole crickets (Scapteriscus vicinus). Additionally, DALZ9006, DALZ8516 DALZ8508 and 'Emerald' exhibited a high level of resistance to the host specific zoysiagrass mite (Eriophycs zoysiae). Several Zoysia genotypes have been identified with multiple pest resistance. Four new Zoysia cultivars (Diamond, Cavalier, Crowne, Palisades) with insect or mite resistance and other stress resistances have been released to the Turf Industry. In particular, Cavalier exhibits resistance to all four of the chewing insects evaluated.

Index terms: Spodoptera frugiperda, Herpetogramma phueopteralis, Eriophycs zoysiac, Scapteriscus vicinus, Melanoplus differentialis

[0064] POPULATION DYNAMICS OF *BREVIPALPUS PHOENICIS* ON DIFFERENT CITRUS VARIETIES IN BRAZIL: I - INFLUENCE OF CITRUS LEAF MINER INJURIES

J. C. V. Rodrigues¹ & O. Bonato², ¹ Centro de Energia Nuclear na Agricultura, Univ. de São Paulo, C. Postal 96, 13400-970 Piracicaba, SP, Brazil. E-mail: jevrodri@pira.cena.usp.br. / Centro de Citricultura –Inst. Agron. de Campinas; ² IRD (ex ORSTOM), EMBRAPA Meio Ambiente, C.P. 69, 13820-000 Jaguariúna, SP, Brazil.

Brevipalpus phoenicis (Acari: Tenuipalpidae), the vector of 'Citrus Leprosis Virus', is considered as a key-pest and periodic inspections are recommended for its control. The citrus leaf miner (CLM), Phyllocnistis citrella (Lepidoptera: Gracillariidae), was reported in São Paulo State region (Brazil) in March 1996. During its developmental process, this microlepidoptera mines the adaxial and abaxial surfaces of newly formed leaves. Because of their altered morphology, leaves can become a refuge and reproduction places for small insects and mites. The objective of this work was to compare the percentage of infestation of B. phoenicis between non-infested leaves and leaves infested by CLM in the region of São Paulo (Brazil). Then, 9 sweet-oranges varieties were examined: 'Valência' (1), 'Pêra-Rio' (2), 'Lima' (3), 'Bahia' (4), 'Seleta' (5), 'Barão' (6), 'Natal' (7), 'Lima verde' (8) and 'Hamilin' (9), and one of 'Persia Lime' (10), all grafted on *Citrus limonia*. The experimental design was, for each variety, randomised blocks of 12 plants of two years old. Six plants were infested with 30-40 infected adult females of B. phoenicis/plant. The six non-infested ones were kept as control and received periodic pesticide treatments. Mite populations were monitored monthly from August 1997 to August 1998. At each sampling procedure, 4 leaves without and 4 leaves with CLM injuries were collected at random inside of each infested plant and 8 mature leaves were collected for each plant belonging to control. In the laboratory, the presence of B. phoenicis (eggs, immatures and adults) were observed under binocular. For all varieties at all sampling dates no mites were found on control. Statistical analyses revealed significant differences between CLM infested plants and non infested ones The observed percentage of leaves with B. phoenicis was significantly greater on CLM infested plants of all varieties except for 'Pêra-Rio' (2) and 'Persia Lime' (10) (P <0,05, Sinal tests). The number of mites recorded was significantly higher on CLM infested leaves than on non infested ones, for all varieties except 'Seleta' (5) (P <0,05, Sinal tests). These results indicated that the introduction of a new element inside a complex system like citrus orchard can lead important implications from a pest management point of view. In our case the new element, i.e., CLM, can indirectly enhance mite infestations and thus shift the system equilibrium and finally increase disease damages.

Index terms: Leprosis mite, Phyllocnistis citrella, 'Citrus Leprosis Virus', pests interactions

[0065] POPULATION DYNAMICS OF *BREVIPALPUS PHOENICIS* ON DIFFERENT CITRUS VARIETIES IN BRAZIL: II - INFLUENCE OF CITRUS VARIETY

J. C. V. Rodrigues^{1*}, O. Bonato² & N. L. Nogueira¹, ¹ Centro de Energia Nuclear na Agricultura, Univ. de São Paulo, C. Postal 96, 13400-970 Piracicaba, SP, Brazil. E-mail: jevrodri@pira.cena.usp.br. / * Centro de Citricultura –Inst. Agron. de Campinas; ² IRD (ex ORSTOM), EMBRAPA Meio Ambiente, C.P. 69, 13820-000 Jaguariúna, SP, Brazil.

In 1997, was estimated US\$ 75 million to mitecides acquisition by Brazilian citrus farmers for the control of leprosis mite, Brevipalpus phoenicis. This mite is vector of 'Citrus Leprosis Virus' and is a polyphagous and cosmopolite specie. Many physical and environmental factors interact to influence the likelihood of a mite and plant disease outbreak. Among these factors that contribute to mite dynamics the nutrition afforded by the host plant and its relative susceptibility or resistance to the mites. The objective of this work was to compare the infestation of B. phoenicis on differents citrus varieties in the Piracicaba region of São Paulo (Brazil). Then, 9 sweet-oranges varieties were examined: 'Valência' (1), 'Pêra-Rio' (2), 'Lima' (3), 'Bahia' (4), 'Seleta' (5), 'Barão' (6), 'Natal' (7), 'Lima verde' (8) and 'Hamlin' (9), and one of 'Pérsia Lime' (10), all grafted on Citrus limonia. The experimental design was, for each variety, randomized blocks of 12 plants of two years old. Six plants were infested (June 1996) with 30-40 infected adult females of B. phoenicis/plant. The six noninfested ones were kept as control and received periodic pesticide treatments. Mite populations were monitored monthly from August 1997 to August 1998. At each sampling procedure, 4 leaves without and 4 leaves with CLM injuries were collected at random inside of each infested plant and 8 mature leaves were collected for each plant belonging to control. In the laboratory, the presence of B. phoenicis (eggs, inunatures and adults) were observed under binocular. For all varieties at all sampling dates no mites were found on control. Statistical analyses by Kruskal-Wallis Tests in dates from infested plants revealed significant differences among varieties: (A) The mite number/infested leaf was great on (3, 9,8)>(4,1,6)>10>2>5>7 varieties, (B) the mite number/infested plant was great on (3, 9,8)>(4,1)>6>10>(2,5,7) varieties, and (C) the observed percentage of infested plants was 3>(9,8,4,1,6)>(10,2,5,7) (P≤0.001). On the other hand, the observed percentage of infested leaves/infested plants was not significantly different (P≤0.07) among varieties. The (3) variety showed the maximum value on (A), (B) and (C), however this variety has not showed the maximum leprosis disease index, what can be indicating distinct resistance mechanism on citrus varieties to mite and leprosis virus. The variety factor should be consider in citrus IPM programs that have leprosis mite as a key-pest.

Index terms: Leprosis mite, sweet orange, 'Citrus Leprosis Virus'

[0066] INVESTIGATIONS OF THE SOIL DWELLING PREDATORY GAMASINA MITES (ACARI, MESOSTIGMATA) IN LATVIA

I. Salmane, Inst. of Biol., LU, LV-2169, Salaspils, Latvia, e-mail: incis@email.lubi.edu.lv

Material collected from the diverse habitats in the territory of Latvia (Eastern Europe) was investigated. The highest species diversity was found in the salty coastal meadows. Driftline (washed ashore material), xerophytic and hygro-mesophytic habitats were investigated here and 85 Gamasina species recorded. All the selected habitats showed high diversity of Gamasina mites, altogether giving about 1/3 of Gamasina species known in Latvia. Among the coastal meadow habitats as the richest in species were stated hygro-mesophytic habitats with 62 Gamasina species. In the xerophytic and driftline habitats 46 and 40 species, respectively, were found. As the most frequent species in coastal meadows were stated Holoparasitus excipuliger, Pergamasus vagabundus, Hypoaspis praesternalis, Hypoaspis aculeifer and Cheiroseius borealis. Sixteen species here were recorded for the first time in fauna of Latvia. Comparison with inland meadow fauna was made. About 1/3 of the species were found in both coastal and inland meadows, but they differed by the structure of dominance. Along the sea coast of Latvia 113 Gamasina species were recorded. As the most diverse were found driftline habitats with 60 Gamasina species. Thirty-five species were collected from the primary and yellow dunes. Primary dune habitats were stated as the poorest with only 22 Gamasina species. Thinoseius spinosus, Halolaelaps balticus, Halolaelaps incisus, Parasitus halophilus and Veigaia nemorensis were found as the most numerous in the seashore habitats. Thirty-four species from the seashore habitats were stated for the first time in fauna of Latvia. Sampling was made in the pine forest stands of different age and altogether 40 Gamasina species were recorded. The oldest pine forest stand (150-200 years old) was the richest in Gamasina species. Thirty species were registered here, as well as the number of specimens here was the highest. The middle-age stand (60-80 years) and the youngest one (40-50 years) had 25 and 22 Gamasina species, respectively. Only 14 species most of them known as ubiquitous were stated as common for all three pine forest stands. The most abundant Gamasina species in the pine forest soils were determined Veigaia nemorensis and Parazercon sarekensis. Some case study in the beech forest soils also was made and 15 species were determined here. From them the most frequent were Veigaia nemorensis, Pergamasus vagabundus and Pergamasus lapponicus. Altogether about 170 species were registered from the investigated habitats in Latvia, thirty-six of them were recorded as new for fauna of Latvia.

Index terms: Veigaia nemorensis, coastal habitats, forest soils, species diversity

[0067] POLIPHAGOTARSONEMUS LATUS (ACARI: TARSONEMIDAE) DAMAGES IN "ERVA-MATE" SEEDLINGS

D. L. O. Santana¹; L. F. A. Angeli² & P. S. B. Pucci³, ¹ Embrapa Florestas, Estrada da Ribeira, Km111, Colombo, PR. C. P. 319, 83411-000 - Colombo - PR francis.santana@bbs2.sul.com.br ²Dept. Zool. UFPR, C. P. 19020, 81531-990, Curitiba, PR. ³Dept. Física. UFPR, C. P. Curitiba, PR.

It was observed in march 1999 a soaring of Poliphagotarsonemus latus mite in "erva-mate" (Ilex paraguariensis Hill.) seedlings in a nurserys located in São Mateus do Sul, Paraná State, Brazil. A sample of 300 seedlings of "erva-mate" was transferred to the glasshouse conditions and observed during three consecutive months. One part of this sample was maintained free of mites by chemical control, while the other was infested and the symptoms were observed. P. latus cause damage preferentially in young leaves. A few mites were found on leaves located in the half height position on the plants. It was rare to find mites in old leaves. In average, were observed 11,4 mites per leaf and at maximum 51 individuals/leaf. One week after infestation young leaves became wrinkled followed by an unequally growth of nervure with give the leaves an orange peel appearance. Afterwards the leaves fall or they became leather like with a slightly bronze colour. The upper part of the crown is the most damaged and when the attack is sever, only a few leaves remained. At the end of three months leaves were collected, oven dried and weighed. On average, infested plants loose 42% of the total biomass. Recovery of strongly attacked plants were observed two weeks after chemical control, with the development of new leaves. Deformed leaves were not able to recover. Index terms: Ilex paraguariensis pests, mite

[0068] NEW SPECIES OF ERIOPHOID MITES FOR WORLD FAUNA OCCURRING ON ORNAMENTAL PLANTS IN POLAND

<u>G.M Soika</u> & G.S. Labanowski, Research Institute of Pomology and Floriculture, 96-100 Skierniewice, POLAND.E-mail: gsoika @ insad.isk.skierniewice.pl

Up till now in Poland about 100 species of eriophyoid mites on ornamental shrubs and trees were found. Observations carried out during 1995-1999 in ornamental nurseries and Botanical Gardens showed on trees and shrubs 57 species of eriophoid mites new for Polish fauna including 18 species new for world fauna. Among species new for science only six were described and illustrated: Rhinophytoptus platani Boczek & Shi, 1995 on Platanus occidentalis L., Vasates viburnifoliae Boczek & Shi, 1995 on Viburnum lantana L., Epitrimerus taxifoliae Labanowski, 1999 on Pseudotsuga taxifolia Britt. and Phyllocoptes piceae Soika, 1999 on Picea abies Karst., Aculus cytisi Labanowski on Cytisus x praecox Bean 'Hollandia' and Tetra caraganae Soika on Caragana arborescens Lam. Other 12 identified species of eriophoid mites remains for description in short time: Aceria sp. nov. on Aesculus x carnea Hayne and Berberis thunbergii DC. 'Aurea', Aculops sp. nov. on Syringa vulgaris L., Aculus sp. nov. on Fagus sylvatica L., Anthocoptes sp. nov. on Fraxinus excelsior L., Calepitrimerus sp. nov. on Crataegus laevigata DC. and Quercus robur L., Cupacarus sp. nov. on Fagus sylvatica, Epitrimerus sp. nov. and Eriophyes sp. nov. on Crataegus laevigata, Johnella sp. nov. on Quercus cerris L., Tegontus sp. nov. on Ligustrum vulgare L.

Index terms: Eriophyoidae, coniferales, decidious, trees, shrubs,

Session 01 - ACAROLOGY

[0069] INTERNATIONAL COOPERATION IN THE INSECT INVENTORY, THE INBIO EXPERIENCE IN COSTA RICA

<u>A. Solís</u>, Instituto Nacional de Biodiversidad, Apartado 22-3100, Santo Domingo de Heredia, Costa Rica. E-mail: asolis@inbio.ac.cr

As in most of our countries in Central and South America, the entomofaunistic knowledge in Costa Rica is poor. Historically we can separate the effort for getting entomological knowledge in 3 general phases: First, "The Biologia Centrali-americana phase" (1876 - 1912), coordinated by Frederick Godman y Osbert Salvin. In this phase the work was done with specimens gotten from European expeditions, mostly from British people, and the number of described species in this period showed a significant increase. Next, "The Sporadic work phase" (1913 -1989), period basically scattered of personal efforts from international experts, mostly from USA, and the rate of the species description was relatively low. Finally, the "INBio's Inventory of Insects phase". It started with INBio (1989 - 2000) but it is also part of the global boom about the conservation and biodiversity. This phase was initiated with the British collaboration (NHM) and simultaneously and afterward was followed up with a punctual collaboration mostly from USA, Mexican, Canadian, and European taxonomists with the development of inventory methodologies very particular. In 1994-97 into the "All Taxa Biodiversity Inventory" project and later into the "Development of the knowledge and the sustainable use of the Biodiversity" project, were established Working Groups in Coleoptera, Hymenoptera, Diptera and Lepidoptera, as part of a redesign of strategies process. Personnel of INBio, national universities people, and international expert entomologists integrated these groups. The mission of these groups was the design of strategies of inventory into 5 Conservation Areas. The general objective defined was "Decrease the lack of information about the insects, and make this information available to the people of Costa Rica and the rest of the world, for a rational use, and for the conservation and development". We are right now in the implementation phase of the strategies. We are showing to the world the collection work, infrastructure, processes, and methodologies accumulated through the last 10 years. We are making available the parataxonomists system, the data base information capture system, the bar code system, and an adequately curated and accessible collection, presented in a physical and computerized way. Also, a information publication system for facilitating the work of the international resourse denominated Taxasphere. We have established some agreements and have achieved some products.

Index terms: Neotropics, Biodiversity, Taxasphere.

[0071] REPELLENCY OF GREEN ONION TO THE TWO-SPOTTED SPIDER MITE

G. Tito, <u>N.E. Sánchez</u> & M. Theiller, Centro de Estudios Parasitológicos y de Vectores, Univ. Nacional de La Plata, CONICET, 2 N° 584 (1900) La Plata, Argentina. E-mail cepave@museo.fcnym.unlp.edu.ar

Alternative cropping systems may improve or replace conventional management practices relying on chemical pesticides as the only control tactic. The association of green onion (*Allium cepa*) with strawberry crop in commercial greenhouses of La Plata showed reductions in *Tetranychus urticae* Koch (Acari: Tetranychidae) populations, one of the most serious arthropod pests affecting strawberry. Associated plants may affect an individual's ability to find the host plant. Encountering a nonpreferred host may increase the probability of a faster or further emigration, increasing the likelihood of leaving the crop. Moreover, allelochemical factors present in non host plant may act as repellents that direct herbivorours away from plants. The objective of this study was to investigate whether or not green onion has a repellent effect on *T. urticae*. The experiment was conducted using glass containers (5 cm wide by 25 cm long by 5 cm deep). One leaflet belonging to a strawberry plant growing in a pot was inserted into holes at two opposite facing walls of the containers. One cut

strawberry leaflet infested with 30 T. urticae individuals was placed on the floor at one end. Two treatments were evaluated : 1) Green onion: the floor and the walls at the end of the container where the infested leaflet was placed, were rubbed with green onion sap. 2) Control: with no green onion sap. Each treatment was replicated 50 times and the containers were placed randomly in an experimental greenhouse. After 24 hours, the number of individuals on each leaflet at both ends of the containers were counted. The data were square-root transformed and analysed by ANOVA. T. urlicae emigration was significantly affected by treatment. The number of individuals colonizing the leaflet at the opposite end to where the infested leaflet was placed was higher in the green onion treatment (F= 5.05; df =1,78; P< 0.03), while in the control a higher number colonized the closest leaflet (F= 4.37; df=1,78; P< 0.04). The number of individuals that did not colonize any leaflet was higher in green onion treatment, although the differences were not significant (F= 0.4; df= 1,78; P> 0.53). We believe that these results are related to volatile allelochemicals present in green onion that produce an effect of repellency to T. urticae, leading to higher levels of emigration. Further chemical analysis will increase our understanding of the effect of green onion on T. urticae abundance and the feasibility of the association as a potential management tactic. Index terms: Tetranychus urticae, Allium cepa, repellents, alternative cropping systems.

[0070] TOXIC AND MUTAGENIC EFFECTS OF A FEW CARBAMATE PESTICIDES ON SILKWORM BOMBYX MORI

<u>G. Subramanya¹</u>, Hiriyanna & S. A. Deepak, ¹Department of Studies in Sericultural Science, University of Mysore, Manasagangotri, Mysore-570 006, India. E-mail: Subramang@hotmail.com

Several carbamate pesticides are widely used to control fungal diseases during silkworm culturing and mulberry cultivation. In the present investigations four carbamate pesticides were selected namely Dithane M45, Benlate, Bavistin and Captan witch were very commonly used fungicides to eradicate fungal diseases of silkworm and mulberry. The stress has been laid on the utilization of silkworm *Bombyx mori* for environmental toxicity and mutagenecity. In view of this, the above pesticides were analysed for their effects by administering the pesticides through different methods to silkworm. The mutagenic effects of the pesticides were analysed through dominant lethal and specific locus test. Different sub-lethal concentrations of 100 ppm to 800 ppm were used. The results have revealed that at higher concentrations all the four pesticides produced toxic effects and dominant lethals. Contrary to this, only Dithane M-45 revealed the tendency to produce mutations at *pe and re* locus at higher concentration. The importance of the pesticides in Sericiculture with a stress on the utilization of silkworm *Bombyx mori* as test system to screen environmental toxicants and mutagens are discussed.

Index terms: Silkworm, Bombyx mori, Dominant lethals, Specific locus, toxicity

[0072] POPULATIONAL FLOTATION OF ACARI EDAPHICS ON TILLAGE AND NO TILLAGE SYSTEMS IN THE AREA OF DOURADOS – MS

<u>M.H.P.Vieira</u>¹, H. R. Santos², P. E. Degrande² & W. D. Fernades¹, ¹DEB/CEUD/UFMS, Caixa Postal 322 CEP-79825-070, Dourados-MS, E-mail: mhveira@zaz.com.br. ²DCA/UFMS, Caixa Postal 533 CEP: ídem, Dourados-MS, E-mail: hrsantos@ceud.ufms.br.

This work was carried out in field and in the laboratory of Entomology of the NCA/UFMS, in Dourados, MS. The main objective was to study the to dinamic populacional of mites, in proper agricultural soils for the production of grains and hadlings under the systems of no tillage and tillage. The experiment was conducted driven entirely under an experimental accidental outline, in an outline fatorial 24 x 2, with three repetitions. The field collections were made from July 1996 to June of 1998, being used of the of Berlese funnel (modified). For the extration of mites, the soil samples were placed in the same position for seven days. After identified, with base in the obtained results, we get to the conclusion that, the accentuated falls of the population were attributed to the implantation of cultures in the system of tillage, with drastic effects in function of the methods of preparation of the soil. There are indications that the fall observed in the population under the system of direct plantation á factors abióticos is associated. The largest pick populacional can be possibly attributed to unbalances provoked by the herbicids application and larger indexes pluviometrics happened in the corresponding period. The population of mites in the system of no tillage was larger than in the system of tillage. Sazonalidade didn't influence the number of the edaphic population of organisms.

Index terms: Population, mites, tillage no tillage

[0073] STABILITY ANALYSIS IN A CLASSICAL PREDATOR-PREY MODEL: EXAMPLE OF CASSAVA MITES SYSTEM

A. C. S. Vilcarromero¹, T. Ohishi¹, <u>O. Bonato</u>^{2,3}, ¹DENSIS/FEEC/Unicamp, C.P. 6101, 13083-970, Campinas, São Paulo, Brasil; ²IRD (ex-ORSTOM), França; ³Embrapa Meio Ambiente, C.P. 69, 13820-000, Jaguariúna, São Paulo, Brasil, E-mail : angela@densis.fee.unicamp.br.

Phytophagous mites belonging to Tetranychidae family are one of the major constraints for cassava crop. Among them, the cassava green mite Mononychellus tanajoa is the most economically important in South America where it comes from, and in Africa where it was accidently introduced in the 1970ies. In Brazil, M. Tanajoa is most abundant in the Nordeste region and high yield losses (untill 50% of dry matter) are reported. Ecological and biological studies suggested that phytoseiid mites would be the most approriate predators to control M. Tanajoa. The objective of this work was to analyse the stability of a predator-prey model with special reference to cassava system where M. Tanajoa is the prey and Typhlodromalus aripo the predator. T. aripo, native from Brazil, is a phytoseiid frequently found in association with M. tanajoa in brazilian cassava fields. Besides, in the context of M. tanajoa control programmes, this predator was recently released and established with success in Africa. Our study consisted to analyse mathematically the effect of changing the functional response in the predator-prey Rosenzweig-MacArthur type model: dH/dt = rH (1-H/K) - aPF(H) and dP/dt = sP + bPF(H), where H and P = populations of prey and predator, respectively, t = time, a, b, r, s = constants, F(H) = functional response. Four functional responses were choosen: 1) Ivlev (1961): $F(x) = b \cdot (1 - exp(-a \cdot x));$ 2) Holling (1959): $F(x) = a \cdot x/(1 + a \cdot T \cdot x);$ 3) Rosenzweig (1971): $F(x) = a \cdot x^{s};$ 4) Takahashi (1964): $F(x) = a \cdot x^{2}/(x^{2} + b^{2})$. Numerical simulations were done to show qualitative differences between functional responses. Mathematical analyses of equations allowed interpretation of numerical results and exploration of structural stability. Use of functional response (2) gave numerous oscillations showing high sensibility to parameters used. Function (3) also showed numerous oscillations and/or extinction of populations. From a mathematical point of view these two functions are inapropriate to represent interactions between predator and prey because populations never reach an equilibrium or extinguish. The adequate functions would be (1) and (4). They showed little oscillations but they stabilize very quickly. From a mathematical point of view, the function (4) would be the best one because stability was reached faster. However, numerous biological studies have shown that no or little predatory mite species display trophic interactions leading to behave as function (4) shows. Therefore, from both biological and mathematical point of view, the functional response (1), the Ivley model, seems to be the best for representing interactions.

Index terms: sensibiliy analysis, functional response, M. tanajoa, T. aripo

[0074] NUMBER OF PREY NECESSARY FOR COMPLETING DEVELOPMENT OF CHEYLETUS ERUDITUS (ACARINA: CHEYLETIDAE.)

E. Zdárková & P. Horák, Res. Inst.Crop Production, Drnovská 507, 161 06 Prague 6, Czech Republic, E-mail: Zdarkova@hb.vurv.cz.

Biological control is a part of the integrated pest management of stored food mites. The predator used is *Cheyletus eruditus* (Schrank). In order to optimise the technique it is desirable to have all relevant information about this species. It is already known that (1) *C. eruditus* is resistant to low temperature and organophosphates, (2) it does not develop at temperatures below 12°C, (3) the length of its development lasts from 18 to 164 days depending on temperature, and (4) it prefers slowly moving prey species to fast moving ones. However, not much is known about its voracity. The aim of the present research was to fill this gap. Fifty larvae of C. eruditus were fed either by eggs, larvae, protonynphs, tritonymphs or adults of *Acarus siro* from hatching to the adult stage. No food related differences in the lengths of development of the predators were evident as far as the number of prey specimens consumed was concerned; individual developmental stages consumed prey of corresponding sizes. Larvae predominated in the food of all stages, while adults were consumed least frequently. The eggs were also eaten in spite of the fact that the predators prefer moving prey. Females that fed on adults and tritonymphs laid most eggs. Index terms: *Acarus siro*, biological control, voracity

[0075] NOTE ON A NEW LAELAPTID MITE FROM SHANXI PROVINCE, CHINA (ACARINA: LAELAPTIDAE)

<u>L-T. Zhang</u> & H.-J. Zhang, Dept. of Vector Biol. & Control, Inst. of Microbiol. & Epidemiol., 20 Dongdajie Str., Fengtai D., Beijing 100071, P. R. China, E-mail Zhangjt@nic.brni.ac.cn.

A new laelaptid mite collected from Yicheng County, Shanxi Province, northern China in Nov. 1995 off Apodemus speciosus is herewith described as follows: Laelaps shanxiensis sp. nov. Diagnoses: Allied to Laelaps nuttalli but is distinguishable by the following characters: 1) the distance between VI₄ longer than that of VI₁; 2) S₈ is as 2/3 long as S₇; 3) the sternal plate is pretty long with a deep concave at its posterior margin. Female: Elliptical in shape, 723 um long and 550 um width. Dorsal plate 696 um long aud 528 um width, almost covered over the dorsal part with 39 pairs of acicular setae. S & is as 1/2 long as M 11. Terminal part expanded of pilus dentilis of digitus fixus of chelicera with an acuminate apex, much similar to that of Laelaps turkestanicus. Middle anterior margin of sternal plate slightly narrowed(122 um long), and 165 um in length at the place of St 2, with a deep concave at the posterior margin, the top line of this concave reached the base of St 3. Apex of St $_1$ not reached the posterior margin of sternal plate, while that of St $_2$ extended beyond the margin. A pair of metasternal plate located at the place between the coxae of leg III and leg IV. Epigynial plate 310 um long, with an extreme width at the base line of VI 3 (119 um). The distance between VI 1 110 um, much longer than that of VI 1 (80 um). Metapodal plate ovoid in shape, 8~9 pairs of epithelial setae on the ventral epithelium. Anal plate 156 um long and 140 um width. Adanal setae located at the posterior margin line of anal pore with apexes reaching the base of postanal seta. A spiniform seta and an acicular seta set on the coxae of leg I, leg II and leg III, with the acicular seta located at the anterior margin of the coxa, while only an acicular seta set on the coxa of leg IV. Holotype, female, collected from Yicheng County of Shanxi Province, northern China in Nov. 1995 off Apodemus speciosus, deposited in the Collections Hall of the Institute of Microbiology and Epidemiology, Academy of Military Medical Sciences, PLA, China.

[0076] CAUSES OF MITE PEST OUTBREAKS IN BAMBOO FORESTS IN FUJIAN, CHINA: ANALYSES OF MITE DAMAGE IN MONOCULTURE VERSUS POLYCULTURE STANDS

<u>Y. X. Zhang¹</u>, ZQ. Zhang², L. X. Tong³ Q.Y. Liu⁴ & M.G. Song⁵, ¹Plant Protection Institute, Fujian Academy of Agricultural Sciences, Fuzhou 350013, China, E-mail: zyxlj@pub3.fz.fj.cn; ²Manaaki Whenua -Landcare Research, Private Bag 92-170, Auckland, New Zenland; ³Yongan City Forest Protection Office, Yongan, Fujian, China; ⁴Fujian Forest Protection Office, Fuzhou, China; ⁵Yanping District Forest Protection Office, Nanping, Fujian, China.

Damage caused by the phytophagous mites Schizotetranychus nanjingensis Ma & Yuan, Aponychus corpuzae Rimando and/or Aculus bambusae Kuang to the moso bamboo (Phyllostaychs pubescens) was examined for ten pairs of mono culture versus polyculture forests at six locations in Fujian, China. Mite damage in the monoculture forests (35%) was on average twice as high as that in the polyculture forests (17.5% < the injury level of 20%). The relative contribution of each mite species to total damage varied among sites, but Ap. corpuzae was the dominant pest at all sites except one, where S. nanjingensis was the major pest. Polyculture forests overall had more predatory mites than monoculture forests. Mite damage was inversely correlated with the altitudes of individual forests across sites. These results are discussed in light of ecological theories on the effects of plant diversity on animal abundance and suggestions for possible measures to control pest mites on bamboo in Fujian. Index terms: Acari, bamboo, outbreak, plant diversity, pest control. [0077] POTENTIAL OF AMBLYSEIUS CUCUMERIS (ACARI: PHYTOSEIIDAE) AS A BIOCONTROL AGENT AGAINST SCHIZOTETRANYCHUS NANJINGENSIS (ACARI: TETRANYCHIDAE) IN CHINA

<u>Y. X. Zhang¹</u>, Z. Q. Zhang², J. Z. Lin¹ & J Ji¹, ¹Institute of Plant Protection, Fujian Academy of Agricultural Sciences, Fuzhou 350013, China, E-mail: zyxlj@pub3.fz.fj.cn; ² Landcare Research, Private Bag 92170, Auckland, New Zealand.

The predatory mite Amblyseius cucumeris (Oudemans) was studied in the laboratory to evaluate its potential as a biocontrol agent against the spider mite Schizotetranychus nanjingensis Ma & Yuan, a pest of the moso bamboo in Fujian, China. When fed S. nanjingensis females and eggs, the life cycle of A. cucumeris (developmental time from egg to egg 7.68 days for the first generation and 7.80 days for the second generation) was as long as its life cycle on its normal diet in the laboratory, Tyrophagus putrescentiae (Schrank) (7.84 days) at 27-28°C. Adult females of A. cucumeris started to lay eggs at the age of 3 days with a daily rate of 1-4 eggs (average of 2.2) over a period of 7-18 days and a total fecundity of 35.8 (14-47) eggs. The number of prey consumed by predators increased with prey density and the number of eggs produced was directly correlated with the number of prey consumed. Female predators (6 versus 3 per day at 9 prey per leaf). A. cucumeris females were unable to invade intact webnests of S. nanjingensis but were able to invade and liked to stay and lay eggs in broken nests with existing openings or holes.

Index terms: Acari, spider mites, predatory mites, biocontrol, bamboo

[0078] SCARAB LARVAE - A WORLDWIDE PEST PROBLEM

A. C. Bellotti¹, D. Peck¹, ¹Integrated Pest and Disease Management, CIAT, A.A. 6713, Cali, Colombia, E-mail A.Bellotti@cgiar.org, E-mail D.Peck@cgiar.org.

Soil dwelling arthropods are among the most destructive and troublesome of agricultural pests. Although research has intensified in recent years, and knowledge of the biology, behavior and ecology has improved, there is still a lack of information on the damage and management of soil insects. White grubs, the larval stage of certain scarabaeids (Fam: Scarabaeidae) are important soil welling pests that damage a wide range of crops throughout the tropical and temperate regions of the world. Crop damage is reported from North, South and Central America, Africa, Europe and Asia, as well as Australia and New Zealand. Damage is manifested by grubs feeding on the roots of numerous plant species causing plant degradation and death of young plants and seedlings: Adult beetles can feed on plant foliage which may contribute to yield loss. The white grub complex, especially in tropical ecosystems, is characterized by considerable species richness. In Colombia more than 575 species, belonging to 107 genera, have been recorded, and 22 species have been identified as agricultural pests. Similar species diversity is also reported from Panama, Brazil and Mexico. Worldwide, the most important genera include Phyllophaga, Cyclocephala, Costelytra, Anisoplia, Melolontha, Lipidiota, Ligyras, Hypopholes, Holotrichia, Phytalus, Dermolepida and Amphimallon. Despite their importance, there is a dearth of information on economic damage to agricultural crops due to white grubs. There are literature reports of yield losses on surgarcane (28 to 39%), beans (70 to 80%), potatoes (40 to 60%), maize (30 to 50%), sorghum (27%), asparagus (12 to 15% damaged spears), peanut (50%), roses (10 to 20%), rice (20 to 25% plant loss), cassava (95% loss in stake germination); damage to sugarcane by cane grules in Australia has been estimated at 10 million dollars annually. Additional crops reported as damaged by white grubs include to mator, grape, citrus, wheat, barley, pastures, onion, cotton, sunflower, coffee, and numerous fruits, vegetables and ornamentals. Toxic soil pesticides are frequently used by rural farmers to control grubs; these applications have been linked to soil and water contamination and human health problems, especially in developing countries. Index terms: Phyllophaga spp., white grubs, crop damage, yield loss.

[0079] TAXONOMY AND BIOLOGY OF THE SCARABAEIDAE

<u>M. A. Morón</u>, Departamento de Entomología, Instituto de Ecología, A.C. P.O. Box 63, Xalapa, Veracruz 91000, MÉXICO, E-mail moron_ma@ecologia.edu.mx.

Chafer beetles and their larvae, known as white grubs, are well known around the world. Some white grub species cause damage to the roots of a wide range of crops in many regions. Most of the injurious species are included in the genera Melolontha, Rhizotrogus, Phyllophaga, Holotrichia, Schizonycha, Brahmina, Lepidiota, and Costelytra (Melolonthinae) or Anomala (Rutelinae). Studies on the species taxonomy, larval identities, detailed life histories, food preferences and reproductive behaviour are scarce and sparse or incomplete and inaccurate. Field data from 1960 to the present indicate that white grubs constitute a major pest of food and industrial crops, rangelands, forests, and recreational areas in nearly all parts of the world. However, the patchy distribution of white grubs and sporadic nature of damage, each 3-5 years, makes it difficult to convince farmers or technicians to take adequate control measures when they are needed. Apparently, some species have a wide host range including both crop and weed species, as well as a wide ecological and geographical range. Severe damage frequently occurs in maize, potato, sugarcane, peanuts, beans, chili-pepper, sweet-potato, carrot, cabbage, onion, pastures, and ornamental flowers. One of the main problems in management of white grubs is the great diversity of species. For example, more than 340 species of Phyllophaga have been described from Mexico and Central America. They are distributed in 8 subgenera, and 44 groups of species. The high number of Phyllophaga species represent nearly 60% of the Melolonthinae species found in the region. It is certain that the relatively low number of species reported from some countries is mostly due to lack of information. The coexistence of several species from one or more genera in a site must influence the results from any control action. Unfortunately, species diversity is rarely taken into account in reports of control of white grubs. Great diversity of species, found in every biome, clearly indicates that scarabs are still going through a diversification process, and in many cases taking advantage of the agricultural monocultures that humans have established. For each species identified as a pest, there are 16 others that could potentially substitute for it as plant pests. Apparently, these beetles are using only 13% of their adaptive potential on cultivated plants. The list of host plants of larvae and adults of Melolonthinae larvae and adults include species from at least 57 plant families. Thus, to meet the challenge of these pests there is a need for precise identification of the species included in the white grub complex. There is also an urgent need for information on their life cycles, food preferences, natural enemies and other factors that limit their spread and influence their response to different control techniques. Index terms: White grubs, Melolonthinae, pests, biology, taxonomy

[0080] LARVAL BEHAVIOUR IN THE SCARABAEIDAE

<u>M. G. Villani</u>, Department of Entomology, NYSAES, Cornell University, Geneva, NY 14456, USA, email: mgv1@nysaes.cornell.edu

Movement patterns of Japanese beetle, Popillia japonica Newman and European chafer Rhizotrogus majalis (Razoumowsky) grubs as influenced by gravity, host plant position, and external disturbances were studied in laboratory soil-turfgrass microcosms. Second instal grubs through third instars just prior to pupation were monitored using radiographic techniques. Neonates were monitored using destructive sampling. Results indicate significantly different movement patterns between species and among age groups. The development stage of the grub had a large effect on Japanese beetle grub behavior and a measurable, if lesser effect, on European chafers. All life stages of European chafers and all stages of Japanese beetle, except neonates and post -overwintering third instars, displayed a downward movement in response to disturbance. Neonate Japanese beetles showed little movement while post-overwintering Japanese beetles moved upward when disturbed. European chafers of all age classes displayed random vertical movement with some arrestment in or near sod. Pre-overwintering and post-overwintering third instar chafers showed less dramatic arrestment behavior than other instars tested. Second instar Japanese beetles behaved similar to European chafers, however, third instars behaved very differently. All third instars except those tested in late winter and early spring showed some inate downward movement in the soil microcosms. Japanese beetles tested in late winter displayed random movement with some arrestment in sod while those tested in early spring exhibited upward movement and arrestment in sod. Fluctuations in temperature had little impact on the position of European chafer grubs, in contrast, Japanese beetle grubs moved from the upper root zone downward with the onset of cooling soil (14° C) and returned to the surface as temperatures increased. Radiographs of soil blocks containing third instar grubs indicated that both species respond to simulated irrigation and drought. Individual grubs moved upward after the addition of moisture in dry soils.

Index terms: scarab, grub, soil insects, movement, behavior

[0081] TOWARDS THE MANAGEMENT OF SCARAB BEETLES WITH SYNTHETIC SEX PHEROMONES AND OTHER SEMIOCHEMICALS

W. S. Leal, Dept. Entomology, University of California, Davis CA 95616, USA, Email: wsleal@ucdavis.edu

Most of the research programs concerning the identification of pheromones and other semiochemicals with potential application for scarab beetle management have focused on the subfamilies Cetoniinae, Melolonthinae, Dynastinae, and Rutelinae because of the economic importance of these groups as agricultural and/or turt pests. In addition to the identification of male-released aggregation pheromones for a few dynastines, various female-released sex pheromones have been identified in rutelines and melolonthines. Utilizing pheromone blends that consist of just a few semiochemicals or even a single constituent, closely related scarab species in Japan have attained separate chemical communication channels and reproductive isolation. Chiral pheromones play a pivotal role in the isolation of Popillia japonica and Anomala osakana, which share the same habitat in parts of the Japanese archipelago. The Osaka beetle produces and responds only to (S)iaponilure, the activity of which is completely inhibited by the presence of (R)-japonilure, the sex pheromone of the Japanese beetle. Examination of the olfactory perception in scarab beetles demonstrated that most scarab beetles cannot detect nonnatural enantiomers of their chiral pheromones (enantiomeric anosmia) and that the agonist-antagonist effect of the enantiomeric pheromones is more the exception than the rule. The synthetic pheromones and other plant-derived semiochemicals can be used to monitor the level of scarab populations as well as for quarantine. Although there is no direct evidence that the application of pheromones has an effect on suppressing scarab populations, some pheromone systems have been used in Japan for pest control.

Index terms: Anomala osakana, Popillia japonica, Rutelinae, Melolonthinae
100821 NATURAL ENEMIES OF THE SCARABAEIDAE

A. Jackson, AgResearch, PO Box 60, Lincoln, New Zealand. Email T. jacksont@agresearch.cri.nz.

Beetles of the Scarabaeidae often occur at high densities providing abundant resources for predators, parasites and pathogens. Vertebrate predators, mammals and birds, can consume high numbers of insects, but will often cause more damage than the insects themselves while searching through the soil. Flocks of birds, such as starlings, can be an indicator of high densities of scarab larvae below the ground. In cultivated land, improved grasslands and amenity turf, invertebrate predators of scarabs are usually rare, but these may be more common in old natural grasslands. Scarabaeids can be parasitised by scoliid and tiphiid wasps and tachinid flies. Levels of parasitism are highest at grassland/forest margins, which has led to the suggestion that planting of appropriate trees in agricultural land could increase the impact of parasitoids on scarab pest populations. While predators and parasitoids generally have only a localised impact on scarab populations, the impact of pathogens can be far greater. Scarabaeids are hosts to a wide range of nematodes and insect diseases, including a number of species which are only known from this insect family. Nematodes of the genus Psammomermis have a world-wide distribution, but are only found as parasites of scarab larvae. The bacteria Paenibacillus popilliae and Serratia entomophila and the Oryctes virus are only infective to scarabaeids and have been used in pest management of this group. The occurrence of a large number of pathogens, many of which are family and even species specific, reflects the evolution of this family for more than 200 million years in the microbially-rich soil environment Natural enemies often respond to their hosts in a density-dependent manner. Suppression of scarab natural enemies together with their hosts by the use of broad-spectrum insecticides has frequently led to pest resurgence. Where cropping practices and environmental management have led to outbreaks and high densities of scarabs, management to exploit the benefit of natural enemies should be an integral part of IPM systems.

Index terms: predator, parasite, pathogen, disease, density-dependence

[0084] MANAGEMENT OF RHINOCEROS BEETLES IN MALAYSIA

M. B. Wahid¹, R. Moslim¹, T. Jackson², T. R. Clare², N. Kamarudin¹, S. R. A. Ali¹ & N. Barlow², ¹Palm Oil Research Institute of Malaysia (PORIM), P. O. Box 10620, Kuala Lumpur 50720, Malaysia, E-mail basri@porim.gov.my: ²AgResearch, P. O. Box 60, Lincoln, New Zealand.

Major replanting programmes since 1985, as well as changes in agricultural practices and the need to comply to environmental regulations has elevated the status of Oryctes rhinoceros from that of an occasional to a key pest of oil palm in Malaysia. These changes include zero-burning technique of land clearing for replanting, under-planting of new palms within old ones which will be killed and left to rot in-situ within two years, and application of empty fruit bunches (EFB) as a partial source of nutrients. Population studies indicate that the under-planting technique supported the highest population of rhinoceros beetles (39,000 grubs/hectare) compared to felled poisoned palms (17,000 grubs/hectare) and shredded trunks (9,000 grubs/hectare). This information can lead to a more rational management of the rhinoceros beetles. Various methods have been integrated in the management of this pest. These methods involve cultural, chemical, pheromonal, and microbial control. Cultural control involves maintaining a good sanitation, the planting of leguminous cover crops and the removal of adults from the palm crown by a hooked piece of wire. Chemical control using carbofuran and cypermethrin is adopted in the prophylactic treatment of immature palms. Pheromonal control can only be adopted in areas where the population is relatively low (<5 adults/night/trap). Current emphasis is on the development of Metarhizium and Oryctes rhinoceros virus (OrV) as biological control agents of these beetles. Molecular technique has been used in the characterization of both pathogens. Of four isolates of Metarhizium examined, two were highly pathogenic. A suitable formulation of *Metarhizium* has been developed for the control of rhinoceros beetles. PCR analysis of rhinoceros adults from 30 estates in Malaysia revealed a widespread occurrence of OrV. Subsequent strain analysis of this virus using the restriction endonuclease reaction revealed the presence of three strains of OrV. The pathogenicity of the virus has been confirmed by histopathological examination of the mid-gut of the beetle. Cell-culture and bioassay techniques are being developed so that the most virulent strain can be selected for subsequent field release and control of rhinoceros beetles. All data will eventually be incorporated into a discrete model that is aimed at monitoring and predicting the fate of released virus in the field.

Index terms: Oryctes rhinoceros, Metarhizium, microbial control.

[0083] ERADICATION OF A SCARAB PEST FROM A NATIONAL WILDLIFE REFUGE

M. G. Klein¹, C. M. Mannion², A. Asquith³, N. Hoffman⁴ & W. S. Leal⁵, ¹ USDA, Agric. Res. Serv., 1680 Madison Ave., Wooster, OH 44691, USA; ² Univ. FL, TREC, 18905 SW 280th St., Homestead, FL 33031, USA; Kauai National Wildlife Refuge, PO Box 1128, Kilauea, HI 96754, USA; Dept. Interior, FWS, Midway Atoll NWR, P.O. Box 29460, Honolulu, HI 96820, USA; Dept. Entomol., Univ. CA, Davis, CA 95616 USA

The "Emerald Beetle", Protaetia pryeri, (Coleoptera: Scarabaeidae: Cetoniinae) is a serious pest on the Midway Atoll National Wildlife Refuge. Beetles were probably introduced from China-Japan in the early-mid 1900s. Favorable larval habitat in organic matter under ironwood trees, Casuarina equisetifolia, and lack of natural predators, probably exacerbated by eradication of rats, allowed beetle populations to explode. Beetles inhabit both main islands, and create guarantine concerns about their movement to the main Hawaiian Islands. Beetles also destroy fruits and flowers (tomato, papaya, okra, corn, hibiscus, grapefruit) in island gardens, and are a nuisance by landing on, and clinging to, visitors. During 1999 investigations were started on the beetles biology, an attractant for adults, and an insecticide to control larvae. There is one generation per year on Midway. Adults fly from May to October, and may be present in low numbers even longer. Adult emergence likely takes place over several months. Larvae are very highly correlated with ironwoods, with few in turf areas, and even fewer associated with shrubs or the beach community. Since ironwoods are not native vegetation, they are being killed with a herbicide and cut down when dead. Fewer larvae were found under recently killed trees, and very few were found past the drip line of living trees. Larvae break down the organic matter in fallen ironwood needles, and have created vast areas of frass up to 12+ inches deep under some trees. Although previous cetoniid attractants did not capture P. pryeri adults, several were excellent attractants for carpenter bees, Xylocopa sonorina, the primary pollinator on the island. However, L-Isoleucine Methyl Ester (LIME), a pheromone component for certain melolonthids, attracted over 400 Emerald Beetles to a Japanese beetle trap in a day. Preliminary tests indicate that ca. 20 mg of LIME will last at least one week, and that traps near the ground with plastic bags replacing the standard canisters can increase the captures of beetles. Following application in June, the insecticide MACH2 killed 94-100% of P. pryeri larvae by October. The availability of an excellent adult attractant, an effective insecticide, and the removal of ironwood trees which create larval habitat, gives us the chance to develop an IPM program for eradication/suppression of the Emerald Beetle on Midway.

[0085] IPM OF SCARAB PESTS IN SOUTH AMERICA

R. Alzugaray, INIA La Estanzuela, CC 39173, 70.000 Colonia, Uruguay. e-mail: rosario@inia.org.uy

Many scarab species are important pests of crops and pastures in South America. The larvae feed on the roots of major crops such as potatoes, corn, wheat, barley, oats, soybeans, sugar cane, rice and cultivated pastures. Most scarab pests are endemic species and can be found among the roots of grasses in native pastures. In the southern cone of South America, the natural pasture and forest ecosystems have been highly modified by introduction of livestock and agriculture after colonization. Burning of tall grasses, transformation of woodland into prairies, introduced animal and plant species, different types of dung, and the disappearance of native plant and animal species have all modified the environment. The increase of grazing pressure has made scarab feeding evident in pastures and the disturbance produced by agricultural practices has converted natural living organisms into pests. The problems of scarabs are greatest in crops following pastures. The subterranean habits of the larvae, together with the difficulties of sampling these species, has resulted in relatively few identified species and a scarcity of biological studies. IPM strategies vary depending on the crop and the scale of production. These include timing and nature of agricultural practices such as crop rotation, no-till cropping, date of planting and residue management. Application of insecticides to the soil has been a common practice, with consequent effects on soil and water contamination. Seed treatment with insecticides has been adopted in recent years, in crops such as wheat and corn, reducing the dose of chemicals and the cost of control as well as diminishing environmental contamination. Biological control may be considered as the only applicable method of control in pasture ecosystems. In surveys for natural control agents a number of pathogens have been isolated from scarab larvae, including several species of Metarhizium, Cordyceps sp. and Beauveria sp. Bacillus popilliae has been detected in natural infections of Phyllophaga species. M. anisopliae has been cultured and tested as biological control agent in several countries. Parasitic nematodes, insect predators and parasitoids and some viruses are known as natural enemies of different species of scarabs. However, there are no biocontrol programs currently adopted in farm conditions. Index terms: South America, scarab pests, IPM

Symposium and Poster Session

[0086] DETECTING EXOTIC PESTS: THE SCIENCE AND PRACTICE OF SAMPLING WHEN THE ECONOMIC THRESHOLD IS ONE

D. R. Lance, USDA-APHIS-PPQ, Otis Plant Protection Center, Bldg. 1398, Otis ANG Base, MA 02542, USA, E-mail david.r.lance@usda.gov.

Regulatory surveys for agricultural pests of quarantine significance are designed to detect and delimit incipient populations of exotic insects and/or to provide data that can be used to assess risk associated with export of commodities. Detection trapping, in particular, is carried out to demonstrate to a country and/or its trading partners that populations of an exotic species have not become established within the area in question (often the entire country). Surveys to detect introductions of tephritid flies into the mainland U.S. are among the largest, best organized and most expensive insect trapping programs in the world. Despite this, a lack of a basic understanding of how the trapping and pest systems function has, over the years, led (1) to inadequacies in survey design or execution that resulted in expensive and politically unpopular area-wide eradication programs, and (2) to a controversy over the possible existence of resident populations of Mediterranean fruit fly, Ceratitis capitata, in California. Indeed, the probabilistic nature of trapping makes it impossible to prove absolutely that an area is pest-free, but a relative degree of assurance can be developed through a sound understanding of sensitivity of the detection survey. Specifically, the probability that populations of various sizes will be detected (at least one insect will be found) can be estimated based on the relationship between distance to a trap and the probability of catching an individual insect. Examples are given in which releaserecapture and related techniques were used to develop distance-capture functions, and simple probability equations were then used to compute working estimates of detection sensitivity given different sampling efforts. Pronounced variation distance-capture functions was observed at different locales, confirming the potential influence of such factors as the state of the insect, weather, habitat structure, and local availability of food, mates, and host plants. To optimize the design of a detection survey, this basic understanding of how the detection technology functions must be juxtaposed with information from pest-risk assessments. That information can include, for example, the pest's potential geographic range (based host availability and climate), the risk of introduction, host-plant quality and density in the surveyed area, ease of eradication from an area, and even human demographics. Regulatory agencies are increasingly pressured to detect populations of invasive pests while they are small enough to eradicate with environmentally friendly tactics. To that end, incorporation of information on trapping sensitivity and pest risk assessment is essential for the design and optimization of detection surveys

[0087] METHODS FOR ESTIMATING THE SENSITIVITY OF DETECTION TRAPPING SYSTEMS

A. J. Sawyer

ABSTRACT NOT RECEIVED

[0088] USE OF A DATABASE AND GEOGRAPHIC INFORMATION SYSTEM TO MONIFOR A FRUIT FLY ERADICATION PROGRAM

AW Meats, P Gleeson & <u>AD Clift</u>, Fruit Fly Research Centre, School of Biological Sciences, A08, The University of Sydney, New South Wales 2006, Australia, E-mail clifta@agric.usyd.edu.au.

The exotic fruit fly Bactrocera papayae Drew and Hancock was first detected in North Queensland, Australia in October 1995. The extent of the infestation was surveyed during October/November 1995 and an eradication program started by December of that year. The last wild flies were caught in July 1997, area freedom claimed in August 1998 and eradication declared in May 1999. The Pest Quarantine Area comprised 70,000 km² north of 19°00'S and east of 144°15'E, with up to 3000 male lure traps using methyl eugenol as the lure. The successful eradication program was assisted by the use of the database Microsoft Access[®] and the Geographic Information System (GIS) Arcview[®]. The unique designation code and Global Positioning System (GPS) location of each trap was entered into a Location Table within the data base. The trap catch and trap clearance date for each trap clearance was entered into a different Table within the database, with the unique designation code linking the two tables. The GIS could plot the location of each trap onto a map grid, with overlays showing World Heritage Rainforest, agricultural land use, settlements and/or elevation. It was therefore possible to directly map, at any given date, the distribution of B papayae, locations where trap catches exceeded any given number per fortnight and changes in these distributions with time. Spatial analysis of initial trap catches provided indirect evidence of how the infestation established as a series of separate foci in urban areas before a more widespread distribution was achieved. Analysis of subsequent catches provided direct evidence of the dynamics of the eradication process whereby the population collapsed into another series of foci, which could then be targeted for intensive treatment. Methods for location of breeding sites and risk analysis of predictions of local eradication events were also developed using GIS data. Index terms: Bactrocera papayae, database, GIS, GPS, eradication.

[0089] QUALITY ASSURANCE IN LARGE-SCALE DETECTION TRAPPING PROGRAMS

B. J. Taylor¹, ¹Pest Detection/Emergency Projects, California Department of Food and Agriculture, 7845 Lemon Grove Way, Lemon Grove, CA 91945, USA, E-mail: btaylor@cdfa.org.

Large-scale trapping programs for insect pests are being utilized to justify: the pest-free status of exporting countries; the validity of agricultural quarantines of importing countries; the delimitation of exotic pests; and the feasibility of eradication programs. These trapping programs must be both biologically sound and economically feasible. Quality assurance of these programs must be based on sound biological principles as well as good management and supervisory practices, including proper training of employees, written training materials, accurate record keeping, consistent follow-up, observation of work, real-life experiences, achievable standards, independent evaluation, and effective discipline. Programs must also ensure appropriate quality when purchasing traps and lures through standards and field bioassays. Unique to insect trapping programs is the requirement of employees to identify target pests. Supervisors must be willing to monitor employees' performance using in-field observation of the employee's work and "seeding" traps with the target pest. Program evaluations must be performed on a regular basis using global evaluation techniques. Individuals having expertise in the detection of the target pests, the respect of the program administrators, the ability to recommend and implement appropriate changes and submit their findings to funding authorities, should perform these A trapping program without standards and regular quality assurance evaluations. inspections will not justify the pest status ratings that the program may be seeking and will fail to detect exotic pests in a timely manner.

Index terms: employee standards, supervision, training, trap seeding.

[0090] OBTAINING INTERNATIONAL CONSENSUS AND APPROVAL ON DETECTION TRAPPING EQUIPMENT, PROTOCOLS, AND PROCEDURES

<u>R. R. Heath</u>, United States Department of Agriculture, Agricultural Research Service, South Atlantic Area, Subtropical Horticulture Research Station, 13601 Old Cutler Road, Miami, FL 33158-1334 USA, E-mail miarh@ars-grin.gov.

Every day, new discoveries to protect agriculture from pest insects are made. Unfortunately, very few are developed to a point where the discovery would be considered as new technology that should be transferred to action programs. While the process of the "learning experience" is useful for developing strategies for obtaining consensus and approval on detection trapping equipment, protocols, and procedures, it is seldom accomplished. The conundrum involved in the "learning experience" related to the technology transfer of most discoveries is neutralized by the effort required to make it transpire. Consideration of impact, patent ability, validation, and consensus are arduous and complex. Because the process of advancing new technologies can be arduous, the scientist can be disadvantaged in their research effort realizing that the technology transfer adventure may never come to fruition. International recognition of new technologies requires supplementary effort. How technology transfer happens; the fusion and fission of science and politics, and the tactics needed will be presented. Examples of several technologies that were developed, including fruit fly attractants and sweetpotatoe weevil attractants, which are being used to protect agriculture will be presented to illustrate the technology transfer process.

Index terms: Technology Transfer; Detection Systems; Detection Protocols

[0092] POLLINATION AS A PROBLEM: AN INTEGRATED APPROACH IN ECOSYSTEM HEALTH FROM AGRICULTURE TO CONSERVATION OF NATURE

P. G. Kevan, Environmental Biology, University of Guelph, Guelph, Ontario N1G 2W1, Canada

Pollination is a process central to the functioning and sustainability of all but a few terrestrial ecosystems. Much pollination depends on animals, especially insects. The crucial role of pollinators in the reproductive biology of flowering plants, and the central importance of floral resources for pollinator populations enmeshes two major components of global diversity, productivity, and biomass. Because of the increasing levels of environmental stress faced by pollination systems (habitat destruction, fragmentation, pollution, etc.), an ecosystemic approach should be taken. The log-normal relationship between diversity and abundance has become recognized as reflecting ecological and evolutionary interactions between organisms that share ecological roles. This relationship for guilds or taxocenes of pollinators scems to be disrupted in stressed situations, and butterflies stressed by habitat destruction. Thus, a way of examining the health of pollinator communities is presented along with evidence for the potential value of using the log-normal relationship of diversity and abundance in assessing ecosystem health in nature, forestry, and agriculture.

[0091] THE INTERNATIONAL POLLINATORS INITIATIVE

B. F. S. Dias¹ & A. Raw², 1. Ministry of the Environment, Brasilia, Brazil; 2 University of Brasilia & Santa Cruz State University, Ilheus, BA, Brazil

The importance of the sustainable use of biological diversity for society is clearly demonstrated in the pollination of crops by animals. At least one-third of the world's food production relies on insects visiting the crops' flowers so that the plants can produce seeds and fruits. The total value of this pollination service worldwide is estimated at US\$ 67 billion annually. By far the greatest part of the pollinating service is provided by many species of bees which are responsible for the pollination of some 75 % of the world's crops. There is also an enormous dependence of plants on insect pollinators in natural habitats. The numbers of pollinator species are said to be declining. The estimated crop loss through lack of pollination for 30 crops is cited at US\$ 54.6 billion per year. Presumably the declines are linked to the use of agrochemicals, disease and habitat damage; the latter resulting in losses of nest sites and alternative food plants. The problem of varroatosis on honeybees demonstrates the risk involved in relying on a single species. However, there is insufficient information on the insects' taxonomy, their roles as crop pollinators, how serious the problem is and how it might grow. We urgently need convincing information in all these areas. An international workshop in São Paulo (1998) produced clear messages over the identification of the problem and what, in general terms, needs to be done to begin to resolve it. The International Initiative on the Conservation and Sustainable Use of Pollinators was proposed from the meeting. Capacity-building for taxonomy should be linked to the effective implementation of the Convention on Biological Diversity. We need more information on the pollination requirements of plants. A comprehensive monitoring programme is needed to collect data on changes in the sizes of populations of species of pollinators so that we may evaluate the scope and seriousness of the problem. Varroatosis has made it clear that native pollinators need be managed for the service they can provide and agricultural practices should be designed to incorporate the protection and the sustainable management of these insect populations. Few species of wild bees have been managed for the pollination of crops. A call is made for international cooperation on pollinators conservation and sustainable use.

[0093] TOWARDS AN INTERNATIONAL PROGRAMME ON POLLINATORS AND THEIR ROLE IN ECOSYSTEM RESILIENCE

R. Krell, T. Putter & P. Kenmore, FAO, Rome, Italy, email: Rainer.Krell@fao.org

Pollination of crops has received attention only in some agricultural systems and regions. However many producers even in those regions do not regard pollinators as important for improved production. Some studies exist on the natural and managed pollination of agricultural crops, but far less has been done on the impact of pollinators in natural ecosystems and little is known about most pollinator species and their relationships with their plants. The decline of natural pollinators in intensive agriculture and urbanized areas has consequences on agricultural production and most likely also on natural ecosystems. Pollination is as basic as sunlight in assuring primary food production for all organisms in the terrestrial food chain. Thus natural diversity of pollinators is essential for ecosystem maintenance as well as for global food security. With growing concern over biodiversity, increasing understanding of pollinator-plant relationships, and annual pollination benefits to global agricultural crop production of at least US\$ 50-60 billions, pollinators are gradually being given more attention. The International Workshop on the Conservation and Sustainable Use of Pollinators in Sao Paulo, Brazil in 1998 clearly demonstrated the need for globally coordinated efforts and human resources and knowledge to deal with pollination and pollinators adequately. Already existing initiatives are making important contributions, but a global effort for a coordinated international programme will unite forces and create the focus required to improve integration of pollination in agricultural management and other conservation practices, to work on the most urgent research needs, and also to create opportunities to involve other players at different levels - decision makers, agricultural extensionists, nature conservationists and land-use planners. Including pollinators in conservation thinking requires a different approach to habitat preservation, like the inclusion of disturbed habitats for specific pollinator requirements. These changes in approach alone will contribute considerably to ecosystem stability. Pollinator diversity and individual pollinator species have very high potential as indicators of biodiversity and ecosystem health. FAO has a well established data collection and distribution system. Inclusion of relevant pollinator data in the large ECOPORT plant database can be used to establish a global pollinator support system. Gathering and disseminating this information, building expertise and general awareness for improved agricultural production and production security while assuring ecosystem diversity and sufficient reproductive capacity will be the prime results of a global cooperation Establishing pollinators as important indicator species could be another programme. outcome. Under the umbrella of an international organisation, with the initiative of the various institutions and interested experts, an international programme on pollinators has all the elements of rapid progress and success.

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[0094] ARE POLLINATOR NUMBERS DECLINING OR FLUCTUATING NORMALLY ?

G. W. Frankie & S. B. Vinson, University of California, Berkeley, CA, USA

Concern about the suggested worldwide decline of pollinators has raised questions among researchers over whether there is a general global decline, if it is only local or if recorded declines are just natural fluctuations in pollinator populations. Other questions are over the most appropriate methods to study the phenomenon. The situation has provoked lively discussion over possible causes of decline and whether any of the long list of these possibilities can be altered so as to reverse downward population trends of pollinator numbers. In Costa Rica, we have monitored species diversity and frequency of bees in two nearby study areas in what was dry forest. The numbers and species of bees have been recorded at the flowering leguminous tree Andira inermis for 28 years at one site near an evergrowing rural community, and for the 10 years at the other in modified wooded savanna. Substantial declines in bee species diversity and frequency have been documented at both sites. At the first, habitat destruction through human development around the Andira trees is the most obvious cause of the decline. The causes at the second are not so clear and a combination of unusual weather factors, high natural bee mortality, and habitat fragmentation may be contributing to the decline of the bees' numbers.

[0096] THE STATUS OF POLLINATORS IN EUROPE

<u>J. Banaszak</u>, Institute of Biology and Environmental Protection, Pedagogical University in Bydgoszcz, 30 Chodkiewicza St., 85-064 Bydgoszcz, Poland, E-mail lednica@wsp.bydgoszcz.pl.

In the climatic conditions of Europe the most important for the pollination of plants are the representatives of Apoidea superfamily. Compared with other parts of the world, Europe is the best known continent as far as bee species diversity is concerned. The composition of fauna has been regularly researched for at least 150 years and the existence of over 1250 species of wild bees has been identified. Local lists of species, made for the majority of European countries, have proved a great success of the last decade of the XX century. Increase in crops, especially in forage crops (alfalfa, red clover) became the focus of interest, which brought about first estimates of apoids density in the crops after II World War. Whereas it was only in the eighties when density in natural ecosystems was first estimated and proper methods worked out. Research on the resources of pollinating insects must be considered as top priority; it constitutes one of the main achievements in the contemporary apidology. It became the basis for research on bee ecology in a landscape aspect, and in future will allow for objective estimate of changes in fauna. First regular studies of changes in bee fauna in long term cycles have already been undertaken (e.g. in Poland). The basic source of information about endangered species are quite common red lists and red data books of animals, bees included (Germany, England, Poland, etc.). The paradigm of protection by law of bees as well as other insects and its efficiency is quite controversial. Many countries still do not have any legal regulations concerning protecting Hymenoptera. Under the rules for conservation of wild bees, the main stress is put on preserving their natural habitats - fauna refuges by means of preserving or creating the structure of landscape based on ecological rules. Other measures taken to protect bee populations included breeding wild bees and their reintroduction to a landscape or breeding for agricultural purposes etc. New problems appear as a result of the development of bombiculture and breeding of other wild bees. Freedom of hybridization of honey bee races makes maintaining the purity of traditional local races difficult and genetic protection of honey bee populations necessary.

Index terms: pollinators, Apoidea, Europe, diversity, density, protection of bees

[0095] INSECT POLLINATION IN AUSTRALIA – CURRENT ISSUES AND DIRECTIONS FOR THE $21^{\rm ST}$ CENTURY

C. L. Gross, School of Rural Science and Natural Resources, University of New England, Armidale NSW, Australia

Insect pollinators in Australia include moths, butterflies, ants, flies, beetles and some 2,000 species of native bees, the latter including a significant and diverse assemblage of Colletidae and Halictidae (short-tongue bees). Australian vascular plants number c. 18,000 species of which 80% are endemic. Pollination ecology in Australia has developed from a descriptive phase at the turn of the century to studies in the 1980s that focussed on issues of evolutionary ecology. In the last decade conservation has been a focus of some research although there is much to be done. Insect pollination is poorly researched in Australia. However a number of initiatives have started to database the identity of floral visitors. The impact of the introduced honeybee on the native biota has generated much interest although very few researchers have actually investigated the impact of honeybees on the fitness of plants and/or their native pollinators. Recently bumblebees were introduced to Australia and there are growing concerns about their potentially adverse effects on the native biota. Honeybees may be seriously contributing to the success of weeds in Australia in both natural and agricultural systems and studies are urgently required to examine this. Moreover the incursion of bumblebees into Australia may exacerbate the weed problem, particularly in those species with poricidal anthers, e.g. Solanaceous taxa. Australia has a very high incidence of threatened plant species (c. 23%) and it is unknown for almost all of these rare taxa whether or not pollination failure has contributed to their rarity. Even less is known about the conservation status of their pollinators. The importance of insect pollinators at the community level is virtually undocumented although available evidence suggests that Australian rainforests rely heavily on insects for pollination services. Finally the global decline in insect pollinators has not generated the concern in Australia that it should partly because (1) honeybee populations are healthy, (2) because baseline data of insect pollinators are lacking and (3) there is virtually no recognition among the general public of the importance of native bees, let alone other insects, as pollinators.

[0097] THE STATUS OF POLLINATORS AND BIODIVERSITY IN ASIA: AN OVERVIEW

<u>A.J. S. Raiu,</u> Dept. Environmental Sciences, Andhra University, Visakhapatnam - 530 003 Andhra Pradesh, India

Asia has a large variety of climates and ecosystems with a wide range of plant and animal species. However, the pressures on the poor to meet their essential needs (food, fuel wood and fodder) and the elite's desire to accumulate wealth and maintain socio-economic power are major factors causing the continuing destruction of forests and diminishing forest resources and their biodiversity to the extent of disrupting the ecological balance. Many forests are now fragmented which has resulted in losses of many plant: pollinator relationships. However, forest fragments may still have adequate pollinator and plant diversity. The value of pollinators has been recognised since the dawn of agriculture, but measures for their conservation and management in wildlands have been considered only The Rio Convention is instrumental for the conservation of pollinator recently. biodiversity. India has identified pollination ecology as a major area for research and recognised the value of pollinators in conserving biodiversity. Detailed studies on pollination ecology and on pollinators of agricultural and non-agricultural plants are being conducted to analyse the interactions between native pollinators and their native host plants. In Japan, populations of many species of native pollinators are declining or have become dependent on introduced plants as their native hosts disappeared. In urban areas, the greatest numbers of pollinator insects are in public gardens and parks with less plant diversity. Excellent work is being conducted in Israel to discover the roles of pollinators in maintaining plant diversity. Indonesia, Malaysia, China and other countries have pollination projects. Environment warming is influencing the reproductive cycles of pollinators. Pesticides, insecticides, etc. reduce the numbers of pollinator species. Pollinator numbers also decline due to losses of nest sites and native host plants through cultivation, urbanization and the burning of their habitats. The published information on pollination ecology of native species in Asia mostly comprises lists of pollinators of plant species, but does not provide information on the status of pollinator species in a study area or on the entire ecosystem of a region. Investigations on the status of pollinators must take into full consideration the importance of the sustainable availability of forage plants for larvae and adults, the availability of nest sites, the influence of climatic factors, etc. This information is required to plan measures for the effective conservation and management of pollinators of wild plants and hence sustain biodiversity in natural and manmade habitats.

[0098] NOR'IH AMERICAN POLLINATORS AND HABITAT FRAGMENTATION: DURABLE BEE FAUNAS AND THE PROMISE OF SMALL RESERVES

J. H. Cane, Bee Biology & Systematics Laboratory, Logan, UT, USA

Few studies directly address the consequences of habitat fragmentation for communities of invertebrate pollinators, particularly for bees; the most important group of pollinators. The present studies define fragments by remnant patches of floral forage or living woody vegetation, and not by bees' nesting substrates. Several of the studies conclude that such habitat fragmentation is broadly deleterious, but overlook native species in their own data sets that proliferate more in fragments than in intact habitats. Several other studies find the densities of native bees at flowers increase in larger remnants relative to intact habitats, with little change in species richness but with marked shifts in species composition and relative abundances. Bees are typically well-adapted to habitats wherein their nesting substrates and floral resources are both patchily distributed and spatially dissociated. provided that the coarseness of such pattern does not exceed their flight vagility. Furthermore, many bee species occupy or even require habitats of intermediate successional stage or modest disturbance. Perceptive future studies of habitat successional stage or modest disturbance. fragmentation and bees will account for and evaluate fragmentation, alteration, and loss of nesting habitats, and not just patches of food plants. Inasmuch as floral associations, floral specializations and nesting habits of bees are typical attributes of species, or at most, subgenera, authoritative determinations of specimens to these levels is an essential prerequisite for any biologically meaningful interpretation. Studies must also anticipate and accommodate the statistical problems that attend bee community or pollinator guild samples. For bees, broadly deleterious habitat fragmentation may need to be extensive to overcome their flight vagilities, dispersal abilities and orientation capabilities. Given the sheer area of intervening matrix that must be rendered inhospitable in order to fully isolate fragments from outside bee foragers and immigrants, such scenarios might be better relegated to cases of habitat loss, not fragmentation. Conversely, the prolonged persistence of substantial diversity and abundance of native bee communities in some habitat fragments and reserves of even moderate size gives hope for practical solutions. If selection, design and management can address bees' foraging and nesting needs, networks of small reserves should be able to sustain considerable pollinator diversity and their ecological services.

[0100] HOST PLANT RESISTANCE TO *BEMISIA TABACI* AND OTHER WHITEFLY SPECIES, AND ASSOCIATED VIRUSES

<u>A. C. Bellotti¹</u> & F. Morales², Integrated Pest and Disease Management, Cassava Entomology, CIAT, A.A. 6713, Cali, Colombia, E-mail A.Bellotti@egiar.org, ²Virology, CIAT, A.A. 6713, Cali, Colombia, E-mail F.Morales@egiar.org.

Host plant resistance (HPR) to whiteflies in cultivated plants is rare. At CIAT, in Colombia, more than 5000 cassava varieties have been evaluated for resistance to Aleurotrachelus socialis. Several varieties have been selected for high levels of resistance. Nymphal mortality on the cassava variety MEcu 72 reached 72.5%. Greenhouse and fields studies showed that A. socialis feeding on resistant clones had less oviposition, longer development periods, reduced size and higher mortality than those feeding on susceptible ones Whitefly resistant cassava varieties are being evaluated for release to farmers in Colombia. Different breeding populations have been obtained from crosses between resistant and susceptible cassava genotypes. Using AFLP's, bands co-segregating with resistance to A. socialis have been found. These bands are being sequenced to generate SCAR's markers, which will be used for the identification of resistant materials in breeding programs. The search for genetic resistance to plant geminiviruses has been a long and frustrating process. The intra-specific genetic variability present in the main cultivated plant species affected by whitefly-transmitted geminiviruses, does not confer immunity to these pathogens. The common bean (Phaseolus vulgaris) is attacked by different whitefly-transmitted geminiviruses, such as Bean golden mosaic virus, Bean dwarf mosaic virus and Bean calico mosaic virus. Of over 20,000 common bean accessions screened for resistance to BGMV, none has shown immunity to this geminivirus. Similar results have been obtained for other cultivated plant species, such as cassava, tomato, pepper, cucurbits, cotton, etc., attacked by geminiviruses. This situation has forced plant breeders to search for sources of resistance to geminiviruses in related species. Resistance to one of the most severe geminiviruses affecting horticultural crops, Tomato yellow leaf curl virus (TYLCV), has only been found in wild Lycopersicon species. The first commercial resistant tomato cultivar released. TY20, came from a cross between L. esculentum (the domesticated tomato) and the wild species L. peruvianum. In the case of common bean, considerable progress has been made by exploiting various mechanisms of resistance identified in different races of P. vulgaris. The pyramiding of the genes responsible for the observed resistance mechanisms, has resulted in the selection of bean cultivars possessing high levels of geminivirus resistance. Index terms: Cassava, Beans, A. socialis, geminivirus.

[0101] ECOLOGICAL CONSIDERATIONS FOR MANAGEMENT OF A MULTIPLE-CROP PEST

A. Pauw, W. Bond, S. Johnson & F. Field, Department of Botany, University of Cape Town, Cape Town, South Africa

[0099] HABITAT FRAGMENTATION AND ITS CONSEQUENCES FOR PLANT-

POLLINATOR MUTUALISMS IN SOUTH AFRICA

South Africa, and in particular the Cape, is world renowned for its high levels of plant diversity and endemicity. Also unique are the very high levels of specialization in plant pollinator relationships. In contrast with the Northern Hemisphere, where specialized pollination systems are rare, South African plants often depend on a single pollinator or small group of related pollinators. For this reason, there is concern over the dramatic decline of specialized pollinators in recently fragmented habitats. In the high altitude grasslands of the KwaZulu-Natal Province, plants depending on hawkmoths, long-tongued flies and solitary bees set significantly fewer seeds in landscapes fragmented by exotic pine plantations. Similarly in the Cape shrublands, oil-collecting bees (Melittidae) and tangle-winged flies (Nemistrinidae) were extinct from several small nature reserves. These reserves protect the last remnants of endangered lowland vegetation and are surrounded by urban sprawl and agriculture. Here, seed production in plants without pollinators varied from zero in some allogamous orchids to 100% in facultatively selfpollinating Iridaceae. However, the consequences of decreased seed-set on plant populations are not obvious, because they are determined by the degree to which the plant species depends on seeds for reproduction and persistence. For example, plants that reproduce clonally via underground runners or extra bulbs may persist despite zero seed production, but initial results indicate that these persistent populations experience a loss of genetic diversity. Demographic studies of clonal orchids and non-clonal amaryllids have been initiated to elucidate the real consequences of pollinator extinction for these divergent life histories. The balance of evidence suggests that the conservation of many South African plants depends on the conservation of their pollinators, however, pollinator conservation is hampered by the lack of basic information on pollinator life cycles and nesting requirements.

P.C. Ellsworth¹, J.C. Palumbo², S.E. Naranjo³& S.J. Castle³, ¹Dept. Entomology, Univ. of Arizona, Maricopa Ag. Ctr., 37860 W. Smith-Enke Rd., Maricopa, AZ, USA 85239; Email: peterell@ag.arizona.edu; ²Dept. Entomology, Univ. of Arizona, 6425 W. 8th St., Yuma, AZ, USA, 85364; ³USDA-ARS, Western Cotton Research Lab., 4135 E, Broadway, Phoenix, AZ, USA, 85040.

Whiteflies (*Bemisia* spp.) are important pests of numerous crops all over the world. Their polyphagous nature, especially in the recently-identified strain (B. tabaci, Strain B) or species (B. argentifolii), has elevated the importance of understanding the ecological contexts where they are most pestiferous. With the exception of protected agriculture (e.g., glasshouses), Bemisia whiteflies are major pests limited mainly to tropical, subtropical. arid, and semi-arid crop production regions of the world. One common thread among these diverse biomes is the lack of harsh winter conditions. Occasional field outbreaks in more temperate regions of the world are often associated with spatially and temporally local efflux from protected environments. Thus, there are ecophysiological constraints on the range of this insect that include an array of abiotic parameters governed mainly by low temperatures. Bemisia whiteflies are freezing intolerant with little ability to survive subzero temperatures of short duration. They have no distinctive overwintering life stage or any capacity for diapause. Another shared characteristic of Bemisia-endemic regions of the world is a year-round growing environment. Bemisia whiteflies cannot live away from living plants for any length of time. Thus, in addition to the ecophysiological constraints, Bemisia dynamics are also subject to the host ecology and phenology present in the system. Regions of the world that report significant outbreaks of Bemisia whiteflies also tend to have a sequence of strategically important whitefly plant hosts year-round. The year-round ecology of this pest includes seasonal dynamics, overwintering ecophysiological constraints, host-mediated development and mortality differences, movement, host temporal and spatial availability, and control dynamics. The latter component is the factor that is most influenced by grower action, but long-term, growers will need to also consider the manipulation of these other components of Bemisia seasonality to ensure successful management on any particular target crop. Thus, management systems for Beniisia must consider the intercrop dynamics and crop ecology of large areas. "Avoidance," in its broadest sense, is the foundation of integrated pest management (IPM). Investigation of the seasonal ecology of this pest should lead to more ecologically stable IPM strategies that are wholly integrated within multiple crops over large areas.

Index terms: Whiteflies, *Bemisia tabaci, Bemisia argentifolii*, integrated pest management (IPM), overwintering, seasonality, areawide management.

[0102] CONSERVATION AND EVALUATION OF NATURAL ENEMIES IN IPM SYSTEMS

<u>S. E. Naranjo¹</u> & W. A. Jones², ¹USDA-ARS, 4135 E. Broadway Rd, Phoenix, AZ 85040, USA, Email snaranjo@ix.netcom.com; ²USDA-ARS, 2413 E. Hwy. 83, Weslaco, TX 78596, USA, Email w-jones@pop.tamu.edu

Evidence from many of the agricultural systems affected by Bemisia tabaci (= B. argentifolii) suggests that natural enemies are an important component of natural control. Maximization of the effects of natural enemies should form the foundation of modern pest management systems. However their integration into IPM has been hampered in many systems by a poor understanding of the overall impact of natural enemies on pest population dynamics and the interaction of their impacts with other control tactics. The relative effects of aphelinid parasitoids (Eretmocerus and Encarsia spp.) on Bemisia have been characterized in a number of cropping systems by measuring percentage parasitism. Clear geographic as well as host plant-related patterns have been identified. Still, great care must be used in relating such measures to pest population control. Predation is less well understood because of measurement difficulties; however, serological and other techniques have helped to identify key predator species in several cropping systems and it is clear that a large number of generalist predator species attack Bemisia. The impact of pathogens is poorly known in most systems. Conservation of natural enemies in IPM systems depends on a number of factors. The greatest impediment to conservation biological control in IPM systems for most crops are insecticides. Toxicological studies have been conducted on various parasitoid and predator species attacking Bemisia. These studies have revealed potential direct and sublethal impacts, but it is difficult to extrapolate findings to the field. Controlled field studies in some cropping systems have also been used to characterize the gross effects of insecticides; however, such studies can overlook behavioral and more long-term effects. More selective insecticides are available in some systems and may contribute significantly to conservation of natural enemy abundance and activity. Ultimately, many interacting mortality factors impact the population dynamics of Bemisia in IPM systems and it is critical that we examine the contribution and potential of natural enemies within this context. We highlight field life table studies that have been conducted to identify and quantify sources and interactions of mortality forces within alternative IPM systems in cotton in the southwestern USA. We discuss strengths and limitations, and suggest the life table approach as a paradigm for evaluating and developing conservation biological control programs for all affected crops.

[0103] INTERNATIONAL AND NATIONAL RESEARCH PROGRAMS FOR THE DEVELOPMENT OF *BEMISIA* IPM SYSTEMS

<u>P.K. Anderson¹</u>, T. J. Henneberry² & M. R. Vilarinho³,¹CGIAR Whitefly IPM Project, CIAT, A.A. 6713, Cali, Colombia, Email p.anderson@cgiar.org, ²USDA-ARS, Phoenix, Arizona, USA, Email thenneb@asrr.arsusda.gov, ³Embrapa/Cenargen, Cx Postal 02372, Brasilia-DF, Brazil, Email vilarin@cenargen.embrapa.br

In the United States, at the end of the 1991 growing season, it was apparent that unacceptable losses in cotton and vegetable field crop production, as well as ornamental and vegetable losses from whiteflies in glasshouse cultures, were being experienced in California, Arizona, Texas, and Florida. A five-year sweetpotato whitefly (SPW) national research and action plan was developed. The need for "stop gap" control measures was Standardized experimental procedures, data collection protocols, report urgent. preparation, and results exchange systems were established for a national testing program of promising chemicals, natural products, microbial insecticides and improved application resistance management program (IRM) was also established. Over 30 federal and state experiment station scientists, in 8 states, were involved in the overall program. The results have provided the basis for highly effective SPW chemical control and ongoing SPW-IRM. A complete management system for SPW is a goal for the currently operational 2rd five-year plan. Throughout the Tropics, whiteflies are causing devastating losses on a broad array of food security and income-generating crops. In response, the project on "Sustainable Integrated Management of Whiteflies as Pests and Vectors of Plant Viruses in the Tropics" was initiated in 1997 by the Consultative Group on International Agricultural Research (CGIAR), as one of the projects within the Systemwide Program on IPM. The CGIAR Whitefly IPM Project is structured into 6 sub-projects that operate in 30 countries in Latin America, Africa and Asia. The Project focuses on: 1) whiteflies as pests in Tropical highlands; 2) whiteflies as vectors of plant viruses in mixed cropping systems of the low-to-mid-altitude Tropics; and 3) whiteflies as pests and vectors of plant viruses in cassava. The principal objective of Phase 1 (1997-1999) has been to generate a more comprehensive characterization of these whitefly problems to provide the foundation for a basic research program on whitefly pest and disease dynamcis, and IPM component testing, during Phase 2 (2000-2003).

[0104] IPM OF BEMISIA TABACI IN AUSTRALASIA

P. J. De Barro¹, F. Driver², I. D. Naumann², S. Schmidt², J. Trueman² & J. Curran², ¹CSIRO Entomology, PB 3 Indooroopilly, QLD 4068, Australia, paul.debarro@brs.ento.csiro.au; ²CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia; ³ Research School of Biological Sciences, Australian National University, Canberra 0200, Australia.

Bemisia tabaci biotype B was first discovered in Australia in October 1999. This lead to the initiation of a wide array of research aimed at helping Australian producers prepare for and manage the whitefly. Key elements to the first phase (3 years) of this research was to determine the diversity of parasitoids already present that may be of use against the pest. This work led to the development of easy to use keys for the various species found. In addition, the phylogenetic relationship of world populations of B. tabaci was investigated. Here, the research aimed at determining where Australia's indigenous B. tabaci fitted in terms of the world fauna. As part of this work a rapid screening protocol was developed to enable the exotic and indigenous biotypes to be distinguished. This work was then broadened to investigate the distribution of B. tabaci across the Pacific Island Countries with the aim of assessing the likelihood of further incursions of exotic biotypes. Another key component of the research was assessing the potential of five parasitoid species already present in Australia. This concluded that, Eretmocerus mundus (Australian Parthenogenetic Form) offered the best potential for control. Research also determined the efficacy of insecticides currently available, the insecticide resistance profile of the B biotype and the registration of more effective products. The interaction between the indigenous and exotic forms of B. tabaci was also investigated, as were the damage thresholds for at risk crops such as tomato. The research is know focusing on developing field management protocols and in screening for resistance to tomato geminiviruses that are beginning to move southwards towards our major tomato growing regions. In Asia, Australia, AVRDC and cooperating scientists in Bangladesh, Indonesia, Nepal, Philippines, Sri Lanka and Vietnam are part of the Consultative Group on International Agricultural Research initiative on whitefly IPM (Sustainable Integrated Management of Whiteflies as Pests and Vectors of Plant Viruses). The program is being convened through the International Centre for Tropical Agriculture. This programme is gathering baseline data on the biotype/host plant/geminivirus interaction.

Index terms: Australia, Asia, biological control

[0105] IMPLEMENTATION AND ADOPTION OF IPM SYSTEMS

<u>I. L. Martinez-Carrillo¹</u>, P. C. Ellsworth², L. Hilje³ & R. Ausher⁴, ¹INIFAP Calle Norman Borlaugh Km. 12 Cd. Obregón, Sonora. México: ²Dept. Entomology. Univ. of Arizona, Maricopa Ag. Ctr., 37860 W. Smith-Enke Rd., Maricopa, AZ, USA 85239; ³Plant Protection Unit. CATIE, Turrialba, Costa Rica, E-mail: Ihilje@catie.ac.cr; ⁴Dept. Crop Prot. Ext. Serv., POBox 28, Bet Dagon 50250, Israel.

Whiteflies (Bemisia tabaci and B. argentifolii) are among the most important pests worldwide, either as direct pests or geninivirus vectors. They can cause severe damage to at least 23 crops, as well as to several ornamental and wild plants. The need to develop economically and environmentally sound management systems in a coordinated manner prompted the appointment of task forces (local, regional or national level) involving researchers, extension agents, pest control advisors, growers, policy-makers, and industry representatives. In addition, both national or international networks were created in order to set research and extension agendas aimed at the development and implementation of integrated pest management (IPM). This presentation summarizes achievements in the implementation and adoption of IPM programs in North America, Mexico, Central America and the Caribbean Basin, and Israel. Despite differences in agricultural systems, as well as in cultural, educational, and economic aspects, there are several common trends, which are highlighted here. Task forces drafted action plans and defined priorities on: whitefly bioecology, geminivirus epidemiology, and management tactics (cultural practices, host-plant resistance, biological control, chemical control and insecticide resistance management), biotype and geminivirus diagnosis, training of extension agents and growers, on-farm validation and transfer of IPM tactics, and regulatory and industrial development of strategic, novel and effective insecticides. Even though accomplishments between countries have been rather uneven, in general growers are now better aware of the implications of the problem in economic, agricultural and environmental terms, and thus are more prone to adopt and implement IPM. They understand the need to look for multitactic approaches instead of a single-tactic, and are willing to participate in area-wide preventative and curative approaches. These include: quarantine regulations and cultural practices (planting dates, short-season production, weed and crop destruction, host-free periods, and avoidance of susceptible crops); other farm level exclusion practices such as seedbed or greenhouse coverage with special netting, floating row covers, and mulching; coordinated sampling and use of thresholds over large areas; and strategic or restricted use of novel insecticides in a sustainable use pattern. Despite these remarkable advances, there is still the need to increase coverage of successful IPM programs, especially by involving growers through participatory research in order to strengthen adoption and implementation of such programs.

Index terms: Whiteflies, Bemisia tabaci, Bemisia argentifolii, geminivirus, integrated pest management (IPM)

[0106] THE POTENTIAL EFFECT OF UNITED STATES LEGISLATION, THE FOOD QUALITY PROTECTION ACT, ON INTERNATIONAL TRADE

J. J. Brown, Department of Entomology, Washington State University Pullman, WA 99164-6382.

The United States Congress passed and the Food Quality Protection Act [FQPA] was signed by the President on August 3, 1996. This legislation set in motion its implementation by the Environmental Protection Agency [EPA] over a 10-year period ending in 2006. This legislation targeted pesticide residues on crops most often consumed by children, therefore much attention has and will be given to pest management practices on fruits and vegetables. The EPA announced its first implementation action on August 3. 1999; when it banned the use of methyl parathion on tree fruits and reduced the amount of azinphos methyl that can be sprayed on tree fruits each growing season from 6.0 down to 4.5 pounds of active ingredient per acre. The EPA will continue to announce implementation actions between now and August 2000, the time of the Congress. The worst case' scenario could cause major shifts in fruit and vegetable production within the United States and perhaps provide other countries a significant opportunity to market their fruits and vegetables to the United States. Within the United States, apple growers with severe pest pressure, may find that management practices without broad spectrum pesticides will limit profits to where growers might shift to alternative crops. However, the real 'winners' may be exporters to the United States. Where growers will not be restricted in management practices, their concern will be to avoid detectable residues. A practice that is well developed in many countries already, because pesticide residues on imported fruits and vegetables routinely are lower than residues detected on domestic produce. EPA's action on azinphos-methyl will have no international effect on orchard pest management, but its 'ban' on methyl Parathion could pose cause any shipment with a detectable residue to be rejected.

Index terms: Orchard Pest Management, FQPA, codling moth

[0108] THE POTENTIAL EFFECT OF UNITED STATES LEGISLATION, THE FOOD QUALITY PROTECTION ACT, ON INTERNATIONAL TRADE. THE CASE OF CHILE

R. H. Gonzalez, University of Chile, e-mail: rgonzale@uchile.cl

Chile, as a major fresh fruit exporting country from the Southern Hemisphere must meet a wide array of pesticide tolerances set by world markets. With respect to the United States, current EPA tolerances could be easily met through a national supervised scheme to establish pre-harvest intervals for each crop/registered pesticide combination. When the U.S. Congress enacted the Food Quality Protection Act (FQPA) in 1996, notwithstanding there were no provisions specifically aimed at regulating foods imported into the United States, there was an immediate local reaction to cope with impending limitations, at the same time, anticipating domestic benefits emerging from these actions. Thus, in line with planned FQPA regulatory activities, the Chilean private sector set new priorities aimed at reducing broad-spectrum pesticides, a process currently under assessment, and searching for new alternatives such as insect growth regulators (IGR's), molting accelerating compounds (MAC's) and chemicals of biological origin.New IGR's field tested include flufenoxuron, nuvaluron and fenoxycarb for early control of Cydia pomonella, a key pest of pome orchards. Among the MAC's, tebufenozide is already in full usage whilst metoxyfenozide is awaiting for registration. The insecticides of biological origin, abamectin (avermectin) and spinosad seem promising for mites and thrips control, respectively, apart from other benefits which are under evaluation. Among IPM tactics, the male confusion approach has been tried out for over a decade, testing too many formulations that the method is still far from acceptance, particularly with respect to the Codling moth. For a fruit exporting country suffering from plant quarantine barriers which do nothing but increasing pesticide usage, the adoption of a full integrated management scheme seems a heavy proposition. Zero quarantine risk increases pesticide use. not necessarily of newer, target specific compounds.

[0107] FOUR -YEARS OF FQPA: IPM CHALLENGES FOR THE US APPLE INDUSTRY

<u>L. J. Gut</u>

ABSTRACT NOT RECEIVED

[0109] POTENTIAL EFFECTS OF THE UNITED STATES FOOD QUALITY PROTECTION ACT LEGISLATION ON TREE FRUIT PRODUCTION IN BRITISH COLUMBIA, CANADA

<u>M. J. Smirle</u>, Agriculture & Agri-Food Canada, Pacific Agri-Food Research Centre, Summerland, British Columbia, VOH 1Z0, CANADA, E-mail smirlem@em.agr.ca

The United States is the largest market for exported Canadian fruit. As such, access to this market is of primary importance to Canadian producers. New legislation in the United States, the Food Quality Protection Act (FQPA), may severely limit the types of insecticides allowable for fruit grown for export, and may therefore represent a serious challenge to Canadian production practices. Tree fruit production systems, including insect control strategies, are different from region to region in Canada, and my presentation will focus on the effects of FQPA on tree fruit production in British Columbia (BC). The key pest in BC pome fruit production is the codling moth, Cydia pomonella, and historically the most widely used control chemical has been azinphos methyl. This situation has changed somewhat since the introduction of the Sterile Insect Release Program, but azinphos methyl has remained an important material for codling moth population supression prior to sterile insect release and for control of leafrollers (Tortricidae). Application rates of azinphos methyl are lower in BC than the Environmental Protection Agency (EPA) tolerances, with currently recommended label rates of 1.4-2.2 kg/ha for codling moth and 1.4 kg/ha for summer leafroller control on apples. However, it remains to be seen how the reduced tolerances imposed by the EPA for use by US growers will translate to azinphos methyl tolerances on apples imported from Canada. It is also likely that moves to restrict the use of azinphos methyl and other organophosphates in the US will affect the availability and cost of these materials. An additional important factor in determining the potential effect of FQPA will be the availability of mite control products that are compatible with the current BC program of biological control. Currently, predaceous mites are resistant to organophosphates, which can be used to control other insect pests without disrupting biological mite control on apples. This program is vital to advances in integrated pest management, and the effect of having to move to other classes of insecticides, such as pyrethroids, would have serious consequences. The FQPA legislation in the US will have important effects on tree fruit production in western Canada, as it will on other fruit growing areas worldwide, but it is also true that advances in and particularly grower adoption of integrated pest management systems often come as the result of "having no choice". Those producers wishing to continue to export their fruit to US markets will be forced to change the way they have traditionally controlled their insect pests. The consequences of this will hopefully be the adoption of more advanced and sustainable integrated pest management systems. Index terms: Cydia pomonella, FQPA, tree fruit IPM, organophosphates.

[0110] THE NEW ZEALAND APPLE INDUSTRY: THE AGROCHEMICAL AND PHYTOSANITARY CHALLENGES FOR GLOBAL EXPORTS

J.T.S. Walker, HortResearch, Private Bag 1401, Havelock North, New Zealand.

New Zealand produces 1% of the global apple crop with 90% of this production shipped to over 60 countries, primarily through the exporter, ENZAFRUIT. Europe and North America are important markets with about 25% of our production reaching the US market. The paradoxical relationship between international quarantine requirements and regulatory and market demand for lower pesticide residues, required development of two different pest, and pesticide, risk management strategies for these markets. In 1996 the apple industry began to develop an Integrated Fruit Production (IFP) programme to meet EU supermarket requirements of food safety and environmental integrity. During this development we identified alternative pesticides to replace classes such organophosphates (OPs), which we considered to be 'at-risk' pesticides under developing US Food Quality Protection Act (1996) legislation. This IFP programme, covering many aspects of orchard management, led to development of an apple pest management programme based on selective insecticides, such as buprofezin, tebufenozide and lafenuron. Pest thresholds were developed and IFP programme information documented in industry manuals. Implementation followed in 1997 with consultant and grower training programmes. Growers were required to monitor pest populations and maximise use of biological control by using these insecticides only when justified. During implementation, industry-wide pest risk analyses were undertaken to refine recommendations for specific markets. This included a lower threshold for leafroller activity in crops destined for the US due to stringent quarantine requirements. Using this process, the confidence of growers, exporters and regulatory authorities developed in IFP pest management as evidenced by 85% industry-wide adoption by 2000. Since the introduction of IFP the frequency of insecticide use has decreased by 49%, OP use by 82% and azinphosmethyl use by 97% when compared to traditional programmes. US quarantine requirements have limited insecticide reductions in crops intended for that market but, a variant of the programme for US market crops (IFP-USA), has still seen OP and azinphosmethyl use decline by 58% and 78% respectively. Other pest risk reduction procedures, such as apple washers and modified storage regimes, have been introduced to further reduce reliance on OP insecticides to meet quarantine requirements. The low level of OP use remaining (primarily chlorpyrifos and diazinon for control of mealybugs and scale insects) is targeted for elimination within two years. New products and tactics for the control of pests are presented within the context of New Zealand's readiness for the further implementation of the Food Quality Protection Act (1996).

Index terms: organophosphates, residues, pest risk, IFP adoption

[0111] THE POTENTIAL EFFECT OF UNITED STATES LEGISLATION, THE FOOD QUALITY PROTECTION ACT, ON SOUTH AFRICAN FRUIT EXPORTS

M. F. Addison, Hortec, P.O. Box 1231, Stellenbosch, 7599, South Africa, e-mail matthew@hortec.co.za.

The potential impact of the Food Quality Protection Act (FQPA) on fruit exports from South Africa is vast. Deciduous fruit and citrus make up the bulk of exports and South African fruit is sold in approximately 70 countries world wide. Europe has been the principle market for South African fruit where an estimated 80% is sold annually. After 1993, with the lifting of trade sanction and the resumption of fruit exports to North America, approximately 10% of fruit exports are directed to this market. The FOPA has a direct impact on pest management practices within the South African fruit industry. The example pest management in apple and pear production illustates this. Due to the marketing strategy of selling fruit in a number of countries, including Europe and North America, pesticide application programs have to accommodate a number of residue standards. The restrictive nature of the FQPA dictates that a limited number of pesticides are available for use on export crops. While this limits the number and type of pesticides applied, it also excluded the use of more recently developed pesticide groups such as certain insect growth regulators. The developing problem of insecticide resistance in codling moth (Cydia pomonella) populations poses a unique threat to the industry Resistance to organophosphate insecticides is widespread and resistance management programmes require the use of alternative pesticides. Thus fruit produced in orchards under resistance management programmes is withdrawn from export to North America. The future export of apples and pears from South Africa to the North American market will depend on the FQPA. The loss of certain key pesticides would result in South African fruit exporters withdrawing from the North American market. Index terms: FQPA, South Africa, Cydia pomonella, insecticides

[0112] OVERVIEW OF FDA's PESTICIDE RESIDUE MONITORING PROGRAM

<u>Y. H. Lee</u>, P. M. Bolger & T.C. Troxell, Office of Plant and Dairy Foods and Beverages, Center for Food Safety and Applied Nutrition, U.S. Food and Drug Administration, 200 C Street (HFS-308), Washington, DC 20204, USA.

The US Food and Drug Administration (FDA) shares responsibility with two other federal government agencies for the regulation of pesticides. The US Environmental Protection Agency (EPA) registers the use of pesticides and also sets tolerances (the maximum amount of residue that is permitted in or on a food), if use of that pesticide may result in residues in or on food. FDA is responsible for enforcing these tolerances in imported and domestically produced food shipped in interstate commerce, except for meat and poultry for which the U.S. Department of Agriculture is responsible. FDA's pesticide residue monitoring program consists of three approaches; regulatory monitoring, incidence/level monitoring, and the Total Diet Study (TDS). FDA's regulatory monitoring program is conducted under the guidance of the Center for Food Safety and Applied Nutrition, FDA. Domestic foods are collected as close as possible to the point of production in the US; import samples are collected at the point of entry into the US. Emphasis is on raw agricultural products, which are analyzed unwashed and whole (unpeeled); however, some processed foods are also included. If illegal residues (above tolerance or no tolerance for particular food/pesticide combination) are found in domestic samples, FDA can invoke sanctions such as a seizure or injunction. For imports, shipments may be stopped at the point of entry when illegal residues are found. "Detention without physical examination" may be invoked based on the finding of one violative shipment, if there is reason to believe that the same situation will exist in future lots during the same shipping season for a specific shipper, grower, geographic area, or country. Factors considered by FDA in planning the types and numbers of samples to collect include review of recently generated state and FDA residue data, regional intelligence on pesticide use, dietary importance of the food, information on the amount of domestic food that enters interstate commerce and of imported food, chemical characteristics and toxicity of the pesticide and production, Incidence/level monitoring is a complementary approach to the regulatory monitoring, This approach is used to increase FDA's knowledge about particular pesticide/commodity combinations by analyzing certain foods to determine the presence and levels of selected pesticides. The TDS is an annual market basket program that provides data on pesticide levels that are present in table-ready foods; the data also enable us to estimate dietary exposure in specific age-sex groups in the US. Findings of FDA's residue monitoring will be discussed.

Index terms: pesticide residue monitoring, Total Diet Study, FDA.

[0113] PARTICLE PROCESSING

D. G. Sekutowski, Engelhard Corporation, 101 Wood Ave, Iselin, NJ USA 08830.

The mineral Kaolin is the active ingredient in the majority of the papers presented during this symposia session. Many of the chemical and physical properties of mineral particles can be engineered during processing. A review of kaolin processing is given demonstrating how various particle properties are controlled or modified to yield particles with enhanced performance. A brief overview of kaolin safety and industrial markets is also provided.

Index terms: kaolin, mineral

0114] PARTICLE FILM TECHNOLOGY FOR CONTROL OF ARTIIROPOD PESTS AND DISEASES IN PLANTS

G. J. Puterka & D. M. Glenn, USDA-ARS, Appalachian Fruit Res. Stn.,45 Wiltshire Rd.,Kearneysville, WV, 25430 USA, E-mail: gputerka@afrs.ars.usda.gov.

Particle film technology was recently developed at ARS, Kearneysville, as a method for controlling arthropod pests and diseases of agricultural and horticultural crops. The film is based on the inert mineral, kaolin, that is purified has had its size and shape specifically modified, to enable it to coat plants with a protective barrier that will not interfere with photosynthesis. The hydrophobic kaolin particle, M-96-018, was the first prototype of particle film technology applied to trees as dust to make the plant surfaces water repellent. This material suppressed arthropod pests and diseases by a number of different mechanisms. Fungal and bacterial diseases that require moisture to become infective were suppressed by coating the plant with a hydrophobic particle film barrier that prevented disease inoculum or water from directly contacting the leaf surface. Arthropod infestations were suppressed by particle films for several reasons. Plants coated with a hydrophobic particle film barrier become visually or tactilely unrecognizable as a host. In addition, insect movement, feeding, oviposition, and other activities can also be severely impaired by the attachment of particles to the arthropods bodies as they crawled upon the film. Dust applications of particle films were not practical because of drift and lack of particle adhesion to the plant surfaces. For this reason, our research on particle film formulations was directed toward the development of kaolin particles suspended in water so these formulations could be applied with conventional spray equipment. Tests comparing hydrophobic and hydrophilic particle films found that both insects and diseases were controlled equally by both types of films, indicating that only a physical barrier of hydrophilic kaolin was required. However, particle film mineral type and formulation was found to affect arthropod species differently with regard to survival, oviposition, and particle attachment to the arthropod cuticle. Particle films have been field tested for seveal years and many types of arthropod pests have been controlled in a variety of crops. Index terms: dust, kaolin, barrier, repellent

[0116] PARTICLE FILM TECHNOLOGY DEVELOPMENT IN CHILE

<u>E Prado</u>, Inst. de Investigaciones Agropecuarias, INIA. Casilla 439-3, Santiago, Chile. Email: eprado@platina.inia.cl.

Since 1996 field trials have been conducted in Chile to develop Particle Film Technology. Pest control was target at the beginning by means of hydrophobic kaolin. Codling moth and mite control on fruit trees was successfully achieved in organic and commercial conditions. Subsequent seasons included different formulations of hydrophilic particles. These formulations provided a substantial mite control (Panonychus ulmi and Brevipalpus chilensis), on fruit trees and grapevines respectively, but continuous monitoring is necessary. Despite of mite presence on almond trees, leaves kept longer on the tree, making them presumably more resistant to mite attack. Codling moth suppression was also achieved but last generation should be conventionally treated. Scales (Saissetia olene, Lepidosaphes ulmi and Quadraspidiotus perniciosus) and woolly apple aphid were not controlled and particle interfering with natural enemies may cause an increase of these pests. Further research is needed to assess the effect of kaolin on natural enemics. Vegetable pests have been more difficult to control due to the poor coverage of the lower part of the plant and the underneath of the leaf. Pest suppression has been achieved on South American Tomato Pinworm (Tuta absoluta) and leafminers (Liriomyza huidobrensis). Also potato tubers mixed with kaolin avoided potato tuber worm attack on storage conditions. However, twospotted mite (Tetranychus urticae) was not controlled on pepino fruit (Solanum muricatum) and aphids population increased on kaolin treated sweet pepper plants because aphids aggregated on uncovered leaves and apparently because of a detrimental effect of kaolin on aphid natural enemies. Leaves covered with kaolin have lower temperature than uncovered ones and light incidence is reduced. By consequence, pesticide degradation rate could be affected modifying residual activity and pre-harvest interval. Degradation rate was tested in applications of kaolin mixed with insecticides azinphos methyl and dimetoate. No change was found on residues and degradation rate. At the same time, horticultural benefits as better color and sunburn protection were observed on apples, plums and cherries. Main troubles with the new technology appeared to be an uneven coverage with the usual farm turbo sprayer, if this is not correctly regulated, and avoiding kaolin spots on some fruits producing a "green spot". In addition, the formulation to be used must permit an easy washing off of the fruit in the packing line. Further research is carried out to reduce the number of sprayings, doses and an improved coverage.

Index terms: kaolin, pest control, fruit quality, mites, moths

[0115] BENEFICIAL PHOTOSYNTHETIC AND HORTICULTURAL EFFECTS OF PARTICLE FILM APPLICATIONS ON PLANTS: DESTROYING THE DOGMA OF THE NEGATIVE EFFECTS OF DUSTS ON PLANTS

D.M. Glenn & G. Puterka, USDA-ARS Appalachian Fruit Research Station. Kearneysville, WV 25430, USA, Email: mglenn@afrs.ars.usda.gov.

Particle film technology utilizes inert mineral particles to envelope a plant in a protective and porous "particle film". Being porous, the particle film allows free exchange of water and carbon dioxide from the leaf during photosynthesis. The white mineral particles are reflective of infrared radiation and reduce the heat load on the plant. Laboratory, greenhouse, and field trials demonstrate that particle film technology is a viable pest control practice for a wide range of insect and disease problems with additional horticultural benefits due to reduced heat stress. In field studies, reducing heat stress improved red apple color development while reducing sunburn damage and increased photosynthetic rates, yield, carrying capacity, and return bloom. These horticultural benefits demonstrate that particle film technology is not just limited to pest control. Particle films have the added benefits of reducing plant heat stress and improving safety to farm workers, consumers and the environment.

[0117] EFFICACY OF PARTICLE FILMS TO CONTROL TRIBOLIUM SPP. IN MILLS AND FOOD STORAGE FACILITIES

F. II. Arthur & G. J. Puterka, USDA, ARS, Grain Marketing & Production Research Center, 1515 College Ave, Manhattan, KS 66502, USA, E-mail arthur@usgmrl.ksu.edu. USDA, ARS, Appalachian Fruit Research Laboratory, 45 Wiltshire Rd, Kearneysville, WV 25430, USA, E-mail GPuterka@afrs.ars.usda.gov.

Experimental particle films have been developed that will repel or control insect pests in several different agricultural systems. These materials are similar to insert dusts, and were tested for activity toward two stored-product beetles, *Tribolium castaneum* (Herbst), the red flour beetle and *Tribolium confusum* (DuVal), the confused flour beetle. Studies were conducted to determine application rates and exposure intervals required for control, relative susceptibility of the 2 species, effects of environmental conditions on product efficacy, and recovery after exposure. Results for one particle film were comparable to a labeled formulation of diatomaceous earth containing silica. *T. confusum* was less susceptible than *T. castaneum*, and mortality of both species decreased as relative humidity increased. Mortality of *T. castaneum* that were not given food after they were exposed decreased as the original exposure interval increased. However, when given food after exposure, survival of *T. castaneum* was virtually 100% regardless of how long they were exposed to the narticle film.

Index terms: stored products, particle film, dust, *Tribolium confusum*, confused flour beetle, *Tribolium castaneum*, red flour beetle, food, recovery

[0118] POTENTIAL OF KAOLIN BASED PARTICLE BARRIERS FOR TERMITE CONTROL

W.D. Woodson & B.A. Wiltz, USDA-ARS, Southern Regional Research Center, 1100 Robert E. Lee Blvd., NewOrleans, LA,USA, 70179-0687, E-mail: dwoodson@nola.srrc.usda.gov

Recently a particle film technology was developed at ARS, Kearneysville, as a method for controlling arthropod pests and diseases of agricultural and horticultural crops. The film is based on the inert mineral, kaolin, that is purified has had its size and shape specifically modified, to enable it to coat plants with a protective barrier that will not interfere with photosynthesis. Effects of three of these compounds, M-96-018, M-97-009, and Surround WP on tunneling and survival of Formosan subterranean termites, Coptotermes formosanus Shiraki, were determined by a choice test, forced exposure and indirect exposure laboratory bioassays. In the choice test C. formosanus was presented with two 2.5 x 2.5 x .05 cm pieces of southern yellow pine, one treated with one of the kaolin products the other untreated. Mean consumption was significantly different between the treated and untreated wood after 21 days of exposure. There were no significant differences between M-96-018, M-97-009 and Surround WP in the amount of wood consumed over the duration of the study. In the indirect exposure assays, termites were given the choice of tunneling through sand treated with each compound to reach a supplemental food source. Although C. formosanus was unable to tunnel in sand containing 1% M-96-018, this concentration did not prevent it from tubing over the treated sand to reach the supplemental food supply. At the 5% concentration of M-96-018 C. formosanus was unable to either penetrate or tube over the treated soil. Index terms: Coptotermes formosanus, dust, pest suppresson, termite.

[0120] SELECTIVE USE OF PARTICLE FILM TECHNOLOGY IN WASHINGTON POME FRUIT PEST MANAGEMENT

E. H. Beers¹, J. F. Brunner¹, J. E. Dunley¹ & M. Doerr¹, ¹Dept. of Entomology, Washington State Univ., Tree Fruit Research & Extension Ctr., 1100 N. Western Avc., Wenatchee, WA USA 98801 E-mail: cbcers@wsu.edu.

Much of the research to date on particle film technology (PFT) has focused on seasonal programs and their effect on the pest spectrum. The focus of this research was to partition out the effects on various pests to better integrate PFT with existing strategies and technologies and mitigate any undesirable effects. PFT applications targeting the oviposition period of Washington's key apple pest, codling moth, were equally effective as applications directed at the hatching neonates. The same strategy was tested with a noctuid pest, Lacanobia subjuncta. Both oviposition and hatch applications provided some suppression, but the hatch period appeared to be the more critical of the two. In a choice test, larvae of both species of leafroller tested (Choristoneura rosaceana and Pandemis pyrusana) in addition to those of L. subjuncta, avoided PFT residues on foliage in a choice test; however, leafroller larvae were able to successfully utilize any discontinuities in residue coverage. Field tests against C. rosaceana using PFT during the oviposition and hatch period (total of 6 applications) provided good control of this pest. PFT applications suppressed nymphs of white apple leafhopper (Typhlocyba pomaria), but provided no control of twospotted spider mite or first generation western tentiform leafminer (Phyllonorycter elmaella). PFT appeared to suppress phytoseiid mites and their alternate prey, eriophyid mites. This is a possible explanation of the increased levels of tetranychid mites seen in some plots. A prebloom program of PFT targeting pear psylla (with a standard program after bloom) was successful in preventing fruit damage by this pest; however, a postbloom-only or seasonal program of PFT had unacceptable amounts of fruit damage. PFT may have a uniquely useful effect on the expression of damage by mite-susceptible pear cultivars. It appeared to reduce transpiration burn, thus possibly raise the economic injury level and allow more latitude for biological mite control. Index terms: Cydia pomonella, Tetranychus urticae, Cacopsylla pyricola, Tetranychus urticae, Panonchyus ulmi

[0119] MULTIPLE USES OF PARTICLE FILMS IN PEAR PEST MANAGEMENT

R. J. Hilton, Southern Oregon Research & Extension Center, Oregon State Univ., 569 Hanley Rd., Medford, OR 97502, USA.

Particle film formulations were tested on pear in southern Oregon from 1997 through 1999. Field tests included replicated handgun applications to single trees conducted at the Research Center, and air-carrier sprayer applications conducted at the Research Center and in commercial orchards. Repeated applications of the particle films in the foliar period resulted in control of pear psylla-and pear rust mite. Particle film treatment resulted in a significant reduction of codling moth entries. No significant differences were observed between a hydrophobic and a hydrophilic formulation when they were compared in 1998. In some cases, an increased level of twospotted spider mite was observed while predator mites were almost totally absent from the particle film treated trees. Laboratory tests showed little effect of a particle film treatment with respect to twospotted spider mite mortality or oviposition behavior, while another laboratory study demonstrated that pear psylla oviposition was decreased on dormant pear wood which had been treated with a particle film. Particle film treatment improved fruit finish, reducing both sunburn and overall russet on pear fruit.

Index terms: Cacopsylla pyricola, Cydia pomonella, Epitrimerus pyri, Tetranychus urticae, oviposition behavior.

[0121] EVALUATION OF SEASONAL PARTICLE FILM SPRAY PROGRAMS IN A WESTERN APPLE ORCHARD

A.L. Knight¹, <u>G. Puterka²</u> & B. A. Christianson¹, ¹USDA-ARS, Fruit and Vegetable Research Laboratory, 5230 Kannowae Pass Rd., Wapato, WA 98951 aknight@yarl.ars.usda.gov; ²USDA-ARS, Appalachian Fruit Research Station, 45 Wiltshire Rd., Kearneysville, WV 25430 gputerka@afrs.ars.usda.gov.

Studies were conducted in a north central Washington apple orchard in 1998 and 1999 to evaluate the impact of seasonal spray programs of the kaolin-based particle film (PF) hydrophobic formulation, M96-018, on orchard pests, natural enemies, and fruit quality. We evaluated a half- and full-season PF spray program versus an untreated control in 1998, and during 1999, we compared plots treated with one or two years of PF, plots treated the year before with PF, and plots left untreated. PF treatments in both years significantly reduced populations of fruittree leafroller (FILR), Archips argyrospilus (Walker), white apple leafbopper, Typhlocyba pomaria (McAtee) and mullein bug, Campylomma verbasei (Meyer). Stink bug population densities (Euschistus conspersus Uhler and Acrosternum hilare (Say)) were unaffected by PF applications. PF treatments reduced the density of the most abundant generalist predator species, such as spiders and ants, while coccinellids and the earwig, Forficula auricularia L., were not affected. Parasitism of western teniform leafminer Phyllonorycter elmaella (Doganlar & Mutuura) was significantly reduced and the density of mines per leaf were also higher on PF treatments compared with the untreated control. Levels of fruit injury from San Jose scale (SJS) Quadraspidiotus pernicious (Comstock), were significantly higher in PF treatments in 1998, however the use of chlorpyrifos in the spring in 1999 subsequently controlled SJS in all plots. FTLR injury was significantly reduced in 1998 in PF treatments and was significantly lower in plots treated with PF for two years in 1999 at harvest. Nocturd fruit worm injury was significantly lower in the mid-season sample in the PF-treated plots. Fruit size was increased in PF-treated versus untreated plots in both years. Soluble solids were increased in 1998 in the full season PF program.

Index terms: kaolin, pest suppression, natural enemies, barrier, repellent

[0122] USE OF KAOLINIC PARTICLE FILM IN A CITRUS IPM PROGRAM

D. L. Kerns, Dept. of Entomology, Univ. of Arizona, Yuma Agricultural Center, 6425 W. 8th St., Yuma, AZ 85364, USA, E-mail dkerns@ag.arizona.edu.

Citrus thrips, Scirtothrips citri, is the most economically damaging insect pest affecting Arizona citrus. Although the feeding action of citrus thrips can leave citrus leaves highly distorted, it's the scarring of the fruit rind that is of the most economic concern, leaving the fruit unsuitable for fresh market. Traditionally, broad spectrum insecticides have been extensively utilized for managing citrus thrips in Arizona citrus. Chemical control of thrips is costly, sometimes ineffective or short lived, and often results in outbreaks of secondary insect pests and mites. Kaolin (Surround WP) is a mineral particle with insect management potential. It is a highly refined, white, non-abrasive, nonporous, aluminosilicate mineral manufactured by Engelhard. When sprayed on plant surfaces it is similar in appearance to whitewash materials used to protect foliage from sunburn. Kaolin appears to offer insect control through visual repellency, by acting as a physical barrier, and by disrupting insect behavior after attachment to the insect's cuticle. Kaolin has been shown to effectively suppress a number of insect pest in a variety of crops. In field trials on lemons in Arizona, kaolin maintained citrus thrips populations below 3% infested fruit, while a untreated control exceeded 33% infested fruit. At harvest, trees treated with kaolin produced 95% fancy grade lemons, while the untreated control produced 50% fancy fruit. For thrips management in citrus, kaolin should be applied preventively. Treatments should be applied before thrips are numerous, and near petal fall or before fruit set. Additional treatments are necessary to insure coverage of new growth and expanding fruit until the fruit reaches 2.5 cm in daimeter. In addition to citrus thrips control, kaolin may also aid in the tree's heat stress management resulting in higher yeilds. Index terms: Scirtothrips citri, citrus, kaolin, particle film

[0124] CONSERVATION TILLAGE: PHYSICAL CONTROL AT THE LANDSCAPE SCALE

B. R. Stinner

[0123] LITTLE UNDERSTOOD AND DIFFICULT TO MANIPULATE, THE OLDEST CLASSICAL TACTIC HAS UNTAPPED POTENTIAL

M. E. Irwin, Dept. Nat. Resources & Environ. Sci., Univ. Illinois at Urbana-Champaign, 1101 W. Peabody Dr., Urbana, IL 61801, USA .Email: mirwin2@uiuc.edu

Integrated pest management (IPM) implies a set of principles for reducing pest populations in an economically sound and environmentally friendly manner. IPM can be thought to have three organizational levels: a basic knowledge bank; the weaponry to suppress pest populations; and the capacity to deploy these weapons to manage pest complexes. The knowledge bank consists of fundamental information; each category of weaponry is termed a tactic; and putting these tactics to use invokes a management strategy. Several categories of tactics exist; the major ones include host resistance, chemical control, biological control, legal control, and cultural control. Molecular or genetic mechanisms are potentially manifest in several of these tactics. Each category of tactic employs a set of mechanisms for suppressing populations. This symposium focuses on the tactic of cultural control at the landscape scale and explores approaches to ensure that this, the oldest classical tactic, can be both potent and flexible at the larger spatial scales when devising pest management strategies. Cultural control, often taking the form of selected cultural practices or specific manipulations of the habitat, often renders a habitat more favorable to natural enemies or less favorable to pests. At the larger spatial scales, it can also concentrate pests in areas where they do little damage to the target crop by attracting them (e.g., trap cropping) or repelling them (e.g., intercropping in some cases). Designed to disfavor pests and ultimately reduce their ability to cause damage, this ecological approach relies a great deal on behavior responses of target species and requires a solid understanding of how pests and natural enemies respond to changes in the habitat structure, including fragmentation. These larger scale practices can take advantage of temporal windows for planting, cultivating, and harvesting. Similarly, spatial patterns of crop mosaics might be utilized to "hurd" pests to areas where they will do less damage. Both spatial and temporal larger scale manipulations aree considered.

Index Words: IPM, cultural_control, landscape_scale, spatial, temporal.

[0125] LARGE TACHINID PARASITOIDS RESPOND TO HABITAT STRUCTURE AT LARGER SPATIAL SCALES

J. Roland, Department of Biological Sciences, University of Alberta, Edmonton, T6G 2E9. Alberta, and P.D. Taylor. Department of Biology, Acadia University, Wolfeville, Nova Scotia, Canada, B0P 1X0.

We estimate the effect of forest fragmentation on rates of parasitism caused by four species of fly parasitoid attacking the forest tent caterpillar. Parasitism by each species was estimated from collections of host larvae and pupae from 130 population sites across and area of 400 km². Parasitism rates for each species was related to the degree of forest fragmentation at each site. Because the level of fragmentation was estimated at multiple scales (form 53m to 1700m) around each site, we could determine at which scale forest structure affects each fly species most. Supporting data suggest that the scale at which each species is affected by forest structure is in part determined by the scale over which they normally move. For most parasitoid species, forest fragmentation reduces the rate of parasitism, and those thought to move the most are affected by fragmentation measured at larger spatial scales.

Index terms: dispersal, fragmentation, spatial scale, tachinid, parasitoid

[0126] CROPPING PATTERNS, A LANDSCAPE PERSPECTIVE OF CULTURAL CONTROL

G.P. Fitt & M.L. Dillon, Australian Cotton Co-operative Research Centre, CSIRO Entomology, P.O. Box 59, Narrabri NSW 2390, Australia. Email: gary.fitt@ento.csiro.au.

Integrated pest management seeks to optimise the use of a range of complimentary control tactics to achieve management of key pests. Cultural controls, which may involve physical disturbance, crop rotations, intercropping, trap cropping among others, is one IPM component receiving increasing attention from researchers and producers. The significance of this work from a landscape perspective will be illustrated by focussing on a key pest of multicropping agricultural systems. As significant pests of many agricultural systems around the world, Helicoverpal Heliothis species (Lepidoptera: Noctuidae) are the focus of considerable basic and applied research. The ecological attributes of high mobility and polyphagy which characterise the pest species of Heliothines demand that population management operates at the regional, rather than field scale. Adult mobility of pests like Helicoverpa introduce considerable complexity to their dynamics and genetic structure since populations defined at any scale (field, ecosystem, region) can be comprised of individuals with differing ecological attributes which have developed on different hosts or have moved from different populations With increasing understanding of their population ecology, a range of cultural tactics are now being developed and implemented for use in area-wide systems for population management and resistance management. Several of these involve manipulation of the cropping system at varying scales to modify the suitability of the crop environment for pests by introducing trap crops, refuge crops, predator nurseries. Some examples of these cultural controls in cotton systems will be discussed.

Index Words: Helicoverpa, IPM, cultural_control.

[0128] INTERACTIONS BETWEEN PREDATOR SPECIES, THEIR PREY AND THE HOST PLANT

S. D. Wratten & C. N. Merfield, Ecology & Entomology Group, Soil, Plant & Ecological Sciences Division, P.O. Box 84, Lincoln University, Canterbury, New Zealand.

Most studies on invertebrate predation concern single predator or parasitoid species and evaluate their behaviour and ecology with little consideration of other natural enemies in the same or different guild, or of tri-trophic-level effects between plant, prey/host and the natural enemy. In many agricultural habitats however, there may be hundreds of natural enemy species potentially interacting and the crop itself may respond to herbivore feeding via wound-induced changes in plant defences. The interaction between the plant, the herbivore and the predator can therefore involve "top down" (ie predator) and/or "bottom up" (ie plant) effects on the herbivore population. This paper will explore two systems in which these interactions have been recently studied. The first is tomato/caterpillar/predatory carabid interaction while the second concerns commensal relationships between predatory arachnid species. Work on the lepitopteran Spodoptera litura on tomato (Lycospersicon esculentum) and the non-climbing carabid predator Megadromus antarcticus showed that the carabid increased S. litura mortality with a subsequent decrease in leaf damage. Leaf wounding produced a possible decrease in herbivory and there was a trend for the presence of the carabid on the soil to interact with wound-induced changes in the plant; the latter caused a higher proportion of lavac to move to the soil surface, where they were available to the epigeal predator. Using time-lapse video techniques in the field and in the laboratory showed that when some predatory mite species (whirlygig mites: Anystis spp. and mites in the super-family Erythraeoidea) had pierced a dipteran egg, the latter was more likely to be predated by harvestmen (Arachnid: Opiliones). The latter type of commensal interaction, between predators in the same guild with similar feeding mechanisms, has been very rarely demonstrated in predator-prey systems and maybe more common among predators in cropping systems than previously assumed.

[0127] PLANT VIRUS EPIDEMICS. CAN CULTURAL PRACTICES HELP CURB THIS LOOMING THREAT TO MODERN AGRICULTURE?

A. Fereres, Dept. of Plant Protection, Centro de Ciencias Medioambientales, CSIC. Serrano 115 dpdo., 28006 Madrid, Spain, Email: afereres@ccma.csic.es

Most of the known plant viruses causing economic damage are transmitted by insect vectors. Plant viruses depend in one way or another on insects or seeds for their dispersion and spread. Therefore, insect movement and dispersal modulate the temporal and spatial scale of virus epidemics. Sometimes, virus outbreaks are associated to high vector population densities such as the case of viruses that are transmitted in a persistent fashion. However, in many cases viruses are transmitted by transient insects that may never be seen by the farmer because they remain for a very short period of time in the crop. This is the case of the widely spread nonpersistent viruses that are exclusively transmitted by aphids during very brief superficial probes lasting only few minutes. There are a number of cultural control options that theoretically can be used to prevent and reduce the spread of plant viruses. Sometimes, slight modifications of specific crop managment practices (e.g., irrigation, plant density, tillage, chemical applications of synthetic fertilizers and pesticides) may have a direct effect on vector ecology and its associated natural enemies, and hence will influence the rate or timing of virus epidemics. In this sense, the agroecosystem can be manipulated to favor natural enemies or/and disfavor insect pests. Some of the cultural control measures concentrate on removing sources of inoculum (crop volunteers, weed reservoirs, infected seeds or vegetative stocks, etc...), or by avoiding the periods of maximum risk of infection (changing the sowing or harvesting date, changing to a cultivar with a different growth cycle, etc...). Some other control tactics are designed to interfere with the main vectors of plant viruses by modifying their behavior and preventing alighting on the protected crop. Thus, physical barriers (natural or artificial) can significantly reduce the number of insect vectors alighting on the crop. Under greenhouse conditions, several kinds of physical barriers such as insect-proof screens or UV-absorbing plastics have given very promissing results. Also, agrotextile row covers can reduce the spread of several viruses infecting horticultural crops. However, before implementing specific cultural measures to control plant viruses they should be analyzed together with economic and environmental considerations. The viability and compatibility of integrating cultural options to control virus diseases under the scope of other crop management strategies will be discussed.

Index terms: vector, physical barrier, row cover

[0129] LANDSCAPE LEVEL CULTURAL CONTROL: FUTURE PROSPECTS AND LIMITATIONS

<u>M. P. Zalucki¹, M. Miles², D. A. II. Murray² & Wayne Rochester¹, I. Department of Zoology and Entomology, The University of Queensland, Australia, 4072, Email: M.Zalucki@mailbox.uq.edu.au; 2. Farming Systems Institute, Queensland Department of Primary Industries, Toowoomba, Australia, 4350.</u>

Cultural control is part of all pest management systems as it involves activities that are central to agricultural practices at a landscape level. Physical disturbance of the soil as part of ploughing, normal crop rotations, intercropping, refuge crops, and trap cropping (even if these are just alternative hosts) impinge on the distribution and potential abundance of pest species. Increasingly such practices are being advocated as a deliberate ploy to manipulate the agricultural habitat of pests and their natural enemies to make it less favourable to the former. This approach is thought to be particularly useful for polyphagous mobile species such as heliothis, for which standard IPM at the field level is likely to be ineffective. We present a case study of Area Wide Management of Helicoverpa spp. on the Darling Downs in Queensland, Australia. The future of landscape level cultural control will hinge on our ability to assess the impact of any implemented practices. Thus trap cropping may sound plausible but does it make any difference to pest pressure, and how can such impacts be assessed? Increasingly landscape level control will require more detailed information on potential pest pressure and current pressure mapped over the region. Such an approach will demand data sharing among farmers, consultants and researchers as well as ready access to rapid analysis of the changing pest landscape. The problem of suitable 'controls' on which to judge the success of Area Wide Management is discussed. Perhaps there will be a use for "predictive" models after all. The future prospects and constraints to cultural control at a landscape level are discussed in relation to trap cropping, which attempts to implement our detailed understanding of moth behaviour to manipulation of adults moths at a local level leading to regional impacts on abundance.

Index terms: *Helicoverpa* landscape management, IPM, scientific controls, models, data sharing, analysis tools.

Symposium and Poster Session

[0130] TOWARDS INSECTICIDE-FREE VITICULTURE IN AUSTRALIA AND NEW ZEALAND

<u>P.T.Bailev</u>¹ & D.M. Suckling², ¹South Australian Research & Development Institute, Entomology Section, Waite Campus, GPO box 397, Adelaide South Australia 5001. Austrália, E-mail: bailey.peterT@saugov.sa.gov.au; ²HortResearch, PO Box 51, Lincoln New Zealand. e-mail: msuckling@hort.cri.nz

There are few major arthropod pests of wine grapes in Australia and New Zealand, and synthetic insecticides are rarely used. Consequently there is no history of insecticide resistance, and pests can be managed with selective inputs in both countries. In Australia, the grapeleaf blister mite, Colomerus vitis, is a widespread pest, controlled by a combination of sulphur at budburst, and predators. The use of some newly-available fungicides appears to be related to increasing bud damage by this mite, perhaps because their natural enemies have been suppressed. Another key pest, the lightbrown apple moth, Epiphyas postvittana, is controlled by natural enemies and the hot summers of inland areas. In New Zealand vineyards, this insect is generally controlled by one or two Bacillus thuringiensis sprays. Native New Zealand leafrollers are seldom detected in this crop, although they do pose problems for many other horticultural crops. Few vineyards choose to control mealybugs (several Pseudococcus species), although this group can vector grapevine leafroll disease, mainly in the North Island. There has been only limited research on vineyard pests in New Zealand, with most research focussed on diseases. Most Australian vineyards can actively conserve beneficial arthropods by avoiding cover sprays of synthetic insecticides, and use of pheromones for mating disruption, Bacillus thuringiensis or Trichogramma spp. to control lightbrown apple moth, with toleration of some yield loss. However, conservation of natural enemies may be threatened by a number of factors. The high value of wine grapes means that managers are less prepared to accept some losses caused by lightbrown apple moth, and organophosphate use on plantings in some cool viticultural areas is increasing. Fungicide use needs to be integrated into a vineyard pest management program. Some observers note that insecticide use may increase in some vineyards from fears that (yet to be identified) insect vectors are spreading Australian grapevine yellows and grapevine leaffoll disease, and more work is needed on potential vectors of these diseases.

[0131] THE ROLE COVER CROPPING IN VINEYARD IPM

<u>K.M. Daane</u>¹, M.J. Costello² & G.Y. Yokota¹, ¹Div. Insect Biol. (ESPM), Univ. of California, Berkeley, CA 94706, USA, daane@uckac.edu; ² Costello Agricultural Research & Consulting, PO Box 165, Tollhouse, CA 93667 USA

Many California grape growers are managing floor vegetation as one component of their IPM program. Here, we present data from 1993 to 1996 studies in California vineyards testing effects of cover cropping on pest and beneficial insects and vine health parameters. The target pests were leafhoppers (Erythroneura variabilis and Erythroneura elegantula), which cause direct damage to grape leaves through feeding and indirect damage from accumulated honeydew. Results show third generation nymph densities were commonly lower (about 15%) in cover crop treatments at juice, table and wine grapes, but not in the raisin grapes. Research sought to determine how cover crops affected leafhopper densities, focusing on both biotic and abiotic leafhopper mortality factors. There were no consistent differences in the number of mymarid egg parasitoids, Anagrus erythroneurae and Anagrus daanei (formerly grouped as Anagrus epos) between ground cover treatments. The predator community on the vines is dominated by various spider species, which composed >90% of the predators which fed on insects. We found that in 3 of 4 vineyards (8 of 10 annual trials) the addition of a cover crop did not significantly increase the total number of spiders on the vines. Overall spider abundance (vines and cover crop) was higher in cover crop plots because many spiders reside on the cover crop and results showed little movement. We conclude that the cover crop did not provide an important alternate habitat for vine-dwelling spiders. Another, less well studied effect of ground covers, is the change in host pant condition. At 3 of 4 sites (table, wine, and juice) the addition of a cover crop affected vine condition, as indicated by significantly lower pruning weights and petiole nitrate levels. At these same sites there was a reduction in leafhoppers in all but one year. At the raisin site, where cover crops were tilled under by mid-season, there was no measurable vine stress (or difference in leafhopper numbers). The data suggest that the reduction in vine vigor contributed to the reduction in leafhopper numbers. We conclude that cover crops maintained throughout the year (juice, table, and wine grape sites) resulted in lower third-brood leafhopper densities, however, the level of leafhopper reduction was often not economically significant (about 15%). The most commonly observed trait amongst plots with lower leafhopper densities was not a biotic change but an abiotic one. There were relatively few differences in natural enemy densities in cover crop and no cover treatments. However, year-round cover crops, especially resident grasses reduced vine vigor and this was directly related to leafhopper reduction.

Index terms: Erythroneura, spiders, Anagrus, cover cropping, vineyard IPM.

[0132] ROLE OF SPIDERS IN GRAPE IPM

M.]. Costello¹, K.M. Daane ²& D.J. Schmidt², ¹Dept. of Crop Science, California Polytechnic State Univ., San Luis Obispo, CA, 93407, USA, ²Dept. of ESPM, Insect Biology, Univ. of California, Berkeley, CA, 94720, USA

Spiders comprise over 95% of vineyard predators collected in California's central valley. They exist in grape vineyards as a complex of species, which respond differently to environmental conditions and have various methods of prey capture. We conducted a series of studies on spiders and cover cropping in vineyards, and found only one species, the hunting spider *Trachelas pacificus* (Corinnidae), whose population density increased with the presence of cover crop. The feeding habits of web spinning spiders can often be determined by enumerating prey captured in webs, but it is difficult to evaluate predation by hunting spiders, *T. pacificus* and *Cheiracanthium inclusum* (Miurgidae) on omnivorous leafroller (OLR) Platynota stultana (Lepidoptera: Tortricidae). We developed a monoclonal antibody to OLR and assayed for its presence in the guts of spiders using the enzyme linked immunosorbent assay (ELISA). We conducted laboratory studies to determine the OLR digestion rates of *T. pacificus* and *C. inclusum* at a constant temperature of 21°C. In *C. inclusum* reacting positively. More positive reactions were recorded when spiders were diluted with coating buffer at a rate of 1:1000 than at 1:100. Key words: Trachelas pacificus, Cheiracanthium inclusum, Platynota stultana, monoclonal antibodies

[0133] TOWARDS FEWER PESTICIDE APPLICATIONS IN QUEBEC VINEYARDS

N. J. Bostanian & C. Vincent, Hortic. Res. Dev. Centre. Agric. and Agri-Food Canada, St. Jean sur Richelieu, Quebec, CANADA J3B 3E6. E-mail: bostaniannj@em.agr.ca

Viticulture started in Quebec by the first French settlers several centuries ago. However, it has always remained a marginal agricultural activity because of the cool climate. Nevertheless, in recent years there has been a great surge in viticultural activity and several wineries have come to exist. This paper establishes the different arthropods such as the grape berry moth *Endopiza viteana*, potato leafhopper, *Empooasca fabae* and others in their order of importance as pests and discusses their abundance throughout the season-Based on a better understanding of the biology and abundance of these pests, insecticide treaments have now been reduced by 50%. Index terms: Grapes, pests, cool-climate

[0134] INTEGRATED MANAGEMENT OF SPIDER MITES IN CALIFORNIA VINEYARDS

R. Hanna¹, F. G. Zalom² & L. T. Wilson³, ¹Intern. Inst. of Trop. Agric., PHMD, IITA-Benin Station, 08 B.P. 0932, Cotonou, Benin, E-mail r.hanna@cgiar.org; ²Statewide IPM Project, Univ. of California, One Shields Ave., Davis, CA 95616 USA, E-mail fgzalom@ucdavis.edu; ³Beaumont Res. & Ext. Cent., Texas A&M Univ., 12509 Aggie Drive, Beaument, Texas 77713 USA, E-mail It-wilson@aesrg.tamu.edu.

The phytophagous spider mites, Tetranychus pacificus and Eotetranychus willamettei, are the most common spider mites in California vineyards. While both species can cause losses in grape yield and quality, T. pacificus is generally considered much more destructive than E. willamettei. Research over the last 30 years has identified several factors that affect population abundance and pest status of T. pacificus and E. willamettei in vineyards. As on many perennial crop plants, predation by phytoseiid predators, if not disrupted by pesticides used for insect and disease control, can generally provide effective biological control of both spider mite species. Extensive research has also abundantly shown that populations of the two spider mite species, particularly T. pacificus, can be negatively affected by interspecific interactions such as induced resistance and shared predation. In addition, numerous observations have associated increasing severity of mite infestations with increasing vine stress caused by water and nutrient deficiencies and probably exacerbated by nematode damage, but the effect of these factors on spider mites in vineyards has not been rigorously tested. Manipulation of the above factors has been used in developing tactics for integrated management of vineyard spider mites. We will review the successes and challenges in using these tactics with emphasis on predator conservation through selective use of pesticides, predator enhancement through augmentative releases, incorporation of predator-prey ratios in population monitoring, and grower perception and adoption of available IPM tactics.

Index terms: Tetranychus pacificus, Eotetranychus willamettei, Metaseiulus occidentalis, biological control.

[0135] PHYTOSEIID-POLLEN RELATIONSHIPS IN ITALIAN VINEYARDS

V. Girolami, <u>V. Malagnini</u>, A. Di Bernardo & C. Duso, Institute of Agricultural Entomology, University of Padua, Via Romea 16, 35020 Legnaro (Padova), Italy, E-mail ento@agripolis.unipd.it

In northern Italy, Kampimodromus aberrans, Typhlodromus pyri and Amblyseius andersoni are the most important phytoseiid mites in vineyards. They survive and reproduce on different kinds of food. The first two species are able to persist even when prey are scarce. Laboratory studies demonstrated pollen to be a very important alternative food for these generalists. Therefore, pollen availability on grapevine leaves could affect phytoseiid population dynamics. For three years, samples of grapevine leaves from three vineyards were treated by acetolysis, in order to identify pollen grains and assess their density over the time. The pollen diagrams, generally, showed a richness of non arboreal pollen (NAP) in which Poaceae pollen was dominant. Arboreal pollen (AP) was found mostly during spring and grapevine bloom. The pollen density declined in mid summer but increased slightly in September. A comparison between pollen abundance and phytoseiid population dynamics showed that reproduction and juvenile numbers increased after large pollen availability. This relationship was more evident during sprouting, after grapevine bloom, and sometimes in September. Moreover, the application of pollen (hornbeam or hop) was associated with an increase in oviposition and juvenile numbers of K. aberrans. In some areas, K. aberrans and T. pyri releases sometimes fail or phytoseiid densities decrease progressively to very low levels in August and September. On the other hand, the investigation on pollen abundance in vineyards showed a dramatic reduction of pollen densities during the same period. Therefore, phytoseiid decrease could be linked to low pollen availability. Weed management could improve phytoseiid persistence in vineyards. Experiments were carried out on small plots colonized by K. aberrans and characterized by low or frequent mowing. Results showed that K. aberrans populations increased and persisted by flowering grasses.

[0136] MIGRATION AND IPM IN DEVELOPING COUNTRIES

<u>R. J. Cooter</u>, Pest Management Dept., Natural Resources Institute, University of Greenwich, Chatham Maritime, Chatham, Kent, ME1 4TB, UK.

It is projected that world population will increase to 8-9 billion in the next 30 years Currently about 800 million people are food insecure and even with projected improvements in yield the challenge to reduce crop losses to pests remains enormous. Integrated Pest Management or its more holistic relative Integrated Crop Management has been driven in developed countries by pressure from the environment and health lobbics and supported by consumers willing to pay a premium for pesticide-free produce. In developing countries the farmer's priorities are different and food security, yield and stability are the forces driving farmers to reduce crop losses and ICM has a role to play here too. Of migrant or highly mobile insects only those which feed on plants important to man are seen as pests. Whilst it is the larval stage of many of them that cause direct damage to crops (e.g. armyworm) others cause damage both as adults and throughout their lives (e.g. locusts). Whilst armyworm and locusts can cause catastrophic and dramatic damage it is those insects which vector plant, human and animal diseases (aphids, whitefly, leaf and planthoppers, biting flies, etc.) probably cause the most economic damage and which constitute a persistent threat to food security, livelihoods and health in developing countries. In this overview, examples will be given drawn from work on armyworm, Helicoverpa armigera and important plant disease vectors will be given to show how a pests powers of dispersal influence ICM strategies in smallholder cropping systems.

Index terms: *Helicoverpa annigera*, whitefly, armyworm, grasshoppers, locusts, disease vector, migration, Integrated Pest Management, ICM, smallholders

[0137] A EUROPE-WIDE NETWORK FOR MONITORING FLYING APHIDS `EXAMINE': ACHIEVEMENTS AND PROSPECTS

R. Harrington¹, ¹Inst. of Arable Crops Research - Rothamsted, Harpenden, Hertfordshire, AL5 2JQ, UK, E-mail: richard.harrington@bbsrc.ac.uk.

As a family, aphids rank amongst the most important pest invertebrates in many parts of the world. In the 1960s, a monitoring system using 12.2m suction traps was initiated in the UK to provide data to help understand the spatial and temporal dynamics of aphids in order, ultimately, to aid decisions on control. Eighteen countries throughout Europe have now adopted traps of the same design and over 70 are in operation. These provide daily data throughout the aphid flight season on all important pest species, with some countries identifying all, or most, individuals. A 'Thematic Networks' project with the acronym 'EXAMINE' (EXploitation of Aphid Monitoring IN Europe) has recently begun under the European Union FP5 programme 'Energy, Environment and Sustainable Development'. The objective of the project is to provide a common database for 20 pest aphid species throughout Europe and to use the database to examine relationships between aphid dynamics and global change. The project will provide the most comprehensive standardised spatio-temporal database for any terrestrial invertebrate group anywhere in the world, and will also facilitate analyses leading to Europe-wide forecasting of aphid outbreaks. This paper will describe major uses of suction trapping to date and discuss the opportunities presented by the 'EXAMINE' project. Major uses of suction trapping to date include: i) studying the spatial and temporal dynamics of aphids; ii) understanding aphid cold hardiness; iii) analysing conditions leading to wing production, sexual morph production and flight; iv) demonstrating biological impacts of global environmental change; v) analysing gene flow; vi) understanding dynamics of insecticide resistance; vii) pre-season forecasting of pest potential and viii) providing within season advice on pest control. All of the above uses will continue but will be enhanced by the Europe-wide scale of analyses. In the near future, advances will be made in understanding the relationship between aphid dynamics and climate, land use and concentrations of gaseous pollutants. Also, the routine use of genetic markers will allow the build up of a database on subsamples of a few key species, which over time will reveal much about gene flow and migration rates.

Index terms: long term data, forecasting, global change

[0138] SEASONAL MONITORING OF THE INSECT FAUNA FLYING AT ALTITUDE OVER SOUTHERN ENGLAND: RESULTS FROM A VERTICAL-LOOKING RADAR

J. R. Riley, D. R. Reynolds & A. D. Smith, Natural Resources Institute Radar Unit, Univ. of Greenwich, North Site, Leigh Sinton Road, Malvern, Worcestershire WR14 1LL, UK. Email: jriley@nriradar.demon.co.uk.

The unique capacity of radar to observe high-flying insects has been amply demonstrated over the past 30 years, and the bulk of our current knowledge of insect migration at altitude stems directly from this very powerful technique. Although conventional entomological radars are not suitable for long-term observational tasks, the recent advent of nutating-beam, vertical-looking radar (VLR) equipped with novel signal processing capabilities has made season-long monitoring an economic and practicable proposition. This paper describes such a radar, and how it was used in a three-month study of insect flight activity over southern England during the exceptionally warm summer of 1995. Our measurements were made automatically, once every half hour, in the altitude range from 150 to 1050 m. The results showed how insect aerial density varied throughout the summer, revealed the presence of both day time and nocturnal layer concentrations at altitude, and gave estimates of the mass distribution, aerial density, displacement vectors and orientations of the overflying insects. The potential of the new VLR for various operational pest monitoring tasks will be discussed. Index terms: migration, radar, monitoring, layering

[0140] DISTANT NATIVE HOSTS IN SEMI-ARID REGIONS AS A SOURCE OF PEST INFESTATIONS IN CROPPING AREAS: THE AUSTRALIAN EXPERIENCE

P.C. Gregg, Agronomy & Soil Science, School of Rural Science & Natural Resources, Univ. of New England, Armidale, NSW 2351 Australia, E-mail pgregg@metz.une.edu.au.

The semi-arid areas of inland Australia are characterised by extremely variable and patchy rainfall. For extended periods of drought these regions may be absolutely unsuitable for breeding by the many migratory insect pests which originate there. However, rainfall at critical times can produce abundant growth of native host plants for these pests, which include Australian Plague Locust, Chortoicetes terminifera (Walker), common armyworm, Mythimna convecta Walker, cotton bollworm Helicoverpa armigera (Hübner) and native budworm, Helicoverpa punctigera (Wallengren), as well as several other minor noctuid moth pests. The native hosts include perennial grasses which support the growth of populations of C. terminifera and M. convecta. The root systems of these grasses allow them to survive extended drought but respond quickly to rainfall, especially when the rain falls in the warmer months. The host plants for *Helicoverpa* spp. and other noctuits include ephemeral broadleaf species, especially in the families Asteraceae and Fabaceae, which germinate quickly in response to autumn or winter rainfall. These plants can support large numbers of larvae over wide areas, covering several different habitat types. When the warm dry conditions of early spring arrive, there is a rapid and synchronous deterioration of the host plants. This is accompanied by large scale migration over distances of 500 to 1500km, in some cases reaching the cropping regions of southeastern Australia and resulting in serious economic losses. Examples of such migrations will be presented. Comparisons of the suitability of key host plants for the survival and development of *H. punctigera* (which is common in these migrations) and *H. armigera* (which is rare) indicate that both are equally well adapted to the inland native hosts. This suggests that it is the migratory strategy of the pests rather than the availability of hosts which is the key to success in these variable environments.

[0141] *HELICOVERPA* FORECASTING IN AUSTRALIA: STATISTICAL MODELS INCORPORATING LOCAL AND NON-LOCAL FACTORS

<u>M. P. Zalucki¹ & D. A. Maelzer², 1.</u> Department of Zoology and Entomology, The University of Queensland, Australia, 4072, Email: M.Zalucki@mailbox.uq.edu.au; 2. School of Land and Food, The University of Queensland, Gatton, Australia, 4345

The use of long-term forecasts of pest pressure is central to better pest management. Serious infestations of Helicoverpa punctigera Wallengren and II. armigera (Hübner) (Lepidoptera: Noctuidae) are experienced yearly in the eastern cropping regions of Australia. Regression analyses of a long series of light-trap catches were used to describe the seasonal dynamics of both species. The size of the first generation in spring of *II*. punctigera, which is comprised mostly of immigrants from inland Australia, was related to monthly rainfall in inland winter breeding areas. The size of the second generation of *H*. armigera was significantly related to the size of the first generation, to winter rainfall, which had a positive effect, and to spring rainfall which had a negative effect. Rainfall and crop hosts were also important for the size of the third generation. When winter rain was omitted from the analysis, the sizes of both the second and third generations could be expressed as a function of the size of the previous generation and of the areas planted to lucerne, sorghum and maize. For H. punctigera, which declines in abundance after the second generation, winter rain had a positive effect on the sizes of the second and third generations, and rain in spring or early summer had a negative effect. Only the area grown to lucerne had a positive effect on abundance. As rainfall figures prominently as a predictor variable and may itself be predicted using the Southern Oscillation Index (SOI) and the Sea Surface Temperature (SST) we also related trap catches to these variables. The size of the first spring generation of both species was significantly correlated with the SOI in certain months, sometimes up to 15 months before the date of trapping. Forecasts of pest levels from many months to a few weeks in advance are discussed, along with the improved understanding of the seasonal dynamics of both species.

Key words: Helicoverpa armigera, Helicoverpa punctigera, forecasting, light trap, climate, Southern Oscillation Index

[0142] LOCUST FORECASTING AND PREVENTIVE CONTROL IN AUSTRALIA

D. M. Hunter & E. D. Deveson, . Australian Plague Locust Commission, AFFA, GPO Box 858, Canberra, ACT 2601, Australia. E-mail david.hunter@affa.gov.au.

Locust plagues occur when there is a sequence of rains that allow relatively continuous breeding and high survival for at least 4-5 generations. In Australia, locusts are managed through programmes of preventive control where treatment begins with the small bands and swarms that form early in breeding sequences. Locating the small early infestations in the more than 3 million km² of inland eastern Australia has been made possible by integrating data into a Decision Support System (DSS) for locust operations. The critical event that begins a locust generation in a region is rainfall that allows adults to mature their eggs and oviposit. In the arid inland, rain is often localised and locusts normally must migrate in order to locate any rain areas present. Likely areas of invasion are identified by using GIS techniques to integrate data on habitat, rainfall and locust survey. The background layer of favoured locust habitats is overlaid with rainfall information which consists of daily rainfall reports interpolated on a one or several day basis by a Bureau of Meteorology computer programme. This combined favoured habitats/likely rainfall distribution delineate areas suitable for oviposition. However, locusts are likely to be in only a few of the suitable areas, particularly early in outbreaks when preventive control programmes begin. From the distribution of the parent generation and a trajectory model that calculates winds at the 300-900 m height at which locusts undertake long distance night migrations, flight paths taken by migrating locusts are estimated. Locusts are likely to invade areas where their flight paths intersect areas of recent rain. Such areas are surveyed immediately to locate maturing adults and if dense swarms are located a treatment programme begins. For regions where maturing adults are seen, a locust development model is run to forecast when offspring mymphs and adults are likely to be present. These forecasts are used to determine the best time for survey so that offspring bands and swarms can be found quickly and treated as part of a programme of preventive control.

Index terms: Locusts, preventive control, decision support system

[0143] RAINFALL AND RECENT OUTBREAKS OF THE AFRICAN MIGRATORY LOCUST IN THE LAKE CHAD BASIN

G. Balança, P.-E. Gay, T. Rachadi & <u>M. Lecoq.</u> CIRAD, Centre de coopération internationale en recherche agronomique pour le développement, D.P. 5035, 34032 Montpellier Cedex 1, France, E-mail : nuchel.lecoq@cirad.fr

Heavy outbreaks of migratory locusts, *Locusta migratoria migratorioides*, were observed in southwestern Chad and northern Cameroon from September to November 1997. For many years, similar outbreaks were a recurrent phenomenon in this region, with the last one occurring in 1989. An analysis of rainfall distribution from 1986 to 1997, was undertaken according to the ecological requirements of this locust. To assess the possibilities of good breeding and gregarisation, the monthly position of the areas receiving an optimal rainfall for this species (50 to 100 mm/month) was studied. The following parameters, assumed to be key factors, were considered: northern limit of the optimal area in May and June, northern limit of the area with excessive rainfall (>100 mm/month) in June, maximal northern limit of the optimal area during the rainy season, maximal northern limit of the area where the rainfall is excessive, duration of optimal pluviometric conditions around Lake Chad during the rainy season. This study showed that the outbreaks were strongly linked to the extent and distribution of rainfall during the 1988-1989 and the 1996-1997 periods. A simple index, calculated on the basis of rainfall data, was correlated with outbreak years. It appeared that two successive years of suitable conditions are necessary to induce an outbreak.

Index terms : Orthoptera, Acrididae, Locusta migratoria, Chad, Cameroun

[0144] HABITAT RELATIONSHIPS BETWEEN MOBILE INSECT PESTS AND THEIR NATURAL ENEMIES IN DIVERSIFIED AGROECOSYSTEMS: A BASIS FOR FORCASTING AND MANAGING THESE PESTS AND NATURAL ENEMIES

Y. Hirose, Inst. of Biological Control, Fac. of Agriculture, Kyushu University, Fukuoka 812-8581, JAPAN, E-mail hirose@grt.kyushu-u.ac.jp

Mobile pests are defined as polyphagous and multivoltine pests that move freely over large areas and between crops in diversified agroecosystems (Hirose, 1998). Most mobile pests are major pests, and this may be largely because natural enemies of these pests have difficulty in shifting their habitats to follow the seasonal movement of the pests. Thus, habitat relationships between mobile pests and their natural enemies in diversified agroecosystems could provide a basis for forecasting and managing these pests and natural enemies. To explain this, I determined habitat relationships between mobile phytophagous bugs and their major egg parasitoids in agroecosystems in Japan as these bugs are important mobile pests of different many crops and egg parasitoids are effective natural enemies of these mobile pests. The habitat relationships showed a habitat similarity between the major egg parasitoids and their ovipositing hosts, suggesting that these parasitoids often move to follow the scasonal host movement. However, some host species escaped high parasitism because of a habitat discrepancy between hosts and parasitoids. This was also found in parasitism by a mobile egg parasitoid characterized by polyphagy. multivoltinism, high dispersal ability, and high mobility. As shown in this case, it seems impossible that mobile insect pests are always attacked by their mobile natural enemies in diversified agroecosystems. In habitats where mobile insect pests escape attacks of their natural enemies, proper management is needed. Forecasting and managing mobile insecci pests and their natural enemies are also discussed in relation to mechanisms involved in the habitat discrepancy between these pests and natural enemies. Index terms: phytophagous bug, egg parasitoid, movement.

[0145] MOVEMENTS OF PLANTHOPPERS AND THEIR NATURAL ENEMIES BETWEEN HABITATS IN RICE ECOSYSTEM

J.A.Cheng, X.P.Yu & J.M.Chen (Inst. Appl. Entomol., Zhejiang Univ., Hangzhou, China 310027).

The arthropod community in rice paddy will be reestablished 2-3 times every year based on the cropping system. Large-scale investigations were carried out to study the interaction between rice and non-rice habitats during the development of arthropod community in rice paddy. The results showed that the planthoppers and their natural enemies moved from habitats to habitats, and the main source habitats of planthoppers and natural enemies changed from season to season, and from region to region. The main source habitats of natural enemies for the 1^{84} rice crop season were green manure fields (spiders) and wheat fields (*Anagrus*). The main source habitats for the single of/and 2^{164} rice crop season were the paddies planted 1st rice crop season in mono-cultivating area, but Zazania fields in mixed cultivate area. These non-rice habitats provided initial populations, recruits and refuges, as well as alternative and supplemental foods for arthropods in rice paddy. The seasonal movements of planthoppers, Anagrus and spiders between rice paddy and Zazania field were monitored in the Yangtze Delta area. The results showed that more Anagrus moved from Zazania field to rice paddy in May, June and July, but from rice paddy to Zazania field in October and November. More spiders moved from rice paddy to Zazania field after harvesting of previous crop and from Zazania field to rice paddy after transplanting. Experiments indicated that the planthoppers feeding on Zazania (or rice) did not cause any damage to rice (or Zazania), but the Anagrus sp. could parasite the eggs of all the planthopper species in the two kinds of habitats. These results implied that arrangement of Zazania field in fice ecosystem could be used to enhance natural biological control. Index terms: Anagrus; Zazania; Spiders

[0146] HELICOVERPA LOCAL MOVEMENT AND RESISTANCE MANAGEMENT STRATEGIES FOR TRANSGENIC COTTON: STUDIES WITH A SPATIALLY EXPLICIT METAPOPULATION MODEL

M.L. Dillon & G.P. Fitt, Australian Cotton Co-operative Research Centre, CSIRO Entomology, Locked Bag 59, Narrabri NSW 2390, Australia. E-mail: martin.dillon@ento.csiro.au.

Refuges are a key component of the Helicoverpa resistance management strategy for transgenic cotton in Australia. The premise is that refugia will generate sufficient moths with susceptible alleles to effectively dilute the frequency of rare resistant alleles that may arise within transgenic crops. This strategy relies heavily on the assumption that susceptible adult moths from refugia will disperse throughout a region containing transgenic crops. It follows that Helicoverpa local flight behaviour and the distribution of refugia and transgenic crops upon the landscape will be crucial determinants of the effectiveness of the resistance management strategy. Using the HElicoverpa Armigera and Punctigera Simulation (HEAPS) model we simulated Helicoverpa dispersal over landscapes containing varying layouts and proportions of refuges and transgenic crops. HEAPS is a stochastic, spatially explicit metapopulation model that can simulate moth dispersal and metapopulation dynamics within user defined landscapes. We present the results of multiple simulations exploring the interaction between moth behaviour, environmental cues affecting moth flight, the agronomy and phenology of host crops, the spatial and temporal distribution of Helicoverpa within the region, and the distribution of refuges and transgenic crops within the landscape. The results demonstrate that wind speed and direction have the potential to interact with the spatial distribution of host patches to substantially influence the dispersion of moths from refuges and transgenic crops. The timing of moth emergence from different crops, and the phenology and temporal attractiveness of crops hosts for Helicoverpa can also produce heterogeneous moth dispersion. Such heterogeneity may result in parts of the landscape supporting subpopulations that contain high proportions of moths originating from transgenic fields. We conclude that refuges should be placed as close as possible to transgenic crops to maximise the likelihood that resistant alleles will be diluted by susceptible alleles. We discuss refuge placement options in the light of our findings. Index terms: HEAPS, dispersal, refuges, Bt

[0148] POLLEN AS A MARKER FOR LONG-DISTANCE MIGRATION AND LOCAL MOVEMENT OF *HELICOVERPA* MOTHS IN AUSTRALIA

A. P. Del Socorro & P. C. Gregg, Australian Cotton Cooperative Research Centre, Agronomy & Soil Science, School of Rural Science & Natural Resources, Univ. of New England, Armidale, NSW 2351 Australia, E-mail: adelsoc2@metz.une.edu.au.

The cotton bollworm, Helicoverpa annigera and the native budworm, H. punctigera are serious pests of cotton and many other summer crops in Australia. In cotton alone, control of these pests is estimated to cost over AUD\$200m annually. Although both species are recognised migrants, there is little information on the timing, frequency, direction and distance of movement. Moth-borne pollen is a natural marker that has been used to show long-distance migration of moths. Helicoverpa spp. visit flowers of many plants, collecting pollen on their probosces, antennae, head and legs. Pollen carried by these moths on their probosces was identified by scanning electron microscopy. investigated long-distance migration by comparing moth-borne pollen of Helicoverpa spp. collected in western Queensland in early spring with that of moths collected in three cropping areas of eastern Australia. Pollen of Ptilotus (Amaranthaceae), Velleia (Goodeniaceae) and *Eremophila* (Myoporaceae), and the Asteraceae (Tubuliflorae) were found on moths trapped in the east. These plants either did not occur in the areas where the moths were caught, or did not flower there at the time the moths were caught. However, they were abundant in possible source areas such as western Queensland. Pollen from one or more of these plants were found on 30% of H. punctigera and 18% of H. armigera caught in the eastern regions, suggesting that these moths were likely to be migrants. We also conducted field mark-capture experiments to study local movement of II. armigera using sunflower pollen as the marker, in southeastern Queensland. A network of 20 pheromone traps was set up within a 6-km radius from a flowering sunflower crop. The numbers and proportions of moths that had pollen as well as mean pollen loads of moths significantly declined with distance from the sunflower crop. Cage studies suggested that sunflower pollen is a transient marker in the field and may be a reliable marker only of recent (ie, previous 1 or 2 nights) local movement of H. armigera moths.

Index terms: Helicoverpa armigera, Helicoverpa punctigera, movement.

[0147] STUDIES OF APHID MIGRATION USING MICROSATELLITE MARKERS

K. S. Llewellyn¹, <u>H. D. Loxdale²</u>, R. Harrington³ & C. P. Brookes^{4, 1, 2, 3, & 4}. Entomology and Nematology Dept., IACR-Rothamsted, Harpenden, Herts, AL5 2JQ, U.K. E-mail: hugh.loxdale@bbsrc.ac.uk

There are many gaps in our knowledge about the migration of aphids, in spite of the large body of research devoted to this area. We present an alternative approach: the combined use of molecular markers and suction traps to study the population genetics of these insects. If migration is limited, then insects in different geographical regions may become isolated from one another and hence genetically differentiated. We have examined length polymorphism at four microsatellite loci amplified using PCR to assess the degree of genetic differentiation between populations of the grain aphid, *Sitobion avenae* from around the UK. The insects used were collected in 1997 and 1998 from different parts of the country using 12.2 m Rothamsted Insect Survey suction traps. A substantial amount of polymorphism was detected in these populations, with large differences in the numbers of genetic structure (i.e. frequencies of alleles and genotypes present) was found to be remarkably similar throughout the country. We suggest that extensive migration must be occurring in order to maintain this homogeneity, in spite of the forces which would tend to cause genetic differentiation between regions.

Index terms: Aphididae, Sitobion avenae, PCR, molecular markers, suction trap

[0149] THE USE OF POLLEN SPORES AS NATURAL MARKERS FOR DETERMINING MIGRATION

G.D. Jones & <u>W.C. Hoffmann.</u> USDA-ARS, APMRU, 2771 F&B Rd, College Station, TX, USA. E-mail: g-jones@tanu.edu.

Numerous insect species feed on nectar, pollen, and plant exudates that are associated with flowers. As a result of this feeding activity, these adults become contaminated with pollen. Pollen is distinctive, easily recognizable, and identifiable to the family, genus, and often species rank. In addition, pollen is durable and does not easily decay. Thus, pollen remains as a natural marker on or in an insect. From the identification of the pollen found on or in an insect, the geographical origin of the plant, from which the pollen came, often can be determined. Because some plants are endemic to certain habitats or geographical regions, pollen from these plants found on/in an insect can indicate and validate migration routes, support insect migration pathways, and help determine foraging source zones. This is especially useful when there is temporal and geographical variation in the distribution of the identified plant. Besides long range migration, local movement can be determined from pollen or spores. Insects can be marked with non-native pollen or spores, released. and recaptured. This type of marking is non-toxic, relatively easy to use, and does not interfere with the insect. Presence of the pollen or spores on the recaptured insects indicates movement to and from the initial capture area. Likewise, when a plant species only occurs in a particular area near a field, presence of pollen from that plant indicates that the insects moved from the plant's location to the capture point. From understanding insect movement and migration, management techniques can become more effective and less costly.

[0150] MIGRATION AND DIAPAUSE OF HELICOVERPA ARMIGERA IN CHINA

K. Wu, G. Xu & Y. Guo, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing, 100094, China, E-mail wukm@mail.east.net.cn.

Cotton bollworm, *Helicoverpa amigera* (Hübner) is an important insect pest in agriculture in China. Inducement and termination, inheritance and variation of facultative diapause, coldhardiness and overwintering, and biology and routes of facultative migration in China were investigated from 1993 to 1999. The results indicated that the populations of *H. armigera* in the whole country can be divided into four regional groups, namely, the tropical, subtropical, temperate zone and Xinjiang geotypes, their adaptive zones are respectively in southern China, middle and lower Changjiang River valley including Sichun Province, Hubei Province, and Zhejiang Province etc., Huanghe River valley including Henan Province, Hebei Province, and Shandong Province etc., and the southern part and Turfan Basin of Xinjiang Uygur autonomous region. The damage of the temperate zone geotype can be extended into northeastern China such as Liaoning and Jilin Provinces etc., by a long distance facultative migration with east Asia monsoon in Summer.

Index terms: Helicoverpa armigera, diapause, migration, geotype

[0152] INDIVIDUAL-BASED MODELS: VIRTUAL INSECTS ?

D. Morgan & P. J. Proctor, Central Science Laboratory, Sand Hutton, York, UK, YO41 1LZ

Individual-based models, also known as agents, are the basis of an innovative approach to study the temporal and spatial-dynamics of organisms. By representing each individual organism virtually with dynamic and stochastic processes that are biologically realistic it is possible to investigate detailed aspects of their population and spatial dynamics irrespective of scale (e.g. host plant, field, population, meta-population, community). Although the inherent stochasticity of such an approach increases the complexity of model development, implementation and experimentation the ability to manipulate the system methodically and thus, the insight gained greatly outweighs any developmental costs and over-heads. This paper will present a modelling framework that utilises individual-based models to study the temporal and spatial dynamics of insects. The framework employs a modular structure so that generic 'virtual' insect are represented within the system with common population and behaviour processes. Specific information are integrated with the framework to develop models for particular insect species. At present only a single species of insect can be modelled, although further development of the framework is underway that will allow several species of insects to be modelled simultaneously, including predator-prey/parasitoid-host interactions.

[0151] SUMMING UP AND GENERAL DISCUSSION

M. E. Irwin, Dept. Nat. Resources & Environ. Sci., Univ. Illinois at Urbana-Champaign, 1101 W. Peabody Dr., Urbana, IL 61801, USA. Email: m-irwin2@uiuc.edu

This symposium focuses on migratory pests, mostly in agricultural settings. It covers a diverse array of technologies, both tried and new. Included are techniques to follow populations as they move such as genetic, including microsatilite, markers; pollen foreign to the local area but attached to the migrant; and field mark-recapture. Techniques to capture invading species over a large geographic ranges (e.g., the European suction trap network) or observe migrants as they fly by using a nutating-beam, vertical-looking radar are also imbedded in this symposium. Analysis using statistical, trajectory, and qualitative (rule-based) simulation models for forecasting movement are featured. Furthermore, Geographic Information Systems and Decision Support Systems are used to help predict source and impact locations of migrants. The findings from this symposium are many and varied. They include a better understanding of gene flows and migration rates; a knowledge that distant native hosts can be a major source of pest infestations, that local rain events correlate with the buildup of important migrant species; that biotopes, meteorological conditions and the existence of continuous gallery forests help localize and isolate migratory locusts in tropical South America; that natural enemies of mobile pests have difficulty in shifting habitats to follow seasonal movements of their hosts; that populations of mobile insect pests can better avoid attack by their mobile natural enemies in diversified agroecosystems; that in rice fields, planthoppers and their natural enemies move between habitats, and their main source habitats change from season to season and from region to region; that refugia may provide an answer for managing insecticide resistance in highly mobile pest species; and that recent environment changes (i.e., deforestation) in Madagascar have modified some of the locust invasion routes, with swarms progressing quickly along the east coast (a naturally forested region). Demonstrated also are the utilitarian needs to employ technologies to reduce the threat of migrant pests. It was shown, for instance, that dispersal can greatly influence how integrated pest management (IPM) is designed and deployed in developing countries; how the appropriate juxtaposition of alternate crops within a rice ecosystem might be used to enhance natural biological control of planthoppers; and how season-long monitoring by the vertical looking radar is both an economical and practical way of keeping track of mobile pests.

Index Words: Migration, technology, habitat manipulation, economics.

[0153] MODELLING THE SPATIAL DYNAMICS OF INSECT-TRANSMITTED PLANT VIRUSES

K.F.A. Walters & D. Morgan, Central Science Laboratory, Sand Hutton, York, UK, YO41 1LZ

Insect-transmitted plant viruses (IPV) are important diseases of crops throughout the world. Traditionally management of IPV have depended upon the application of pesticides to control vector populations and dispersal. However pesticides tend to be applied routinely and irrespective of the risk of virus infection. Reliable forecasting systems are needed to ensure rational management of IPV but for many IPV thorough understanding of the biological processes involved is often limited, especially the spatial dynamics of vectors and disease^[1]. The paper will present a modelling framework that describes the temporal and spatial dynamics of an insect vector and subsequent spread of virus quantitatively. Initially the framework has been developed to study the epidemiology of barley yellow dwarf virus (BYDV), an aphid-transmitted virus of cereals and grasses. The system combines a cellular automata of plant hosts with individual-based aphid model^[2] and the framework utilises routines to simulate aphid development, reproduction and mortality, and the dispersion of vectors and virus between plants. The predicted spatial dynamics and temporal incidence of both aphids and virus are similar to those observed in fields in the UK and the system has provided useful insights into understanding the complex interactions between biological processes involved in BYDV epidemiology. Furthermore, the modular structure of the framework ensures it applicability to other crop, vector and virus ecosystems.

[0154] PESTICIDES, ECOLOGY AND IPM: OPTIMIZING PESTICIDE USE WITHIN PEST MANAGEMENT SYSTEMS

P.C. Jepson, Dept. of Entomology, Oregon State University, Cordley Hall, Corvallis, OR 97331, USA.

Can pesticides be exploited more effectively, with reduced risks of pest resistance, pest resurgence, impacts on beneficial organisms and environmental contamination? The next phase in the short but complex history of synthetic pesticide use in agricultural crops should make use of accumulated knowledge of pesticide science to tune the selection of active ingredient, and the pattern and level of use, to the agroecosystem in question. Pesticide application and delivery to the target is an inefficient process and there is evidence that efficiency could be improved through more detailed investigation of dose delivery. This includes not only the application and distribution process and the behavior of the pesticide, but also a knowledge of pesticide exposure and uptake by target and nontarget organisms. The small number of current examples of the successes that can be achieved through this process will be outlined, including research on locusts, cotton Lepidoptera, non-target organisms in small grain cereals and pests of potato. The analysis will consider conventional and transgenic means of pesticide delivery. Following application, ecological impacts evolve within and beyond the treated area. There is again, evidence that these impacts can be mitigated by taking physical and ecological attributes of exposed habitats more fully into account in pesticide decision making. This requires integration of our knowledge of environmental fate, susceptibility and exposure of a wide range of taxa, and the ecology and life history of organisms at risk. An analysis of the most recent advances in this area will be presented, including candidate decision aids for pesticide users. Without more widespread us of these approaches, it will not be possible to properly exploit the opportunities that are being presented by new active ingredients. Index terms: bioavailability, ecotoxicology, environmental fate, resistance management, transgenic crops

[0155] MANAGING THE SPATIAL DYNAMICS OF PREDATORS IN AGRO-ECOSYSTEMS

<u>S. D. Wratten¹</u> & G. M. Gurr², ¹Ecology & Entomology Group, Soil, Plant & Ecological Sciences Division, P.O. Box 84, Lincoln University, Canterbury, New Zealand. ²Pest Management Group, Orange Agricultural College, The University of Sydney, P.O. Box 883, Orange, NSW, Australia 2800.

Predators and parasitoids in agro-ecosystems move at a range of spatial scales, often driven by seasonal factors and their need for microclimatically-suitable refuges, prey/hosts and pollen or nectar. Many species of parasitoids, and predators such as hoverflies (Diptera: Syrphidae) need the protein, sugars and amino acids from these floral resources for egg maturation and to enhance "fitness". "Conservation biological control" manipulates these required resources also at a range of spatial scales, up to landscape level. When this is done, it is relatively easy to change positively some aspects of predator biology, while others in the hierarchy of "desired" successes maybe more difficult to achieve. The aspect of natural enemies' spatial dynamics which is most readily changed is the enhancement of populations in the vicinity of floral resources. The next stage in the desired hierarchy is enhancement predation or parasitism rates. The third more, more difficult, step is achieving a reduction in the targeted pest population, ideally to below the economic threshold. In most of these conservation biological control studies, the key aspect missing is a knowledge of the spatial dynamics of the agent and hence the ideal spacing of the plant resources. This latter critical factor will be discussed.

[0156] CASE STUDY: GLASSHOUSE PESTS AND COCCINELLIDS

W. van der Werf

ABSRTACT NOT RECEIVED

[0157] SOUTHERN CORN ROOTWORMS <u>Barbercheek, M</u> ABSTRACT NOT RECEIVED

[0158] INTRODUCTION TO DIABROTICINE PESTS IN THE UNITED STATES

<u>J. J. Tollefson¹</u>, ¹Dept. of Entomology, Iowa State Univ., 17 Insectary Bldg., Ames, IA 50011-3140, USA, E-mail tolly@iastate.edu.

Diabrotica is a New World genus of galerucine chrysomelids. Krysan reported that the catalog of Wilcox lists 338 species in three groups and that the virgifera and fucata groups include pests. Further, the greatest diversity of Diabrotica species occurs in the tropics, with only seven species occurring in the U.S., but four of these species are pests. The two North American pest species of the fucata group cannot overwinter in the temperate north, but the two pest species in the virgifera group can. The fucata group is multivoltine, overwinters as adults, and the adults disperse north during the warm season. The virgifera pest species are univoltine and overwinter as eggs. These two virgifera species, Diabrotica barberi and Diabrotica virgifera, are the most serious pests of maize in North America. Because the virgifera species are univoltine and overwinter as eggs, they have been pests primarily when maize is planted where it was grown the previous year (continuous maize). The practice of planting continuous maize became increasingly common in North America following World War II when inexpensive synthetic pesticides and fertilizers became available. As soon as this practice was adopted, D. barberi became a pest in the temperate maize-growing areas because it is a Nearctic species. D. virgifera was first described in the United States in 1868 just east of the Rocky Mountains. It remained confined to the western maize growing area until the practice of planting continuous maize became common and then it rapidly spread east, reaching the Atlantic coast by 1990. In the 1950s the practice of applying insecticides to the soil to prevent larval injury to maize roots became common practice whenever maize was planted after maize. Initially broadcast applications of the chlorinated hydrocarbons were used. Within 10 years D. virgifera had developed resistance to these insecticides and the organophosphates and carbamates replaced them. Soybeans began to be planted extensively in the U.S. in the 1950s and are now commonly rotated annually with maize. This annual rotation with a non-host crop effectively controlled the pests. Recently varieties of the virgifera species adapted to the annual rotation have been selected for. A variety of D. barberi with a two-year lifecycle that remains dormant during the year soybeans are grown became common in the 1980s and a variety of D. virgifera that oviposits in soybeans has appeared recently. With the adaptability of *virgifera*, what will happen when genetically modified varieties of maize are planted next year? Index terms: Diabrotica virgifera, Diabrotica barberi, corn rootworm, maize

[0159] CROP ROTATION COLLAPSES AS A VIABLE PEST MANAGEMENT STRATEGY FOR WESTERN CORN ROOTWORMS, *DIABROTICA VIRGIFERA VIRGIFERA*, IN THE EASTERN CORN BELT OF THE USA

<u>M. E. Grav</u>¹, S.T. Ratcliffe¹, J.L. Spencer², E. Levine² & K.L. Steffey¹, ¹Dept. of Crop Sciences, Univ. of Illinois, S-320 Turner Hall, 1102 S. Goodwin Ave., Urbana, IL 61801, USA, E-mail m-gray4@uiuc.edu; Center for Economic Entomology, Illinois Natural History Survey, 607 E. Peabody Drive, Champaign, IL 61820, USA.

Western and northern corn rootworms, Diabrotica virgifera virgifera LeConte and Diabrotica barberi Smith & Lawrence, respectively, inflict severe economic damage to maize, Zea mays (L.), throughout much of the USA Corn Belt as well as some regions of Canada. Both species have a univoltine life cycle and a narrow host range that includes primarily maize and a few other grass species (Setaria spp.). For decades, the annual rotation of maize with soybeans, Glycine max, has proven an excellent pest management strategy because corn rootworm larvae are unable to survive on the roots of soybean plants. In the mid-1980s, it was widely reported that some rotated cornfields in Illinois, Iowa, Minnesota, and South Dakota had root injury caused by northern corn rootworms that prolonged their embryonic diapause through two consecutive winters. In 1987, agronomists reported corn rootworm larval injury in several rotated maize seed-production fields in east-central Illinois. Entomologists collected larvae and returned them to the laboratory where they completed their development as western corn rootworms. Explanations for the western corn rootworm larval injury to rotated maize were not lucid. Since 1987, crop rotation has continued to fail as a pest management strategy for western corn rootworms across an expanding geographical region of the eastern Corn Belt of the USA. Rather than prolonging their embryonic diapause, western corn rootworms have seemingly adapted to crop rotation by laying at least a portion of their eggs directly into soybean fields. Oviposition into other crops such as alfalfa, Medicago sativa L., also has been confirmed. Our current hypothesis suggests that the intensive selection pressure of an annual rotation of maize with soybeans has selected for a new western corn rootworm strain that does not restrict its oviposition to maize. The consequence of this novel adaptation to a cultural pest management strategy has been an impressive escalation of soil insecticide use in rotated maize fields in Illinois, Indiana, southern Michigan, and western Ohio. Designing effective resistance management plans for transgenic cultivars for corn rootworms will be a challenge because producers are likely to plant these varieties on both rotated and non-rotated maize acres.

Index terms: Diabrotica virgifera virgifera, Diabrotica barberi, crop rotation.

[0160] INSECTICIDE RESISTANCE IN THE WESTERN CORN ROOTWORM: IMPLICATIONS TO CURRENT AND FUTURE MANAGEMENT STRATEGIES

B.D. Siegfried¹, L.J. Meinke¹, M.E. Scharf¹, R.J. Wright² & L.D. Chandler³, ¹Dept.of Entomology, University of Nebraska, Lincoln, NE 68583-0816, E-mail bsiegfried1@unl.edu; ²South Central Research and Extension Center, university of Nebraska, Box 66, Clay Center, NE 68933; ³USDA-ARS, Red River Valley Agricultural research Center, P.O. Box 5674, Fargo, ND 58501

Insecticide resistance in the western corn rootworm Diabrotica virgifera virgifera (Coleoptera: Chrysomelidae) has been identified in two separate instances. Both times the resistance was first detected in Nebraska. Cyclodiene resistance was detected in the late 1950's and was accompanied a rapid eastward range expansion for this species. Cyclodiene resistance has been maintained in western corn rootworms despite the absence of selective pressures since this class of insecticides was banned from use in the United States since 1972. Resistance to organophosphate insecticides was first detected in 1995 and was associated with areas where adult rootworm control was utilized as the primary management strategy in excess of 10 years. The distribution of resistant populations suggests that the resistance evolved independently in two separate locations. However, populations previously documented as being susceptible have shown increased tolerance to diagnostic concentrations of insecticide in relatively short periods of time (<2 years). The mechanism of resistance seems to be relatively specific because the performance of other organophosphates and insecticide classes are unaffected by the resistance. However, larval rootworms exhibit similar levels of resistance as adults. Similarities and differences between the development of cyclodiene resistance in the 1950's and organophosphate resistance in the 1990's will be discussed and will provide a basis for assessing the risk of resistance evolution to new rootworm management strategies such as areawide pest management and transgenic plants.

Index terms: Diabrotica, resistance, cyclodienes, organophosphates

[9161] AREAWIDE MANAGEMENT OF *DIABROTICA* SPP. (COLEOPTERA: CHRYSOMELIDAE): USE OF NOVEL CONTROL TECHNOLOGIES ACROSS THE LANDSCAPE

L. D. Chandler, USDA-ARS, Red River Valley Agricultural Research Center, P.O. Box 5677, Fargo, North Dakota, 58105-5677, USA. E-mail: chandlel@fargo.ars.usda.gov

Areawide pest management can be an effective tool to control insect pests of economic importance using organized and coordinated attacks on pest populations over large geographic areas. This approach can enhance the effectiveness of biologically-based technologies (e.g., mating disruption, attract and kill systems, augmentative biological control, & sterile male release). Within the United States maize (Zea mays L.) production areas insects in the genus Diabrotica (corn rootworms) inflict serious damage to millions of hectares of maize roots in any given year. In recent years corn rootworms have become more difficult to manage due to behavioral adaptations. The ability to overcome maize/soybean rotations throughout major portions of the production area, plus insecticide resistance development in Nebraska have caused concern among crop managers, and has resulted in the need to develop alternative management strategies. Over the last four years application of a semiochemical insecticide-bait in a coordinated fashion (areawide approach) to maize has occurred at several sites across the United States. These baits are specific to corn rootworm adults and have lowered populations and reduced maize plant damage during preceding growing seasons. Rootworm populations and accompanying damage within these sites in 1999 were lower than in 1997 (the first year of program Recently, studies have been initiated to evaluate the role of genetically evaluation). modified maize for rootworm resistance within an areawide management program. As new maize hybrids with rootworm resistance traits are introduced into the market, strategies will be needed to adequately manage resistance development and hybrid use. Areawide management offers growers the opportunity to use genetically modified plants alongside semiochemical insecticide-baits and other biologically-based technologies to more effectively control corn rootworm and to adequately protect new technologies for future long-term use.

Index terms: Diabrotica virgifera virgifera, Diabrotica virgifera zeae, Diabrotica barberi, integrated pest management, semiochemical insecticide-baits.

[0162] MANAGEMENT OF MEXICAN CORN ROOTWORM (COLEOPTERA:CHRYSOMELIDAE)

W. C. Hoffmann¹ & J. R. Coppedge², ¹USDA-ARS-Areawide Pest Management Research Unit, 2771 F&B Rd., College Station, TX 77845, USA, email: choffmann@tamu.edu; ²USDA-Southern Plains Area, 7607 Eastmark Drive, Suite 230, College Station, TX 77840, USA.

An adult management program for the Mexican corn rootworm (Diabrotica virgifera Krysan and Smith) has been conducted in Texas, USA since 1995. The program has focused on establishing scouting and treatment protocols that can be used by producers, extension agents, and crop consultants to manage corn rootworm populations. Rootworm populations are monitored through traps and plant counts. By working with a private company, traps were developed that made it easier to monitor rootworm abundance. Treatment thresholds were set at 100 cumulative beetles per trap. If treatment thresholds are exceeded, a semiochemical-based insecticide is used to control the adults. This insecticide contains a feeding stimulant that is specific to Diabrotica spp.; therefore, no non-target or beneficial organisms are impacted by the treatment. The management program has been very successful in Texas. At one site in central Texas, the corn that was treated due to corn rootworm infestations was reduced from 810 ha (2000 acres) in 1995 to only 39 ha (95 acres) in 1998. The use of soil insecticides in the area was also reduced to 1/4 to 1/2 of the conventional rate, which greatly reduces to amount of chemicals used in corn production. Due to the success of the adult program at this site, additional sites around Texas were added in 1998 and 1999. The purpose of these additional sites was to introduce the control program to others around the state and to refine the program protocols to each site. By 1999, adult control programs in Texas were being conducted at 5 sites involving 24 producers and approximately 4000 ha (9900 acres). Index terms: rootworm, Diabrotica, areawide management, corn.

[0163] MANAGEMENT OF WESTERN CORN ROOTWORM IN EUROPE

J. Kiss¹, J. Igrc-Barcic² & C.R. Edwards³, ¹Dept. of Plant Protection, Szent István Univ. Gödőll 6. H-2100 Gödöll 6, Hungary, E-Mail jkiss@gikk.gau.hu; ²Faculty of Agriculture, Univ. of Zagreb, Svetosimunska cesta 25, 10000 Zagreb, Croatia, E-mail ibarcic@agr.hr; ³Dept. of Entomology, Purdue Univ, W. Lafayette, Indiana 47907-1158, USA, E-mail rich_edwards@entm.purdue.edu

The western corn rootworm (WCR) was first detected (larval damage) in a cornfield near Belgrade, Yugoslavia, in 1992 (Baca 1993). It is likely to have arrived in Yugoslavia in the early to mid 1980's (Edwards et al. 1998). By 1999 it had spread over about 150,000 km² in Europe (Bulgaria, Bosnia-Herzegovina, Croatia, Hungary, Romania and Yugoslavia). WCR beetles were trapped in 1998 and 1999 in Italy, near Venice airport. WCR spread in Europe has continued in all directions from the original infestation point. The greatest movement was observed on the plains, in valleys with some movement in hilly regions. The population build up in infested areas depends on corn growing practices (continuous or rotation, insecticide application) and on soil properties (moisture, type of soil). By late 1999, an economic population of WCR was well established in Yugoslavia, while larval damage below the economic threshold was observed in Bosnia-Herzegovina, Croatia, Hungary and Romania. Countries around the infested area operated traps as part of the WCR NET networking activity (supported by FAO), but they have not detected any WCR beetles. It is expected that other countries in the region (Austria, Slovakia, Ukraine) will be infested and an economic WCR population will build up in Bosnia-Herzegovina, Croatia, Hungary and Romania in coming years. Its biology in the infested regions is almost the same as that of middle Indiana, USA. The spread and population buildup of the western corn rootworm (WCR) requires that multiple management strategies be developed for the control of this corn pest (crop rotation, soil pesticide application, control of adult

WCRs). The concept of SLAM[®]-based areawide pest management of WCR is being developed in the USA (Chandler, 1998) and has been adapted in Hungary as part of UN FAO TCP 6712 Project, that included the following in Hungary: - selection of suitable area and fields; - adaptation of application techniques; - field scouting of WCR for decision making; - post treatment scouting and evaluation to determine outcomes. SLAMbased areawide management of WCR resulted in efficacy rates of over 90% (5 days after treatment) with a slow decrease after 10 and 15 days in 1998 and 1999. The concept of areawide management has proven to be an effective way to manage WCR and should be considered a viable control strategy in Europe. Details on population level, treatments will be discussed in the lecture. Spiders (Theridiidae and Agelenidae) as predators of WCR adults were proved in confields in Hungary (Toth et al. 2000).

Index terms: Diabrotica virgifera virgifera, spread, biology, control, Europe.

[0164] MANAGEMENT OF DIABROTICA SPECIOSA IN BRAZIL

<u>P. A. Viana¹, ¹</u>Embrapa Milho e Sorgo, Caixa Postal 151, Sete Lagoas, MG 35701-970, Brazil, E-mail pviana@cnpms.embrapa.br.

Diabrotica spp. is a serious pest in the Americas. Two species, Diabrotica speciosa and Diabrotica viridula, occur in Brazil, where D. speciosa is predominant. This pest is distributed in both South and Central America. The adults feed on the leaves of vegetable crops, beans, soybean, sunflower, banana, cotton and corn. The larva damage the corn root and potato tubers. The damage caused by the larva in corn roots interferes in the absorption of nutrients and water and it reduces the stability of the plants, causing lodging under severe wind and rainfall conditions. The eggs of this insect are yellowish-white and they are deposited on the soil around the base of plants. The larvae reach 10 mm in length, are white in color with brown heads a dark plate in the last abdominal segment. The adults beetles measure about 6 mm in length, are green color with six yellow stains with a black tibia and a brown head. The life cycle ranges from 24 to 40 days. There is little information available about the management of this pest. The sampling method most commonly used for larva of D. speciosa is sifting the soil on a black plastic, where the larva can be identified. Other methods, such as the Berlese's funnel and flotation can also be used. Preliminary results indicate that an average density of 3,5 to 5 larvae per plant causes damage to corn root, corresponding to the value of 4,2 on the scale of Hills & Peters (1971), while a density of about 30 larvae corresponds to a 5,7 on the same scale. In Brazil, the control of the larva of D. speciosa in corn is almost exclusively with the use of chemical insecticides, but it is rarely employed. In no-tillage systems, the best results in the control of the larvae with insecticides have been obtained with granular forms tebupirimfos, phorate, chlorpyrifos or spraying with chlorpyrifos, both applied in furrow, In situations where control was not used at planting, the application of terbufos and tebupirimfos granules in the row and chlorpyrifos sprayed on the base of the plants and incorporated into the soil with a cultivator have been the most efficient for larvae control. Although in other countries there is reference to resistant cultivars of corn to other species of Diabrotica, in Brazil, research seeking genetic resistance to this pest is incipient. The occurrence of the biological control has been reported through the use of natural enemies. Celatoria bosqi, Centistes gasseni, and the fungus Beauveria bassiana and Metarhizium anisopliae. Preliminary results indicate that soil moisture is one factor to be considered in the management of D. speciosa. A greater occurrence of larva has been observed in experimental areas in soils with higher moisture content. Soil preparation methods have also been shown to influence the population dynamics of this insect. A larger occurrence of larva has been found in areas prepared with the moleboard plow than in no-tillage. Index terms: corn rootworm, soil insect, insecta, control, Zea mays

[0165] TRANSGENIC MAIZE FOR MANAGEMENT OF DIABROTICINE PESTS

J.E.Foster, Dept. of Entomology, Univ. of Nebraska, 312F P.I. Bldg., Lincoln, Nebraska, USA 68583-0816, Email jfoster1@unl.edu.

Several crops have been developed for resistance to major insect pests. Maize has been transformed for resistance to *Diabrotica virgifera virgifera*, the westorn corn rootworm. This Diabroticine pest is the major maize insect pest in North America. The use of transgenic deployed resistance genes offers a safe and environmentally strategy for management of this insect. The performance of transgenic maize will be discussed and compared and contrasted to use of conventional management tools.

Index terms: Diabrotica virgifera virgifera, corn rootworms, transgenes.

[0166] GLOBAL PERSPECTIVE OF DIABROTICA MANAGEMENT

C. R. Edwards, Dept of Entomology, Purdue Univ., 1158 Smith Hall, W. Lafayette, IN 47907-1158, USA, E-mail rich_edwards@entm.purdue.edu.

The Diabroticites are pests of corn in areas of South, Central, and North America, as well as Central Europe. Although the damage caused by these chrysomelids to corn is similar in all infested areas, the means of control can vary. In South America, Diabrotica speciosa and D. viridula are of importance, although D. s. is the most important. The larvae of D. s. cause damage in southern, southeastern, and west-central Brazil, as well as some areas of southwest-central and northwestern South America. In Brazil, granular and liquid insecticides are applied mostly in-furrow. Also, low numbers of larvae have been observed where soil moisture is low and where no-till is used. In Central America, D. balteata is the most important species, although problems with this species on corn are few. D. virgifera virgifera, D. v. zeae, D. barberi, D. undecimpunctata howardi, and D. balteata are the major Diabroticite pests of corn in North America, although pest status varies from north to south. The species of greatest importance are the D, v, v, D, v, z, and D, barberi. In the Midwestern USA, D. v. v. and D. barberi are the primary pest species with the D. v. v. being a problem primarily in the more central and southern areas of this region, including southern Ontario, Canada, and D. burberi in the northern areas of the Midwest and into parts of southern Canada. D. v. z. is primarily a pest of corn in Texas, Oklahoma, and Mexico. In North America, there are some differences in how rootworms are control, but soil insecticides are often used. These are applied as band or in-furrow treatments in either granular or liquid form. Also, crop rotation is used throughout the infested area for managing these species except where continuous corn is grown or where the variant of D. v. v. is found (parts of Illinois, Indiana, Michigan, and Ohio). In parts of North America, areawide management of adults to reduce egg laying is being evaluated. In Central Europe, the D. v. v. is the only Diabrotica species that has been observed. The primary area of economic infestation is in Serbia, although this species is also found in Bosnia-Herzegovina, Bulgaria, Croatia, Hungary, Italy, Montenegro, and Romania. Where economic infestations occur, farmers use crop rotation and soil insecticides for larval management, or do nothing. Because of the present economic situation in this area, many farmers do not have enough money to purchase insecticides or may not be able to use crop rotation due to their need for corn to feed livestock. Also in this region, areawide management of adults is being tried as noted above for the Midwestern USA.

Index terms: Diabrotica spp., insecticide control, soil insecticides, crop rotation, areawide management.

[0167] FORAGING ACTIVITY OF BUMBLEBEES IN GREENHOUSE MUSKMELON CROP

S. Albano¹, E. Salvado¹, M. C. Godinho² & A. Mexia³, ¹Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal; ²Escola Superior Agrária de Viseu, Campus Politécnico, 2500 Viseu ceugodinho@isa.utl.pt; ³Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras amexia@isa.utl.pt

The use of bumblebees (*Bombus terrestris*) to attend the pollination of greenhouse muskmelon crop is a recent practice in Portugal. Foraging activity of the bumblebees' coloay in muskmelon greenhouse conditions was analysed either at the activity level of the bive (tunnel-traffic) or at individual activity on the flowers. The high number of individuals that entered in the hive without pollen baskets evidenced that the nectar was the main resource explored by this colony. Small amounts of pollen collected to the colony may have contributed to reduce its longevity (1.5 to 2 months) and for the non-emergence of male or female sexual forms. Bumblebees had been observed to collect pollen from the weed plants *Solanum nigrum* that were abundance inside the greenhouse, what meaning that they should work as magnetic plants, since they did allow a greater number of visits to muskmelon flowers. Staminate flowers have received visits after 9:00h and the hermaphroditic only after 12:00h. Bumblebee pollination activity apparently was adjusted to the periods of the day that allow a higher concentration of sugar in the nectar and when the foraging was energetically more advantageous.

Index terms: Bombus terrestris, pollinator activity, Cucumis melo

[0168] GENERAL PATTERN OF BUMBLEBEE VISITS TO TOMATO FLOWERS IN GREENHOUSE CONDITIONS

<u>S. Albano¹</u>, E. Salvado¹ & J. Cadima², ¹Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal; ²Instituto Superior de Agronomia, Departamento de Matemática, Tapada da Ajuda, 13449-017, Lisboa, Portugal.

The behavioural study of bumblebees (Bombus terrestris) during the flower visits and throughout a sequence of visits is important for a more correct evaluation of the pollinator effectiveness in greenhouse tomato crops. The average time visit of a bumblebec to a tomato flower was 5.03 s \pm 0.16 and the buzz time (flower vibration time for pollen extraction) was 2.72 s \pm 0.06. The majority of the visits had been to flowers already visited (revisits). From all observed foragers visiting flowers, 26.99% presented grooming behaviour during the visit and in 73.01% only buzz was detected. The occurred variations in buzz time had not been explained by the oscillations of temperature and relative humidity in the greenhouse. Some factors may explain the variations in visits time: occurrence of grooming behaviour, learning the best way for foraging flowers, size of pollen baskets carried by forager and amount of available pollen in the flowers. Individuals that were followed at his foraging activity in the flowers allowed us to characterise the foraging strategy of bumblebees in greenhouse conditions. The high number of visits per minute and short interflower time have revealed the capacity of one forager to visit many flowers in a short space of time. Throughout a sequence of visits, bumblebees visited more flowers of the upper cluster and only one flower per plant. This behavioural pattern showed an optimal foraging strategy that allow to decrease interflower time, minimising the energy costs of flight, and to maintain a particular direction while moving through a flower patch.

Index terms: Bombus terrestris, pollinator behaviour, foraging strategies

[0169] INFLUENCE OF CROPPING SEASON IN FORAGING ACTIVITY OF BUMBLEBEE IN GREENHOUSE TOMATO CROP

<u>S. Albano¹, E. Salvado¹, E. Figueiredo¹ & A. Mexia², Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal; ²Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras amexia@isa.utl.pt</u>

The effectiveness of bumblebee's (Bombus terrestris) use in greenhouse tomato pollination is variable. Different cropping seasons provide different conditions to the crop, being expectable that foraging behaviour of bumblebees adjusted to those variations and their efficiency, as pollinators, could be affected. Pollination activity at different cropping season (spring and autumn) was analysed, as well as pollinators behaviour in foraging activity on flowers. The main difference was a smaller visit duration at autumn. This result is related with higher temperatures and smaller humidities registered during the autumn, which facilitates pollen extraction from the flowers. In autumn, a bigger portion of pollen is collected in each visit. In order to obtain a certain amount of pollen, bumblebees need to visit a small number of flowers, which result in less time spent by each individual in foraging through this season. The hives tunnel traffic and pollination intensity on the crop was significantly bigger (α =0.05) in the spring. The significant differences were also verified for the individual behaviour of foragers: a higher number of visits per minute and smaller interflower times were observed in the autumn. As a result of these differences in pollinators activity, it was detected a smaller number of marks from bumblebee flower visits in the autumn, and they are less noticeable in this season. In spite of bumblebees efficiency as foragers, which was bigger in the autumn, their contribution to the tomato crop pollination was more important in the spring season. Index terms: Bombus terrestris, pollinator efficiency, cropping season

[0170] AGRONOMIC EFFICIENCY OF INSECTICIDES AT DIFFERENT RATES TO THE CONTROL OF APHIS GOSSYPII IN COTTON CROP

<u>F. A. Albuquerque¹</u>, A. B. Ros¹, S. C. Mendes¹ & L. F. Weber², ¹Univ. Estadual de Maringá, Dept. de Agronomia, Av. Colombo, 5790, CEP 87020-900, Maringá, PR, Brasil, E-mail: faalbuquerque@uem.br; ²Bayer S/A, Proteção de Plantas, Londrina, PR, Brasil.

The cotton aphid has a nearly cosmopolitan world distribution and infest innumerable species of Dicotyledonous plants. The transmission of virus diseases is a further pernicious aspect attaching to their infestations. The purpose of this work was to evaluate the efficiency of different rates of insecticides in the control of Aphis gossypii, in cotton crop. The research was conducted at Iguatemi Experimental Farm, State University of Maringá, Paraná State, Brazil, using a randomized blocks design with 8 treatments and 4 replications. The experimental units had 5 rows (0.8 m apart) by 6 m long. Treatments evaluated were the insecticides: carbosulfan (Marshal) at 120 g a.i./ha, oxydemeton-methyl (Metasystox R) at 200 g a.i./ha, prothiofos (Tokution) at 500 and 750 g a.i./ha, imidacloprid (Provado) at 50 g a.i./ha, thiacloprid (Calypso) at 34 and 48 g a.i./ha and check without insecticides. The products were applied in an unique dose on January, 16th 99, using a CO2-pressurized knapsack sprayer calibrated for an output of 165 liters of water per hectare. The application was done at the beginning of infestation. Three evaluations were realized, being the first one just before spraying and the others at 3 and 8 days after application. For each evaluation, the number of insects was counted in 10 plants in each parcel. The final data were submitted to statistics analyses (F and Tukey tests) and the calculated efficiency percentages by Abbott formula. The results showed that imidacloprid (Provado) at 50 g a.i./ha and thiacloprid (Calypso) at 34 and 48 g a.i./ha were distinguished as the best treatments, showing levels of control of at least 96%, at 3 days after applications, and 80% at 8 days after applications. Carbosulfan (Marshal) at 120 g a.i./ha provided adequate control until 3 days after application. The others treatments did not present the necessary efficiency.

Index terms: carbosulfan, oxydemeton-methyl, prothiofos, imidacloprid, thiacloprid

[0171] AGRONOMIC EFFICIENCY OF INSECTICIDES AT DIFFERENT RATES TO THE CONTROL OF *STERNECHUS SUBSIGNATUS* IN SOYBEAN

<u>F. A. Albuquerque</u>¹, F. C. Pattaro¹, A. V. Zabini¹, J. U. T. Brandão Filho¹ & O. Callegari¹, ¹Univ. Estadual de Maringá, Dept. de Agronomia, Av. Colombo, 5790, CEP 87020-900, Maringá, PR, Brasil, E-mail: faalbuquerque@uem.br

The purpose of this work was to evaluate the efficiency of different rates of insecticides in the control of Sternechus subsignatus, in soybean. The research was conducted in Faxinal city, Paraná State, Brazil, using a randomized blocks experimental design, with 6 treatments and 4 replicates. Each experimental unity was composed by 10 rows, 10 m long, 0.4 m apart from each other. Treatments evaluated were the insecticides: betacyfluthrin (Turbo) at 8 g a.i./ha, methamidophos (Tamaron BR) at 480 g a.i./ha, thiacloprid (Calypso) at 36, 48 and 72 g a.i./ha and check without insecticides. The products were applied in an unique dose on December, 16th, 99, using a CO2-pressurized knapsack sprayer calibrated for an output of 250 liters of water per hectare. The application was done when infestation level reached 2 adults insects/n. Three evaluations were realized, being the first one just before spraying and the others at 3 and 7 days after application. For each evaluation, the number of adults insects was counted in 10 m of soybean rows in each parcel. The final data were submitted to statistics analyses (F and Tukey tests) and the calculated efficiency percentages by Abbott formula. The results showed that thiacloprid (Calypso) at 36, 48 and 72 g a.i./ha provided a excellent control at 3 days after application, showed a efficiency of 91.67%, 100% and 100%, respectively. Betacyfluthrin (Turbo) and methamidophos (Tamaron BR) showed a efficiency of 75% and 83,33%, respectively. At 7 days after application, thiacloprid (Calypso) at 48 and 72 g a.i./ha were the best treatments, with 81% and 86% of efficiency, respectively. Betacyfluthrin (Turbo), methamidophos (Tamaron BR) and thiacloprid (Calypso) at 36 g a.i, Ana, showed a efficiency of 70.59%, 76.47 and 76.47%, respectively.

Index terms: chemical control, betacyfluthrin, methamidophos, thiacloprid.

[0172] EFFICIENCY OF DIFFERENT INSECTICIDES IN THE CONTROL OF THRIPS, FRANKLINIELLA SCHULTZEI, IN LETTUCE

F. A. Albuquerque¹, F. C. Pattaro, J. U. T. Brandão Filho¹, O. Callegari¹ & K. Silva¹, ¹Univ. Estadual de Maringá, Dept. de Agronomia, Av. Colombo, 5790, CEP 87020-900, Maringá, PR, Brasil, E-mail: faalbuquerque@uem.br

This work was carried out in Maringá city, Paraná State, Brazil, from September to October, 1999, to evaluate the efficiency of some insecticides in the control of thrips, Frankliniella schultzei, in lettuce, cv. Veronica. A randomized blocks design with 6 treatments and 4 replications was adopted. Each parcel was composed by 4 lines, 7 m long, 0.3 m apart from each other. Treatments evaluated were the insecticides: thiacloprid (Calypso) at 48 g a.i./ha, imidacloprid (Provado) at 70 g a.i./ha, methiocarb (Mesurol) at 375 g a.i./ha, clorpirifos (Astro) at 338 g a.i./ha, betacyfluthrin (Turbo) at 3.75 g a.i./ha and check without insecticides. The products were applied in an unique dose on September, 28th, 99, using a CO2-pressurized knapsack sprayer calibrated for an output of 500 liters of water per hectare. The application was done at the beginning of infestation. Three evaluations were realized, being the first one just before spraying and the others at 2 and 7 days after application. For each evaluation, the number of insects was counted in 10 plants in each parcel. The final data were submitted to statistics analyses (F and Tukey tests) and the calculated efficiency percentages by Abbott formula. The results showed that imidacloprid (Provado), methiocarb (Mesurol), cloppirifós (Astro) and betacyfluthrin (Turbo) provided a excellent control at 2 days after application, showed a efficiency of 91.25%, 98.99%, 95.62% and 97.31%, respectively. Thiacloprid (Calypso) at 48 g a.i./ha, showed a efficiency of 70.37%. At 7 days after application, the insecticides imidacloprid, methiocarb, clorpirifós and betacyfluthrin showed a efficiency of 95.88%. 92,65%. 83.09% and 82.35%, respectively. Thiacloprid showed a efficiency of 75.74%. Index terms: thiacloprid, imidacloprid, methiocarb, clorpirifós, betacyfluthrin.

[0173] EFFICIENCY OF INSECTICIDES IN THE CONTROL OF PECTINOPHORA GOSSYPIELLA IN COTTON CROP

F. A. Albuquerque¹, F. C. Pattaro¹, J. U. T. Brandão Filho¹, O. Callegari¹ & L. M. Borges¹, ¹Univ. Estadual de Maringá, Dept. de Agronomia, Av. Colombo, 5790, CEP 87020-900, Maringá, PR, Brasil, E-mail: faalbuquerque@uem.br

This work was carried out in Maringá city, Paraná State, Brazil, from February to April 1997, to evaluate the efficiency of some insecticides on Pectinophora gossypiella control in cotton crop. A randomized blocks design with 6 treatments and 4 replications was adopted. The experimental units had 5 rows (0.8 m apart) by 10 m long. Treatments evaluated were the insecticides: lambdacyhalothrin (Karate 50 CS) at 12.5 g a.i./ha; lambdacyhalothrin (Karate 250 CS) at 12.5 g a.i./ha; lambdacyhalothrin (Karate 50 CE) at 12.5 g a.i./ha; deltamethrin (Decis 25 CE) at 7.5 g a.i./ha; betacyfluthrin (Bulldock 125 SC) at 10 g a.i./ha and check without insecticides. Two applications were done; the first one at the beginning of infestation and the second 15 days later. The products were applied using a CO2-pressurized knapsack sprayer calibrated for an output of 250 liters of water per hectare. Evaluations were realized in 3 central lines, the first one prior to insecticide spraying and the other at 4 days after application of insecticides, counting the number of small bolls attacked. The final data were submitted to statistics analyses (F and Tukey tests) and the calculated efficiency percentages by Abbott formula. The results showed that lambdacyhalothrin (Karate 50 CS) at 12.5 g a.i./ha and lambdacyhalothrin (Karate 250 CS) at 12.5 g a.i./ha were the best treatments, both with 71.43% of efficiency. Lambdacyhalothrin (Karate 50 CE) at 12.5 g a.i./ha, deltamethrin (Decis 25 CE) at 7.5 g a.i./ha and betacyfluthrin (Bulldock 125 SC) at 10 g a.i./ha showed a efficiency of 53,57%, 50% and 57,14%, respectively.

Index terms: pink bollworm, lambdacyhalothrin, deltamethrin, betacyfluthrin.

[0174] EFFICIENCY OF INSECTICIDES IN THE CONTROL OF THRIPS, FRANKLINIELLA SCHULZEI, IN COTTON CROP

A. Albuquerque¹, M. A. Kaiser¹, M. Stülp¹ & L. F. Weber², ¹Univ. Estadual de Maringá, Dept. de Agronomia, Av. Colombo, 5790, CEP 87020-900, Maringá, PR, Brasil, E-mail: faalbuquerque@uem.br; ²Bayer S/A, Proteção de Plantas, Londrina, PR, Brasil.

The purpose of this work was to evaluate the efficiency of different rates of insecticides in the control of Frankliniella schulzei, in cotton crop. The research was conducted at Iguatemi Experimental Farm, State University of Maringá, Paraná State, Brazil, using a randomized blocks design with 8 treatments and 4 replications. The experimental units had 5 rows (0,8 m apart) by 6 m long. Treatments evaluated were the insecticides: carbosulfan (Marshal) at 120 g a.i./ha, oxydemeton-methyl (Metasystox R) at 200 g a.i./ha, prothiofos (Tokution) at 500 and 750 g a.i./ha, imidacloprid (Provado) at 50 g a.i./ha, hiacloprid (Calypso) at 34 and 48 g a.i./ha and check without insecticides. The products were applied in an unique dose on November, 12th, 98, using a CO2-pressurized knapsack sprayer calibrated for an output of 187 liters of water per hectare. The application was done at the beginning of infestation. Four evaluations were realized, being the first one just before spraying and the others at 2, 5 and 7 days after application. For each evaluation, the number of insects was counted in 10 plants in each parcel. The final data were submitted to statistics analyses (F and Tukey tests) and the calculated efficiency percentages by Abbott formula. The results showed that imidacloprid (Provado) at 50 g a.i./ha and thiacloprid (Calypso) at 34 and 48 g a.i./ha provided levels of control of at least 90%, in all evaluations. Carbosulfan (Marshal) at 120 g a.i./ha and prothiofos (Tokution) at 500 and 750 g a.i./ha provided adequate control until 2 days after application.

Index terms: carbosulfan, oxydemeton-methyl, prothiofos, imidacloprid, thiacloprid

[0176] EFFICIENCY OF THE FORMULATION 50 SC OF THE PYRETHROID LAMBDA-CYALOTHRIN IN THE CONTROL OF ANTICARSIA GEMMATALIS IN THE SOYBEAN CROP

B. Alleoni ¹ & A. M. De Souza Neto ², ¹Dept. of Agronomy, Ponta Grossa State Univ., Praça Santos Andrade, s/nº, Ponta Grossa, PR, 84010-790, BR; ² Technical Department, Zeneca Brasil Ltda, R. Aldo Vergani, 952, Ponta Grossa, PR, 84035-160, BR.

The effects of rates and formulations of the pyrethroid lambda-cyalothrin in the control of the Anticarsia gemmatalis in soyean crop (Glycine max) were evaluated in this trial in Ponta Grossa, 1998. The treatments conducted as randomized blocs and with four replicates were as folow: Karate Zeon 50 CS (3,75 g i.a./ha), Karate Zeon 50 CS (5,0 g i.a./ha), Karate 50 CE (3,75 g i.a./ha), Karate 50 CE (5,0 g i.a./ha), Thiodan CE (175 g i.a./ha) and control. Each experimental unit was 2,5 m wide and 6,0 m long. The spraying was done once in 04/03/98 with a CO₂ equipment and outflow of 300 l/ha and the evaluations were done 1, 3, 7, 10 and 14 days after the spraying. The evaluations of the mortality of the caterpillars were done with the "cloth method". The results showed that all dosages of the two formulations of Karate were efficient in the control of A. gemmatalis until 7 days after the spraying and until 10 days when the highest dosages were used. The insecticide Thiodan CE was efficient until 7 days after the spraying. The formulations CS (microencapsuled) and CE (emulsionable concentrated) and the dosages of 3,75 and 5,0 g i.a./ha of the insecticide lambda-cyalothrin did not differ statistically in the control of the pest on the seventh day after the spraying, but differed between both dosages of both formulations on the tenth day. The caterpillar A. generatalis that usually reaches high populational levels during the crop development, was efficiently controled by the pyrethroid lambda-cyalothrin.

Index terms: Anticarsia gemmatalis, soybean, Glycine max, pyrethroid, lambda-cyalothrin.

[0175] SURVEY OF THE ARTHROPODS ASSOCIATED TO MALPIGHIA GLABRA IN ANGULO, PARANA, BRAZIL

F. A. Albuquerque¹, F. C. Pattaro¹, L. M. Borges¹ & R. S. Lima¹, ¹Univ. Estadual de Maringá, Dept. de Agronomia, Av. Colombo, 5790, CEP 87020-900, Maringá, PR, Brasil, E-mail: faalbuquerque@uem.br

Surveys to determine the occurrence and abundance of arthropod populations associated to Malpighia glabra were conduced from September 1997 to March 1999, in Angulo city, Paraná State, Brazil. Insects and mites were collected once every two weeks in an acerola orchard. Seventeen families of insects were observed: Acrididae, Chrysopidae, Pentatomidae, Pyrrhocoridae, Coreidae, Reduviidae, Membracidae, Aphididae, Coccidae, Diaspididae, Cicadellidae, Ichneumonidae, Vespidae, Formicidae, Chrysomelidae, Tephritidae e Otitidae. The most common species were: Schistocerca spp., Chrysopa sp, Nezara viridula, Piezodorus guildinii, Euschistos heros, Thyanta spp., Dysdercus ruficolis, D. peruvianus, Leptoglossus zonatus, L. gonagra, Enchenopa gracilis, Toxoptera citricidus, Aphis citricidus, Saissetia coffeae, S. oleae, Coccus viridis, Selenaspidus articulatus, Dilobopterus costalimai, Oncometopia facialis., Diabrotica speciosa, Cerotoma spp., Colaspis spp., Lagria vilosa, Ceratitis capitata, Anastrepha fraterculus and Euxesta sp. C. capitata and D. speciosa were the predominant species. The first specie showed a higher frequency in September, October and November, and the second showed a higher frequency in September, March and April. Five families of mites were observed: Tydeidae, Tenuipalpidae, Tarsonemidae, Tetrannychidae e Phytoseiidae. The most common species were: Lorrya formosa, Brevipalpus phoenicis, Polyphagotarsonemus latus, Tetranychus urticae and T. mexicanus. Index terms: Barbados cherry, West Indian cherry, acerola.

(0177) EFFICIENCY OF THE FORMULATION 50 SC OF THE PYRETHROID LAMBDA-CYALOTTIRIN IN THE CONTROL OF PSEUDALETIA SEQUAX (MYTHIMNA SEQUAX) IN THE WHEAT CROP

<u>B. Alleoni</u>¹ & A. M. De Souza Neto², ¹Dept. of Agronomy, Ponta Grossa State Univ., Praça Santos Andrade, s/n^o, Ponta Grossa, PR, 84010-790, BR; ²Technical Department, Zeneca Brasil Ltda, R. Aldo Vergani, 952, Ponta Grossa, PR, 84035-160, BR.

The effects of rates and formulations of the pyrethroid lambda-cyalothrin in the control of Pseudaletia seguax in wheat crop (Triticum aestivum) were evaluated in this trial in Ponta Grossa, 1997. The treatments conducted as randomized blocs and with four replicates were as folow: Karate Zeon 50 CS (5,0 g i.a./ha), Karate Zeon 50 CS (7,5 g i.a./ha), Karate 50 CE (5,0 g i.a./ha), Karate 50 CE (7,5 g i.a./ha), Lorsban 480 BR (480 g i.a./ha) and control. Each experimental unit was 2.5 m wide and 6.0 m long. The spraying was done once in 03/11/97 when the population of caterpillars averaged 12.5 individuals per square meter, with a CO2 equipment and outflow of 300 l/ha. The evaluations were done 1, 3, 7, 10 and 14 days after the spraying. The evaluations of the mortality of the pest were done with a square wire frame of 0,5 m. The results showed that all dosages of the two formulations of Karate were efficient in the control of P.sequax until 10 days after the spraying, having its efficiency decreased on the fourteenth day. The insecticide Lorsban 480 BR was efficient until 7 days after the spraying. The formulations CS (microencapsuled) and CE (emulsionable concentrated) did not differ statistically in the control of the pest on the seventh day after the spraying, but did the dosages at this time. P.sequax can be efficiently controled by the pyrethroid lambda-cyalothrin.in wheat fields, when its population reaches the threshold of damage during the crop development Index terms: Pseudaletia sequax, wheat, Triticum aestivum, pyrethroid, lambda-cyalothrin[0178] EFFICIENCY OF THE FORMULATIONS 50 CS AND 250 CS OF THE PYRETHROID LAMBDA-CYALOTHRIN IN THE CONTROL OF *DIABROTICA SPECIOSA* IN BEAN CROP

B. Allconi ¹, A. M. De Souza Neto ² & II. Wiecheteck ³, ¹Dept. of Agronomy, Ponta Grossa State Univ., Praça Santos Andrade, s/n°, Ponta Grossa, PR, 84010-790, BR; ² Technical Department, Zeneca Brasil Ltda, R. Aldo Vergani, 952, Ponta Grossa, PR, 84035-160, BR; ³ R. Benjamin Constant, 871, Ponta Grossa, PR, 84010-380, BR.

The effects of rates and formulations of the pyrethroid lambda-cyalothrin in the control of *Diabrotica speciosa* in bean crop (*Phaseolus vulgaris*) were evaluated in this trial in Ponta Grossa, 1997. The treatments conducted as randomized blocs and with four replicates were as follow: Karate Zeon 50 CS (7,5 and 10,0 g.i.a./ha), Karate Zeon 250 CS (7,5 and 10,0 g.i.a./ha), Karate 50 CE (10,0 g.i.a./ha), Ortho-hamidop 600 (600,0 g.i.a./ha) and control. The spraying was done once with a CO₂ equipment and outflow of 200 l/ha and the evaluations were done 1, 3, 6 and 9 days after the spraying. The evaluatins were done with a cage of 0,4 x 0,8 m, covered with a tissue of thin mesh. The results showed that the rates and the formulations of the pyrethroid were efficient in the pest control until 6 days after spraying, decreasing its efficiencies until 9 days. Ortho-hamidop was efficient in the pest control until 9 days. The formulations SC (microencapsuled) and EC (emulsionable concentrate) and also the rates of 7,5 and 10,0 g.i.a./ha of lambda-cyalothrin gave the same control of *D. speciosa*, accourding to the statistical analysis.

Index teerms: bean, Phaseolus vulgaris, Diabrotica speciosa, pyrethroid, lambdacyalotrin.

[0180] SUBLETHAL EFFECTS OF ABAMECTIN SUPPRESSING COLONIES OF THE LEAF-CUTTING ANT ACROMYRMEX SUBTERRANEUS SUBTERRANEUS

E. C. Antunes¹, <u>R. N. C. Guedes</u>¹, T. M. C. Della Lucia¹ & J. E. Serrão², ¹Dept, of Animal Biology, Federal Univ. of Viçosa, Viçosa, MG 36571-000, Brazil, Email:guedes@mail.ufv.br; ²Dept. of General Biology, Federal Univ. of Viçosa, Viçosa, MG 36571-000, Brazil.

The assessment of the sublethal effects of abamectin on queens of the leaf-cutting ant Acromyrmex subterraneus subterraneus (Hymenoptera: Formicidae) was carried out. A concentration-response bioassay was conducted by exposing media workers to impregnated filter paper containing dried insecticide residue. This bioassay allowed the selection of the abamectin concentrations (0, 10, 50 and 100 mg a.i. ml⁻¹) to be used in the next phase in which eight queens were exposed to the insecticide. The highest concentration killed the queens, but the others survived and were placed back in their nests. Reductions in leaf consumption, fungus garden volume, and foraging activity were observed in colonies whose queens were exposed to higher abamectin concentrations. Colonies with queen serves at the other strong decrease in ovarioles per ovary and oocytes per ovariole with increased insecticide concentrations. It seems that abamectin-exposed queens became reproductively impaired producing little or no progeny and not properly replacing the colony members thus leading to the colony suppression.

Index terms: avermectin B1; macrocyclic lactones; reproductive impairment; oocyte development; Hymenoptera; Formicidae; ant control;

[0179] PERFORMANCE OF THE INSECTICIDES BUPROFEZIN 250; PYRIPROXIFEN 100 AND BUPROFEZIN 250 + ACEPHATE, IN CONTROL OF "WHITE FLY", *BEMISIA ARGENTIFOLII*, IN CABBAGE CROP

M. A. R. Alvarenga¹; <u>A.C. Silva²</u> & L. O. Salgado², 1 – Universidade Federal de Lavras/UFLA C.P 37 Lavras/MG 37.200-000 Brazil, 2 - Agroteste - Pesquisa e Consultoria Praça Leonardo Venerando, 284 C.P 201 Lavras/MG 37.200-000 Brazil Email agrotest@ufla.br

A serious problem occur throughout the Brazil for various years with "White fly" in many crops. The efficacy of Buprofezin 250, Pyriproxifen 100 and Acephate against "White fly", was tested at Agroteste Experimental Station - Lavras/Minas Gerais State - Brazil, from 05/02/99 until 25/06/99. The trial was set up in c.v. "Kenzan" planted in 1,0 x 0,5 m spacing. The experimental design used was randomized blocks, with 7 treatments replicated 4 times, each plot with $4,0 \text{ m}^2$. Were realized 4 applications weekly starting in 14/05/99 until 04/06/99. The treatments in commercial product/100L were: 1. Buprofezin 250-100g; 2. Buprofezin 250-150g; 3. Pyriproxifen 100-50 ml; 4. Pyriprofexin 100-75 ml; 5. Buprofezin 250 + Acephate - 150g + 50g; 6. Acephate 750 + Fenpropathrin 300 - 75g + 25ml and 7. Untreated. The products were applied in spray method with volume of 625L/ha. Were realized 3 evaluations in 7DAA (Days after the last application); 14 DAA and 21 DAA. Evaluated 2 leaves/plot established the number of nymphs and pupas living. The means were separate with Tukey (p<0.05) and the efficiency established with Abbott formula. The insecticide Buprofezin 250 showed and efficiency between 80,00 and 95,67% until 21 days after the last application. The insecticide Pyriproxifen 100 showed an efficiency between 78,00 and 92,06% until 21 days after the last application. The associate of insecticides Buprofezin 250 + Acephate showed an efficiency between 87,33 and 97,11 until 21 days after the last application.

Index terms: Bemisia argentifolii, white fly, cabbage crop., chemical control.

[0181] FRUIT FLIES OF THE GENUS ANASTREPHA IN THE FRUIT PRODUCING REGION OF MOSSORO/ASSU, RIO GRANDE DO NORTE, BRAZIL

<u>E. L. Araujo</u>¹, V. E. Silva², M. A. Filgueira³ & R. A. Zucchi¹, ¹Dept. de Entomologia, Fitopatologia e Zoologia Aplicada, ESAL/USP, Piracicaba-SP, 13418-900, Brasil, E-mail: elaraujo@carpa.ciagri.usp.br, ²COEX, Brasil; ³ESAM, Mossoró-RN, Brasil.

The counties of Mossoro and Assu are located in one of the few areas in the world recognized by the USDA as being a South American cucurbit fruit fly Anastrepha grandis free area. Therefore, this region has been one of the most important melon exporters, mainly for the USA and Europe. Besides melon, this region produces other fruits that can potentially be exported, however studies on fruit flies are scarce. An extensive survey of fruit fly species, host plants and parasitoids, population fluctuation, infestation index and biology began in 1999 aiming to obtain basic knowledge on fruit flies of the genus Anastrepha in the Mossoro/Assu region. So far, 5,373 fruit flies were collected, 2,771 (970 males and 1,801 females) of which were captured in McPhail traps and 2,602 (1,287 males and 1.315 females) reared from fruits. The species collected were A. zenildae. A. obliaua. A. sororcula, A. dissimilis, A. distincta and Anastrepha sp. (near A. pickeli). A zenildae is the most common. It is important to emphasize no specimens of A. grandis were collected. More than thirty plant species, native and exotic, belonging to different families, were analyzed. However, only 6, seriguela Spondias purpurea, caja Spondias sp., umbu-caja Spondias sp. (Anarcadiaceae), acerola Malpighia emarginata (Malpighiaceae), guava Psidium guajava (Myrtaceae) and jua Ziziphus joazeiro (Rhamnaceae) were confirmed as Anastrepha hosts. The most heavily infested hosts were guava and jua with infestation induce of 68 puparia/kg of fruit and 112 puparia/kg of fruit, respectively. Were obtained 64 parasitoids from the fruit fly puparia, all of which belong to the species Doryctobracon areolatus (Braconidae). The parasitism index in this region is relatively low, and the highest parasitism index obtained from the fruit samples collected was 5%. Fruit flies populations are low throughout the year in this region, peaking on May, June and July (research supported by FAPESP).

Index terms: Diptera, Tephritidae, host plants, parasitoids, biodiversity

[0182] ATTEMPTS TO MANAGE ANTICARSIA GEMMATALIS (LEPIDOPTERA, NOCTUIDAE) ON SOYBEAN IN COLONIA OKINAWA, SANTA CRUZ DISTRICT, BOLIVIA WITH BACULOVIRUS ANTICARSIA COMMERCIALIZED IN BRASIL

L. Arroyo¹ & <u>O. Mochida</u>¹ ¹CETABOL, Casilla #555, Santa Cruz, Bolivia: cetabol@daitec.scz.com

In our area, A. gemmatalis is a latent defoliator pest on soybean. Baculovirus anticarsia is said to be efficiently used for managing this pest in Brazil & Paraguay. Since Apr 1996, we have been working at the followings how efficiently to use the Baculovirus against A. gemmatalis at farmers' level. Light trap (with a 40-Watt ultraviolet fluorescent tube as light source) record of Anticarsia moths & its larval populations were surveyed in soybean field (see the figure). Egg, larval (via 6 instars), pupal, & adult stage were for 2, 19, 7, & 14 days, respectively, at room temperatures of 25-37°C. We are trying to 1) produce Anticarsia larvae massively, 2) infect them with Baculovirus, 3) propagate virus or virus-infected Anticarsia larvae, & 4) develop the practical application technology in the field. Adult males & females were kept together in 45x45x 100cm (in WxLxH) screen cage boxes with potted soybean plants for oviposition. Eggs were usually deposited on the under surface of leaves. Potted plants with eggs were transferred to smaller screen cage boxes in 35x35x80cm. Eggs hatched out & larvae were also reared with a commercialised artificial diet for insects (Nihon-Noosan-Kakou Co., Yokohama, Japan) & grew very well as those with soybean leaves

[0184] FUNCTIONAL RESPONSE OF CHRYSOPERLA EXTERNA (NEUROPTERA: CHRYSOPIDAE) FED NYMPHS OF UROLEUCON AMBROSIAE (HEMIPTERA: APHIDIDAE) APHID FROM LETTUCE

<u>A.M. Auad¹</u>, S. Freitas¹ & L.R. Barbosa¹. ¹Universidade Estadual Paulista (UNESP), Faculdade de Ciências Agrárias e Veterinárias (FCAV), Departamento de Fitossanidade, Via de Acesso Paulo Donato Castellani, s/n⁰, 14870-000, Jaboticabal, SP, E-mail: amauad@fcav.unesp.br.

The functional response of Chrysoperla externa (Hagen) larvae of 2nd e 3rd instar related to different nymphs densities of 3rd e 4th instar of aphid, Uroleucon ambrosiae (Thomas), from lettuce, was evaluated. The experimental design was randomly chosen, consisting of a 2 x 3 factorial scheme for evaluated of predator larvae response at 1, 2, 4, 8, 16 and 24hs after the beginning of the experiment, and at each 24h until the larvae stage changing (2nd instar) or until the pupation (3rd instar), on the three densities of the prey (30, 40 and 50), with 10 repetitions for each density. The insects were kept at temperature 25 ± 2 °C, UR 70 ±10% and 14 hours photophase. It was observed that for the 2nd instar larvae, during 1 to 24 hours, there was a decreasing on prey consumption for density 30 for 40, followed by an increasing on density 50. After this, period the larvae C. externa presented progressive increasing on nymphs consumption according to prey density, showing no stabilization tendency, which corresponded to a linear positive functional response. The same fact occurred to 3rd instar larvae, from predator in all evaluations. The predator:prey relation, under laboratory condition, was 1:23, 1:27 and 1:33 (2nd instar larvae), 1:27, 1:33 and 1:41 (3rd instar larvae) as studying daily mean consumption, on densities 30, 40 and 50, respectively.

Index terms: Green lacewing, biological control, predation.

[0183] USE OF GAMMA RADIATION TO CONTROL SITOPHILUS LINEARIS (COLEOPTERA: CURCULIONIDAE) ATTACKING TAMARINDUS INDICUS (LEGUMINOSAE: FABOIDEAE)

V. Arthur¹ & <u>E. Berti-Filho²</u>, ¹ Laboratório de Irradiação de Alimentos e Radioentomologia, CENA/USP, caixa postal 96, 13.400-970. Piracicaba, SP. E.mail:vaathur@pira.cena.usp.br; ²Depto de Entomologia, Fitopatologia e Zoologia Agrícola - ESALQ/USP. Caixa postal 9, 13418.900, Piracicaba, SP. eberti@carpa.ciagri.usp.br. Financial support: IAEA - CONTRACT Research N⁰ 10851/RO

This research was carried out to determine the disinfestant doses of Cobalt-60 gamma radiation to *Sitophilus linearis* in tamarind legumes. Previous sampling indicated that the mean number of insects per tamarind legume was 1.4. Each treatment consisted of 26 tamarind legumes and 4 replications totalizing 144 legumes and approximately 201 insects per treatment. The radiation doses used were: 0 (check), 0.1, 0.5, 1.0 and 2.0 Kgy, under a doses rate of 1.756 Kgy hour. The experiment was set in a room with controlled conditions (temperature $25 \pm 3^{\circ}$ C and $79 \pm 5^{\circ}$ relative humidity). The evaluation of the insect mortality was done 24 hours after irradiation. The results showed that the dose of 2.0 Kgy was sufficient to induce total mortality of this insect. Index terms: irradiation, weevil, tamarind, quarantine.

[0185] BIOLOGICAL ASPECTS AND VITAL STATISTICS OF *EDESSA MEDITABUNDA* (IIEMIPTERA, PENTATOMIDAE) UNDER CONTROLLED CONDITIONS

D.S. Avalos & N.C. La Porta, Dept. of Vegetal Protections, Agricultural Zoology. Faculty of Agricultural Science. Univ. of Cordoba. C.C 509. 5000. Cordoba, Argentina, E-mail: d-avalos@agro.uncor.edu.

Edessa meditabunda is a polyphagous insect found on Southern America. In Argentina it has been detected as a species which attacks different horticultural crops such as potato, salt-wort, chicory, capsicum, calabash, tomato, and field crops such as alfalfa, soybean, sunflower, grapevine and tobaeco. Biological aspects of *Edessa meditabunda* were studied under controlled conditions (temperature = 24,81 ± 0,51 °C; relative humidity = 53,76 ± 6,97 %; photoperiod = 16 h light). Stinkbugs were fed with fresh fruits of *Phaseolus vulgaris*. The following results were obtained: mean time from oviposition to adult was: 52,23 ± 6,28 days; nymphal mortality: 36,71% the greatest mortality occurring in the second instar; the sex ratio of adults reared in laboratory: 1,8 females: 1 males. The mean of eggs for female was: $81,75 \pm 69,83$; mean fecundity was $6,05 \pm 5,12$ egg masses per female. The following vital statistics were computed: net reproduction rate (R_0), generational time (T) and intrinsic rate of natural increase (r). Compared to the other Pentatomidae such as *Nezara viridula* and *Piczodorus guildinii* under laboratory conditions, *E. meditabunda* showed a biological cycle, nymphal mortality and generational time more large than those species.

Key words: Edessa meditabunda, Pentatomidae, biological aspects, vital statistics.

[0186] MORPHOLOGICAL, BIOLOGICAL ASPECTS AND DAMAGE OF TENTHECORIS BICOLOR DISTINTUS (HETEROPTERA: MIRIDAE): AN AMARILLIDACEAE AND ORQUIDACEAE PEST

<u>S. G. Bado</u> C. Sills & M.J. Pannunzio, Cátedra de Zoología Agrícola- Facultad de Agronomía. Ave. San Martín 4453 (1417) Universidad de Buenos Aires. Argentina. sbado@mail.agro.uba.ar

Amarillidaceae and Orquidaceae families comprise numerous species of ornamental interest. Damaging some of them it was found *Tenthecoris bicolor distintus*. The aim of this job was to describe their morphological and most important biological aspects, which are fundamental to manage the pest. Damage and hosts are mentioned. In order to achieve the objetives, an individual rearing was made feeding nymphs with *Crinum asiaticum* and *C. zeylanicum*. The duration of nymphal stages for four generations was registered meanwhile the description of their morphological aspects was done. The medium temperature was 24°C and R. H. of 60%. Nymphs are translucid with read spots in head, pronotum and the first abdominals segments. A dark spot due to intestinal content is also noticed in the middle of their abdomen. Female is tead and male reddish orange. Both of them present mesoescutelum black and hemielitres with corium and cunca read. Clavus dark. Membrane with dark spot. The medium period of development was 20 days. The damage consists of diminute clorotic spots covered with dejections and necrotic leaves borders. Plant loses its vigour and ornamental value. *T. bicolor* was found damaging *Crinum asiaticum L. , Crinum zeylanicum* L. *Amaryllis belladonna L*, y *Sprekelia formosissina L.*

Key words: Tenthecoris bicolor distintus, ornamental pest, Crinum asiaticum L., Crinum zevlanicum L

[0188] CONTROL OF ORTHEZIA PRAELONGA IN WEST INDIAN CHERRY, MALPIGHIA GLABRA USING FORMULATIONS AND THREE APPLICATION METHODS OF THIAMETHOXAM

<u>R. Burros¹</u></u>, M. D. R. O. Silva¹ & S. Araújo¹, ¹Fitossanidade, Univ. Fed. Rural de Pernambuco, Av. Dom Manoel de Medeiros S/N, Dois Irmãos 52171-900 Recife, PE. E-mail: rbarros@nelore.npde.ufrpe.br.

The scale Orthezia praelonga (Homoptera: Orthezidae) had been recorded recently as a serious pest in West Indian Cherry (WIC) Malpighia glabra growing area in Brazil. In Pernambuco, Brazil WIC population has been verified seasonally from July to November. The lack of insecticides registered by Agricultural Minister for WIC has impeded the use of this method for *O. praelonga* and others insects pests attacking WIC. Thus, this work aimed to evaluate the efficacy of Thiamethoxam for *O. praelonga* control in WIC. The experiments were set up in a WIC orchard five years old, spaced 3.5 x 3.5 m between and within line. The experiment was carried out in a randomized complete block with 8 treatments and 4 replications composed by two plants each. The treatments consisted by: I - Control; II - Foliar spray (Actara 250 WG) 1g/1.2 L water/plant; III - Foliar spray (Actara 250 WG) 2 g/1.2 L water/plant; IV - Stem spray (Actara 250 WG) 1 g/0.5 L water/planta; V - Stem spray (Actara 250 WG) 2 g/0.5 L water/plant; VI - Soil placement (Cruiser 700 WS) 2 g/plant; VII - Soil placement (Cruiser 700 WS) 4 g/plant and, VIII -Soil placement (Cruiser 700 WS) 6 g/plant. For foliar and stem treatments were used a costal sprayer 40 lbs/pol² and a trigger-pump 1.0 L volume, respectively. Thiamethoxam soil placement was applied by distributing granules in a semi-circle furrow 5.0-cm depth distant = 50% plant canopy projection from plant base. The evaluations were carried out at 9, 18, 27, and 36 days after application for all treatments. Each evaluation consisted of 16 leaves per replication-plant. The samples were took up to laboratory and the number of scale alive/leaf was counted using a stereo microscope and recorded. Application of Actara 250 WG 2 g/1.2 L water/plant through foliar spraying promoted efficiency of 60.7% in the first evaluation and maintained inferior to 45% in following evaluations. The treatment through stem application and soil placement showed efficacy inferior to 52% and only 27 days after application. Based on our results Thiamethoxam applied by foliar spraying, stem application and soil placement did not show an efficient control of O. praelonga in WIC orchard. However, investigation with higher Thiamethoxam doses than those used in this study should be carried to determine an efficient control method for this important pest in WIC

Index terms: Insecta, chemical control, systemic insecticide, scale, orchard pest.

[0187] BIOLOGY OF THE GUAJAVA WEEVIL, *CONOTRACHELUS PSIDII* (COLEOPTERA: CURCULIONIDAE), REARED UNDER LABORATORY CONDITIONS

O. Bailez, A. M. Viana-Bailez, D. Moreira & J. O. G. de Lima, Laboratório de Proteção de Plantas/CCTA, Univ. Estadual do Noroeste Fluminense, Av. Alberto Lamego, 2000, Campos dos Goytacazes, RJ, 28015-620, Brazil. E-mail: obailez@uenf.br

Constrachelus psidii is an important pest of the guaiava fruit in Brazil. The mater female eats cavities into the new fruits and lays a single egg in each hole and usually more than one egg/fruit. As soon as the egg hatches, the larva feeds inside the fruit destroying the pulp. When completing growth, the larva deserts the fruit and pupates in the soil. We studied the biology of the guajava weevil under laboratory conditions (25 ° C and 65-75 % HR). The egg hatches in an average of 3.9 ± 0.58 days (n=677). The larva undergoes four molts over an average period of 9.6 ± 2.58 days (n=247). After leaving the fruit, the mature larva remains in the soil for an average of 165 \pm 26 days (n=80), before transforming in a pupa. Pupation is then completed in an average of 15 ± 1.6 days (n=65), but the adult beetle still stays in the soil for an average of 25 ± 7.2 days. Feeding and sexual activity are initiated fifteen to thirty days after the adult emergence from the soil. Observations realized with a reduced number of females (n=5), showed that they starts ovipositing three days after mating, and may oviposit more than 750 eggs (observation under way) during its entire reproductive life. The highest number of eggs/day oviposited by the female was fourteen. After emergence from the soil, the male and female longevity may be more than 180 days (observations under way). We have developed a rearing method for the guajava weevil that will be reported elsewhere.

Index terms: Psidium guajava, laboratory rearing, guajava, beetle

[0189] BIOTYPIC VARIATION OF THE RUSSIAN WHEAT APHID BETWEEN SOUTH AFRICA AND HUNGARY

<u>Z. Basky</u>¹ & J. Jordaan², ¹Plant Protection Institute, Hungarian Academy of Sciences, P. O. Box 102, Budapest 1525, Hungary, E-mail h10433bas@ell.hu, ²Sensaco Cooperative. Ltd., P. O. Box 566 Bethlehem 9700, South Africa

The Russian wheat aphid Diuraphis noxia (Kurjumov) is indigenous in the Mediterranean in the Iranian-Turkestanian mountain range. However, in these regions D. noxia seldom becomes as serious pest as it has been in South Africa since 1978 and in the United States since 1986. To reduce D. noxia damage, intensive resistance breeding programs were undertaken in South Africa and the United States. Biotypic variation can affect the success of such breeding programs. D. noxia was first detected in Hungary in 1989, but has not become a pest. To test the difference between South African and Hungarian D. noxia, experiments were done in each country with the South African winter wheat cultivars Betta, which is susceptible to D. noxia and the resistant SST 333 and PI 262660 and the Hungarian spring barley cultivar Isis, which is susceptible to D. noxia. The effect of aphid infestation on fresh plant weight, leaf area over time differed between Hungarian and South African D. noxia for the susceptible barley cultivar Isis, and the resistant wheat cultivar SST 333. The aphid infestation significantly affected leaf area between South Africa and Hungary for susceptible wheat cultivar Betta and resistant wheat cultivar SST 333. In Hungary D. noxia feeding resulted in leaf rolling and chlorotic spots and stripes on resistant wheat cultivars SST 333 and PI 262660. Furthermore, the dynamics of the number of aphids per plant differed between South Africa and Hungary for Betta and SST 333. Infestation by Hungarian D. noxia reduced plant fresh weight and leaf area of the resistant wheats SST 333 and PI 262660 as much as the susceptible wheat Betta regardless the growing conditions (growth chamber or greenhouse). In addition water imbalance occurred in resistant wheats SST 333 and PI 262660 in greenhouse. These differences between Hungarian and South African D. noxin suggest genetic differences between these populations. Our results support the idea that resistant plant germplasm has geographical limits because of geographical variation in pest species. Index terms: Diuraphis noxia, resistance breeding, biotype

[0190] DIFFERENT INSECTICIDES AND DOSES FOR EUSCHISTUS HEROS CONTROL ON SOYBEAN CROP

S. Bellettini¹, N.M.T. Bellettini¹, L.H. Kajihara², J. Conte² & L.L. Biaggi², ¹FFALM, P.O. Box 261, ZIP 86360-000. Bandeirantes-PR - Brazil, E-mail: bellettini@ffalm.br; ²Hokko do Brasil. Mato Grosso Street, 1493; 91350-000 Londrina-PR-Brazil, E-mail bokko@tdnet.com.br

Among different bugs on soybean crop, brown stinkbug is one of the most important, due by damage that causes on leaves, pods and seeds. It were evaluated in Londrina-Pr, different insecticides and doses on brown stinkbug control in soybean crop, cultivar OCEPAR-13, with spacing 0,45 m among lines and 20 plants per meter. Experimental design was randomized block using 06 treatments, 04 replications and plots with 135 m² each. It was done a single spraying with following treatments in a.i./ha acephate (Orthene 750 Br) 187,5; 225 and 300 g; endosulfan (Thiodan CE) 210 and 437,5 g and control (with no spraying). For insecticides application it were used a sprayer with constant pression of 65 lb/pol² and volume of 200 l/ha. Evaluations were done by pre-counting and at 4, 9, 12 and 16 days after application. On each evaluation it were done 4 randomized samples per plot, using "cloth method", by counting adults of alive brown stinkbug, fallen down the cloth. It were conclude that a) acephate (Orthene 750 Br) 225 e 300 g and endosulfan (Thiodan CE) 437,5 g a.i./ha, at 4 and 9 days after application showed efficiency above 80% on brown stinkbug control; b) different insecticides and doses had no plants toxicity.

Index terms: Euschistus heros; soybean, chemical control

[0192] EFFECT OF DIFFERENT SEED TREATMENTS ON APHID APHIS GOSSYPH CONTROL VEGETATIVE DEVELOPMENT AND YIELD OF COTTON CROP

S. Bellettini¹, P. H. Aramaki², L.S. de Biaggi¹, A. Minucci & W.G. da Silva¹, ¹FFALM, P.O. Box 261, ZIP 86360-000. Bandeirantes-PR - Brazil, E-mail: bellettini@ffalm.br; ²Novartis Biociências S/A. Research and Development. 04706-900 -São Paulo City-S.P.-Brazil

Higher aphids attack occur since 40 till 70 days of cotton plants age. Seeds treated by insecticides allow plant protection against aphids till 30 days. It were evaluated in Bandeirantes-Pr, with the cultivar COODETEC-401, the effect of different seeds treatments on a.i/100 kg of seeds: thiamethoxan (Cruiser 700 WS) 150; 210 e 300 g imidaeloprid (Gaucho) 140 g; carbofuran (Furadan 350 TS) 700 g; acephate (Orthene 750 BR) 750 g and control (with no insecticide). Experimental design was randomized blocks, with 7 treatments and 4 replications, using plots with 27 m² size. Evaluations were done by counting the number of alive aphids at 15; 20; 25; 30 and 35 days after emergence on 10 summit randomized leaves, per plot; plant height at 10, 20, 30, 40 and 120 days after plants emergence using 10 marked plants per plot and cotton seed yield. If were concluded that: a) different seed treatments showed efficiency above 82% on aphids control; b) insecticides thiamethoxan (Cruiser 700 WS) 210 and 300 g, and imidaeloprid (Gaucho) 140 g showed efficiency among 90 to 97,3% on aphids control respectively; c) 9,3; 17,3 and 11,8% higher plants height and 26,1; 30,7 and 25,9% higher on cotton seeds yield, respectively, relating to control.

Index terms: Aphis gossypii; cotton; chemical control

[0191] DIFFERENT INSECTICIDES AND DOSES TO CONTROL GREEN STINKBUG NEZARA VIRIDULA ON SOYBEAN CROP

<u>S. Bellettini¹</u>, N.M.T. Bellettini¹, L.H. Kajihara², J. Conte² & L.L. Biaggi², ¹FFALM, P.O. Box 261, ZIP 86360-000. Bandeirantes-PR - Brazil, E-mail: bellettini@ffalm.br;
²Hokko do Brasil. Mato Grosso Street, 1493; 91350-000 Londrina-PR-Brazil, E-mail hokko@ldnet.com.br

Among different pests attacking soybean crop, green bedbug is considered most important, due by injury that causes. It were evaluated in Londrina-Pr, different insecticides and doses to control green stinkbug on soybean crop, cultivar OCEPAR-13, at spacing 0,45 m among lines and 20 plants per meter. Experimental design was randomized block using 06 treatments, 04 replications and plots with 135 m² each. It was done a single spraying with following treatments and doses, in a.i./ha acephate (Orthene 750 Br) 187,5; 225 and 300 g; endosulfan (Thiodan CE) 210 and 437,5 g and control (with no spraying). For insecticides application it was used a sprayer with constant pression (CO₂); X_3 nozzle, pression of 65 lb/pol² and volume of 200 l/ha. Evaluations were done by pre-counting and at 4, 9, 12 and 16 days after application. On each evaluation it were done 04 randomized samples per plot, using "cloth method", by counting adults of alive green stinkbug, fallen down the cloth. It were conclude that: a) insecticides endosulfan (Thiodan CE) 210 and 437,5 g at 4 and 9 days after application, acephate (Orthene 750 Br) 187,5 and 225 g at 4,9 and 12 days after application and acephate (Orthene 750 Br) 300 g at 4, 9, 12 and 16 days after applications showed efficiency above 81% on green stinkbug control; b) insecticides and doses had no plants toxicity.

Index terms: Nezara viridula, soybean, chemical control

[0193] EFFECT OF DIFFERENT SEED TREATMENTS ON THRIPS FRANKLINIELLA SCHULTZEI CONTROL VEGETATIVE DEVELOPMENT AND YIELD OF COTTON CROP

S. Bellettini¹, P. H. Aramaki², L.S. de Binggi¹, A. Minucci & W.G. da Silva¹, ¹FFALM, P.O. Box 261, ZIP 86360-000. Bandeirantes-PR - Brazil, E-mail: bellettini@ffalm.br; ²Novartis Biociências S/A. Research and Development. 04706-900 -São Paulo-SP-Brazil.

Thrips are sucker insects of wich higher population densities occur at 10 and 20 days of plants age. Adults and nymphs, during feeding, induce necrosis and leaves deformity, besides temporary stoppage on plants development. it were eveluated in Bandeirantes-Pr, using COODETEC-401 cotton cultivar, following seed treatments in a.i./100 kg of seeds: thiamethoxan (Cruiser 700 WS) 150; 210 e 300 g imidacloprid (Gaucho) 140 g; carbofuran (Furadan 350 TS) 700 g; acephate (Orthene 750 BR) 750 g and control (with no insecticide). Experimental design was randomized blocks, with 7 treatments and 4 replications, each plot with 27 m² size. Evaluations were done by counting the number of alive thrips at 10; 15; 20; 25 and 30 days after emergence per plot; plant height at 10, 20, 30, 40 and 120 days after plants emergence, using 10 marked plants per plot and cotton seed yield. If were concluded that: a) different seed treatments showed efficiency above 81% on thrips control; b) insecticides thiamethoxan (Cruiser 700 WS) 210 and 300 g, and imidacloprid (Gaucho) 140 g showed efficiency among 90 to 97,3% respectively; c) 9,3; 17,3 and 11,8% higher plants height and 26,1; 30,7 and 25,9% higher on cotton seed yield, respectively, relating to control.

<u>J. van den Berg1.</u> Z.R. Khan₂& J. Pickett₃, ₁ARC - Grain Crops Inst., Private Bag X1251, Potchefstroom, 2520, South Africa. ₂ICIPE, PO Box 30722, Nairobi, Kenya, ₃IACR-Rothamsted, Harpenden, Herts AL5 2JQ, United Kingdom. E-mail: Johnnie@igg2.agric.za.

Maize and sorghum are the most important cereal crops in Africa. The stem borers Busseola fusca (Lepidoptera: Noctuidae) and Chilo partellus (Lepidoptera: Pyralidae) are serious pests of these crops and can cause yield losses ranging from 20 to 80 %. New crop protection strategies need to be developed since chemical control is not a viable option and resistant varieties are not available to resource-poor farmers. One such approach is a stimulo-deterent-diversionary strategy or a "push-pull" system, by which wild host and non-host plants are used to manage pests. Such a system was developed in Kenya where intercropping with the non-host molasses grass (Melinus minutiflora) significantly reduced stem borer infestation and increased larval parasitisation by Cotesia sesamiae. Planting of Napier grass (Pennisetum purpureum) as a trap crop around maize fields and intercropping with the legume Desmodium uncinatum, which repels stem borer moths, further reduced stem borer infestation on the main crop. Desmodium uncinatum was also observed to control Striga hermonthica in maize. Kenyan farmers perceived the following as benefits of this habitat management system: reduced borer infestation, increased milk yield and household income. The habitat management system developed in Kenya, where two rainy seasons occur and rainfall is high, is being adapted to the semi-arid conditions in southern Africa where only one rainy season occurs and crops are planted in areas of low rainfall (400 to 600 mm). While a zero-grazing system is used in Kenya and traps crops are fed to cattle, free grazing is largely practiced in southern Africa. The non-host inter-crops and trap crops used in East Africa are therefore not suited to southern African conditions and farming systems. A survey was conducted to search for wild host plants of stem borers for use in a habitat management system in South Africa. Results indicated that wild host plants are rare or absent in areas where annual rainfall is less than 600 mm. Field studies on the colonisation process of C. partellus and B. fusca on cultivated host plants (maize, sorphum, sweet sorphum and pearl millet) and wild host plants (Panicum maximum and Hyparrhenia tamba) indicated that C. partellus preferred sorghum and maize to the other plant species while B. fusca had no distinct preferences. In two-choice tests with maize and Vetivier grass (Vetiveria zizanoides), the latter was preferred for oviposition by C. partellus moths. Vetivier grass and wild sorghum are therefore likely candidates as trap crops for C. partellus in southern Africa.

Key words: Busseola fusca, Chilo partellus, maize, Sorghum spp., Vetiveria sp

[0195] APHID COLONISATION OF LUPIN CROPS; YIELD LOSSES AND CONTROL STRATEGIES

<u>F. A. Berlandier</u>, Entomology Section, Biological Services, Crop Improvement Institute, Agriculture Western Australia, Locked Bag No. 4, Bentley Delivery Centre WA 6983, Australia.

Lupins are the principal grain legume cropped in the State of Western Australia, and since 1993 over 1,000,000 tonnes has been harvested annually. The crop is harvested for its grain, which is primarily used for animal feed, both locally and as an important export commodity. Lupins are winter grown crops and are well adapted to the infertile deep sandy soils of Western Australia. There are currently eight cultivars of narrow-leafed lupin (Lupinus angustifolius) and one of yellow lupin (Lupinus luteus) recommended for cultivation in Western Australia. Aphids are common pests of lupin during the bud and flowering stages, and are most abundant from late winter (August) to early spring (September) in Western Australia. The three most common species found attacking lupin crops are Acyrthosiphon kondoi, Aphis craccivora, and Myzus persicae. Field trials were undertaken to quantify the effects of aphid colonisation and feeding on crop yields. Three cultivars of L. angustifolius (Tallerack, Merrit and Kayla) and one of L. luteus (Wodjil) were sown in replicated field plots and were either treated every 21 days with aphicide until maturity, sprayed once with aphicide, or left untreated. From bud formation onwards, aphid numbers developed very rapidly on untreated plants of cvs. Tallerack and Wodjil, but very slowly on cv. Kayla. Up to 130 and 200 aphids per 10-cm portion of stem tip were recorded for respectively cvs. Tallerack and Wodjil, and only 36 aphids for the cv. Kayla. Acyrthosiphon kondoi was the dominant species, making up over 70% of the species complex. Aphid attack on untreated cv. Tallerack caused grain yield losses of 84% when compared to plots sprayed regularly with an aphicide, and on cv. Merrit losses of between 28 - 34% were recorded, whereas untreated plots of cv. Kayla suffered negligible losses. Yield losses were almost 100% in untreated plots of cv. Wodjil. A single spray of insecticide minimised yield losses in cv. Tallerack to 23% at one site, but greater losses of 42% were recorded at a different site with a longer growing season. Similarly, a single spray could minimised losses in cv. Wodjil to 19% at one site but losses were still almost 60% at the second site with the longer growing season. Aphid colonisation rates are strongly correlated with subsequent feeding damage if plants are left untreated, and the extent of colonisation is influenced by cultivar. Local farmers are advised to frequently monitor their crops from early bud formation, particularly if susceptible cultivars are sown, and to spray if the economic threshold is reached.

[0196] DILOBODERUS ABDERUS (COL. SCARABAEIDAE) CONTROL THROUGH SEED WITH GAUCHO 600 FS IN WILEAT AND BARLEY ON RS

N. G. Bertoldo¹ & W. Caetano¹, ¹Dept. of Entomology, FEPAGRO, Gonçalves Dias Ave. 570 - Porto Alegre/RS 90130-060 e-mail: producao@fepagro.rs.gov.br , BRAZIL.

Diloboderus abderus, knows like "coró-das-pastagens" is between principal soil pests that happens frequently in winter cereals, given rise to great injuries last years. Due to manly difficulties in it control and low efficacy of insecticides applied at conventional way, was install this work with objective to evaluate the effect of Gaucho 600 FS through seed treatment in this pest control. This test was done by FEPAGRO São Borja's Experimental Station, in 1998 season, was doing in wheat and barley. The experimental plan was casual blocks with 4 repetitions and following treatments express in ml (commercial product) / 100 kg seeds: Gaucho 600 FS – 40; 60; 80; 100; Furadan 350 SC – 2000 and check. The experimental unity was represented in an area with 30 m². The evaluations were made at 7; 15; 25 and 35 days after plant stand, through 3 samples / parcel, counting the number of warms / m², in a 20 cm - soil profundity. It was found out by observations that Gaucho 600 FS (80 and 100 ml/100 kg wheat seeds and 60; 80 and 100 ml/100 kg barley seeds) showed high efficacy in *Diloboderus abderus* control.

Index terms: *Diloboderus abderus* control, wheat, barley, seed treatment; insecticide Gaucho 600 FS.

[0197] EFFICIENCY OF INSECTICIDE CRUISER IN THE CONTROL OF DILOBODERUS ABDERUS (COL. SCARABAEIDAE) BY SEED TREATMENT IN THE WHEAT, OAT, AND BARLEY

N.G. Bertoldo & W. Caetano, Eng^o Agronomist researchers from FEPAGRO; Rua Gonçalves Dias, 570 – ZIP CODE 90130-060 – POA/RS – 3:E-MAIL: producao@fepagro.rs.gov.br

In the decade of 70 when pest control managing began, it was recommended the use of adequate insecticides and the use of the direct plantation as new alternative for soil protection. The use of these techniques came to bring great benefits to the agroecosistem, but some time the soil insects colonized plantations again and reaching at insect pest Among the species the Diloboderus abderus, in general called "coró of the level. pasture", comes causing damages quite accentuated in winter cereals in the last years. Due to control difficulty through conventional method and the small number of available products in the market, three experiments was carried out for D. abderus control through seed treatment for wheat, oat and barley cultivation in a experimental field in Rio Pardo -Rio Grande do Sul State, during 1999. The experimental design was a split-plot arranged in randomized blocks with four replications and following treatments with the respective doses in g or 1 of commercial product for 100kg of seeds: Cruiser 700 WS - 35, 50, 75, 100; Gaticho 600 FS -75, Furadan 350 - 2 and control. After 26, 49 and 63 and 91 days from sowing were made three samplings by m² in each portion for evaluation. From the results was verified that insecticide Cruizer 700 WS at the used doses, 50, 75 and 100g/100kg of seeds together with Gaúcho 600 FS and Furadan 350, evidenced high percentage of control for D. abderus in winter cereals, providing larger and better options control.

[0198] CONTROL OF THE *DICHELOPS* SPP. BY TREATING THE CORN SEEDS OF DIFFERENT SIZES WITH A MIXTURE OF THIAMETHOXAM AND THIODICARB

<u>R. Bianco¹</u> & M. Nishimura², ¹Instituto Agronômico do Paraná / IAPAR, C. Postal 481, 86001-970, Londrina-PR, E-mail rbianco@pr.gov.br. ²Novartis Biociências S/A, Av. Rio de Janeiro, 1452, 86010-150, Londrina-PR.

Dichelops spp. became an important pest of corn seedlings in the last years. Seed treatment with new generation insecticides such as the neonicotinoids has resulted in a satisfactory control of this pest. In some cases, however, seed treatment has failed in controlling the insects and this could be associated with the reduction in the dosages of the products induced by variation in size of the seeds. The objective of this work was to determine the efficiency of Thiamethoxam, in mixture with Thiodicarb, using various seed sizes and either correcting or not the dosages of the pesticide. The study was conducted in screened cages (1,20 by 1,00 by 1,00 m) under field conditions. Corn cultivar TORK (NK seeds) was sowed in January 7, 2000 leaving 10 plants per cage. Two and nine days after seedlings emergence each cage was infested with four *Dichelops* adults. Evaluations of the number of dead insects were performed seven days after insect releases. Twenty days after the corn emerged the percentage of plants with strong symptoms of damage was determined. The experiment design was set up in randomized blocks, with subdivided plots, with three corn seed sizes: 1) seed sift 16 (10 kg/ha); 2) seed sift 18 (12 kg/ha); and 3) seed sift 20 (16 kg/ha), and three insecticides dosages: 1) 140 g a.i. (Thiamethoxam WS 70%) + 525 g a.i. (Thiodicarb 350 FROG)/100 kg of seeds; 2) corrected dosage: 100% (sift 16); 60% (sift 18); and 25% (sift 20); and 3) control (without seed treatment). The results showed the following: 1) there were not differences among the treatments (100% of insect mortality) when the insects were released two days after corn emergence; 2) after the second release there was a significantly lower number of insects dying in the treatments where smaller seeds were used, that corresponded to lowest insecticide dosage. When the dosages were corrected, the mortality did not differ (75%); 3) as the size of the seeds increased the number of plants injured decreased even for the corrected dosages. These results emphasize the importance of the greater initial vigor of the seedlings in reducing pest damage.

Index terms: Dichelops spp, Maize, control, seed treatment

[0199] EFFICIENCY OF PYRETHROID INSECTICIDES IN THE CONTROL OF ALABAMA ARGILLACEA IN COTTON CROP

<u>A.L. Boica Júnior</u>¹ & G. L. Barbosa¹, ¹ Dept de Fitossanidade, Univ. Estadual Paulista. Via de Acesso Prof. Paulo Donato Castellane, s/n. 148700-000. Jaboticabal – SP. Brasil. E-mail: aboicajr@fcav.unesp.br.

The efficiency of betacypermethrin 100 SC, betacypermethrin 100 CE, and cypermethrin 200 CE insecticides, in several doses, in the control of Alabama argillacea in a cotton crop was evaluated. The experiment was carried out in a area at Jaboticabal City, State of São Paulo, Brazil. The cotton cultivar was used Coodetec-401, sowed on October 29, 1998. The field experimental plots were set up in a randomized block design, with 7 treatments and 4 replications. The treatments were applied with an application rate of 7.50; 8.75 and 10.00g i.a/ha of betacypermethrin 200 CE; and no application at the control plot. The evaluations were made in the 54m² of the useful area in each plot, accomplished before the application (January 26, 1999) and at the 3rd, 5th and 8th days after the application of the insecticides. The number of alive caterpillars in 20 plants in the useful area of the plot was sampled. It has been concluded that: (1) all the products and evaluated rates presented efficiencies above 80% at the 8th day after application; (2) the average number of A. argillacea per 20 plants was lower when betacypermethrin 100 SC was applied (10.0 g i.a. ha) and betacypermethrin 100 CE (12.5 g i.a. /ha) with efficiency above 80% at the 3rd days after the application, such as lower show betacypermethrin 100 SC was applied (10.0 g i.a. ha) Sth days after the application, reaching efficiency above 90% at the 8th day; and 5th days after the application, reaching efficiency above 90% at the 8th day; and, (3) betacypermethrin 100 SC, in the rate of 8.75 g i.a. /ha, has also presented superior efficiency at 80% in the three evaluations.

Index terms: Insecta, cotton leafworm, chemical control.

[0200] AMMONIUM ACETATE: AN EFFICIENT ADULT ATTRACTANT OF ANASTREPHA SPP & CERATITIS CAPITATA IN MANGOES PLANTATIONS IN MARACAY, VENEZUELA

N. Boscán de M.¹ & F. J. Godoy¹, ¹Plant Protection Dep., Agronomic Research Institute, National Agricultural Research Center, P.O Box 4653.University area, El Limón, Maracay, Venezuela.

Five attractants were tested for the capture of fruit fly adults (Anastrepha spp and Ceratitis capitata) in mango plantations in El Limón, Maracay, Venezuela. The attractants used were hydrolyzed protein Nulure 9% + borax 3%, ammonium acetate 16%, Urea 16%, Torula yeast extract and sugar cane juice 80%. Homemade traps built with plastic bottles with two litter capacity, with a circular hole 3 cm wide, for the entrance of the flies. A totally random design with five treatments and four repetitions. From February 19th to august 08th every 15 days all traps were collected and trapped flies counted. Results show the the best attractant for both species was ananyzed through analysis of variance and Tuckeymeans test at 5% of probability. Ammonium acetate was 2.3, 4.4, 10.7, and 25.6 times higher than urea, nulure, sugarcane juice and torula. Anastrepha showed higher numbers of captured adults, compared to Ceratitis.

Key words: Ammoniun acetate, fruit flies, Mangifera indica, Nulure, Urea, Sugarcane.

[0201] CHEMICAL CONTROL OF MAHANARVA FIMBRIOLATA (HEMIPTERA-HOMOPTERA: CERCOPIDAE) IN SUGARCANE

<u>P.S.M. Botelho¹</u>, N. Macedo¹ & M.S. Campos², ¹CCA/UFSCar, P. O. Box 153, Araras, SP, Brasil,E-mail photelho@cca.ufscar.br; ²Sugarmill Bonfim, Guariba, SP. Brasil.

The insecticides: Thiamethoxan, Imidacloprid, Carbofuran, Clorpirifos etil, Metarhizium anisopliae (fungi) and Carbaril on the control of root froghopper ninfae, Mahanarva fimbriolata, in sugarcane area were studied. Sugarcane was harvested by machine without burning. The experimental design was randomized blocks, three replicates, with five row parcels, 30 m long, being 15 m with and 15 m without (the thrash was amassed inter rows) thrash on the rows. The chemicals were applied straight on the base of the sugarcane plants. After chemical applications the number of alive nymphs/linear meter, at 15, 30, 60 and 90 days were counted. The pest was controlled until 30 days by Carbofuran - 350 SC (6.5 l do p.c./ha) and until 90 days by Thiamethoxan - 10 G (30 kg do p.c./ha). Similar to the two fungi strains of *M. anisopliae*, evaluated until 90 days after application, the pattern insecticide, Carbaril (2 l c.p./ha) was not efficient in froghopper control. When the thrash was put aside from the row the occurrence of nymphs was minor. Index terms: root froghopper, nymphs control, insecticides.

[0202] CERCONOTA ANONELLA (LEP., OECOPHORIDAE) IN SOURSOP (ANNONA MURICATA) IN ALAGOAS STATE, BRAZIL: OCCURRENCE AND CONTROL

S. M. F. Broglio-Micheletti¹ & <u>E. Berti-Filho</u>², ¹FTT/CECA/UFAL, BR 104, Km 85, 57.100-000, Rio Largo, Alagoas, Brasil, ; ²Dept^o de Entomologia, Fitopatologia e Zoologia Agrícola, ESALQ/USP. Caixa postal 9, 13418,900, Piracicaba, SP, E-mail: eberti@carpa.ciagri.usp.br.

The spatial and probabilistic distribution of *Cerconota anonella*, in soursop orchards were studied in Maceió, State of Alagoas, Brazil from March 1997 to April 1998. The spatial distribution of *C. anonella* is binomial negative, characterizes the distribution of the type aggregate or in focus. The dispersion index of the insect was 2.15 and the sample size was 52 fruits/ha. To detect and monitorate the pest in the field the population was surveyed by collecting fruits for observation or dissection and also by using traps with virgin females. *C. anonella* occurred during the whole period of study, with a population acme between April and May and the infestation decreasing with the time. The sex ratio was 0.47 and the mean longevity for females and males was respectively 7.07 and 6.68 days. The mean damage observed on fruits was 17.64%, which represents a control level of 2 holes/fruit, if microperforated plastic bags (0.39 m long x 0.34 m wide) were used. When comparing chemical and mechanical controls used individually or together, the most effective and economic one was the microperforated plastic bags.

Index terms: soursop borer, sampling, damage evaluation, chemical control, mechanical control.

[0204] INFLUENCE OF CULTURAL PRACTICES ON PRE-HARVEST INFESTATIONS OF CORN BY MAIZE WEEVILS (SITOPHILUS ZEAMAIS)

<u>S.L. Brown</u>¹ & D. Lee², ¹Depts. of Entomol., ²Crop and Soil Sciences, University of Georgia, P.O. Box 1209, Tifton, GA 31793, USA, E-mail: bugbrown@arches.uga.edu

The maize weevil (Sitophilus zeamais) is the primary pest of stored corn in Georgia. Infield infestations occur prior to harvest, and kernels containing maize weevil eggs and larvae are often placed into the storage bin. Subsequent, emergence of adults in the storage bin initiates in-storage infestations that can result in severe losses if timely, expensive and sometimes dangerous control measures are not used. A three-year study was conducted to 1) quantify the influence of cultivar and planting date on in-field infestations, and 2) determine when maize weevil oviposition was occuring in the field relative to crop phenology. Each year, four replications of 6-8 cultilvars of corn were planted on 3-4 different planting dates. Beginning at the three-quarter milk line stage, paper bags were placed over 10 ears in each plot and secured with rubber bands to prevent maize weevil oviposition. Bags remained in place for two weeks. Ten more ears per plot were similarly bagged for a second and third two-week period. Individual ears were identified with a tag so that ears that had been bagged for the same time period could be hand harvested and kept separate from others. Kernels from individual ears were removed from the cob, placed into paper bags and bags were placed in a grain bin. After 30 days, the contents of each bag were sieved and maize weevil adults were counted. The first planting date had significantly more infested ears than any other, but the number of maize weevils per 500g of corn did not significantly differ among planting dates. This may indicate that overwintering weevils readily oviposit in the first available corn in the spring but fecundity and/or survivability may not be as great as in subsequent generations. It could also indicate a behavioral difference whereby overwintering weevils oviposit in many different ears attempting to find suitable hosts whereas subsequent generations tend to oviposit in the ear from which they emerged. In terms of percentage of infested ears and number of weevils per 500g, the cultivar Pioneer 3146 had a significantly lower level of infestation than Mycogen 7559, indicating maize weevils may 1) have ovipositional preferences for certain host characteristics and/or 2) have greater larval survival on certain cultivars. More weevils were found in unbagged ears than in ears that had been bagged for any of the three exclusion periods. Prevention of oviposition during the third exclusion period had the greatest impact on final weevil numbers, indicating that period was when the greatest oviposition was occuring in the field.

Index terms: stored products, integrated pest management, post-harvest

[0203] AREA-WIDE CONTROL OF MEDFLY (CERATITIS CAPITATA) IN CITRUS IN SOUTH WEST AUSTRALIA

S. Broughton & C.P.F. de Lima, Entomology Division, Agriculture Western Australia, 3 Baron-Hay Crt, South Perth, Western Australia. E-mail smbroughton@agric.wa.gov.au.

The Mediterranean fruit fly (Medfly), *Ceratitis capitata*, has become an extremely important pest of commercial orchards in Western Australia in recent years. Research has shown that while recommended treatments are effective, control failures resulted from insufficient knowledge of the ecology of the pest. It was suspected that the increase in the Medfly problem was taking place in response to climatic change (global warming) and to change in the host environment with the increase in the trend towards rural sub-division and neglected orchards. In 1999, an area-wide approach to Medfly control was initiated in citrus. Male and female traps were installed on grower's properties in 5 citrus-growing areas in Western Australia. Adult fly populations peak in January, when few ripe citrus crops are present on commercial properties. A second peak occurs in autumn when Medfly disperse into citrus for over-wintering. Adults are active in winter when temperatures exceed 12°C, and Medfly over-winter as adults, ggod control of Medfly is achieved. Index terms: *Ceratitis capitata*, area-wide control.

[0205] SELECTIVE TARGETING OF LOCUSTS WITH ULTRA-LOW DOSES OF FIPRONIL INSECTICIDE IN RANGELAND AND SORGHUM

R. M. Bull, Aventis CropScience Australia P/L, 261 Tingira Street, Pinkenba, Brisbane Q4008, Australia

Ultra-low doses of fipronil were applied to outbreaks of Australian plague locust (Chortoicetes terminifera), spur-throated locust (Austracris guttulosa) and migratory locust (Locusta migratoria) in a number of large field trials in sorghum crops and rangeland to determine optimum commercial dose and assess environmental impact. Fipronil treatments were sprayed from aircraft over banding hoppers and concentrations of adults as oil based ULV at 150-300ml/ha on 100m track spacing, or by conventional high water volume (15-201/ha) methods at 25m spacing, Juveniles and adults of all 3 species were shown to be highly susceptible to fipronil at ultra-low (1.25-5g ai/ha) dose rates, 1.25g a.i./ha being optimum and resulting in >98% mortality. Intoxication and loss of coordination of locusts occurred within 2 hours of application at 26-38°C but maximum mortality took 2-7 days depending on species and diurnal temperatures. A. guttulosa and L. migratoria adults ceased to feed on sorghum crops as soon as first symptoms of intoxication developed. High volume water treatments produced slightly more rapid speed of kill than the ULV, but both achieved =100% locust mortality at all dose rates. Low Fipronil doses were shown to have high environmental safety for almost all non-target arthropods within the treated areas as cicadas, spiders, adults and larvae of Coccinellidae and Neuroptera and other beneficial species were unaffected in both pasture and sorghum crops. Studies of organisms in small temporary ponds within sprayed areas found aquatic insects, tadpoles, freshwater crabs and pulmonate snails also unaffected. Hundreds of insectivorous birds attracted to 3 trial sites soon after spraying were unaffected despite gorging for several days on debilitated or dead locusts. Non-target insects killed by fipronil were mostly solitary grasshoppers, crickets or phytophagous pest species in sorghum crops. Australian registration for Adonis 8.5UL and Regent 200SC at 1.25g a.i./ha for control of C. terminifera, A. guttulosa and L. migratoria in rangeland/pasture and grain sorghum was approved in December 1999.

[0206] EFFECT DIFFERENT DOSES OF THE INSECTICIDE CRUIZER FOR CONTROL OF THE "LARVA-PIN" DIABROTICA SPECIOSA (COL.; CURYSOMELIDAE) IN MAIZE CULTIVATION

W. Caetano & N. G. Bertoldo, Engº Agronomists researchers from FEPAGRO: Rua Gonçalves Dias, 570 - ZIP CODE 90130-060 - POA/RS - 3: E-MAIL: producao@fepagro.rs.gov.br

Rio Grande do Sul State, southeastern of Brazil, is constituted of 467 regions occupying a territorial area of 282. 062 Km2. The corn crops, Zea mays L. has significant socioeconomic importance. The cultivating of corn grain reaches 26% approximately of the total areas for grain cultivation. The larva -pin " is the most serious among the insect pests that damage the corn cultivation. A diagnosis was conducted to investigate the occurrence of soil-pests in 28 crops group of economical interest at conventional planting system. This study identified more than two dozens of soil-pests being classified in order of larger frequency, nematóides (73%); "corós" (64%); ants cutters (50%) and other (41%). The objective this study was to evaluate the effects of insecticide Cruizer 700 WS in the seed treatment in the "larva-pin" corn cultivation control. The trial was carried out at experimental field in São Borja - Rio Grande do Sul State, during 1999. The experimental design was a split-plot arranged in randomized blocks with four replications with six treatments. The following treatments were used with the respective doses in g. i. a./hactare for 100 Kg/seeds: Cruizer 700 WS, 50, 100, 150 and 200; Gaucho 600 FS, 80 and control. After 25, 45 and 60 days from field emergency five randomized plants were removed from two central arrays for evaluation. From the results was verified that insecticide Cruizer 700 FS at the used doses, together with the Gaucho 600 WS, evidenced high control index for the insets pest when accomplished the seeds treatment. Index terms: Control of " larva-pin", insect pest control

[0208] IMPACT OF CHRYSOPERLA (NEUROPTERA: EXTERNA CHRYSOPIDAE) ON CINARA SPP. (HOMOPTERA: APHIDIDAE) IN LABORATORY

J. T. Cardoso & S. M. N. Lazzari, Depto. de Zoologia, Universidade Federal do Paraná, Curitiba, PR, BR. E-mail lazzari@bio.ufpr.br.

Recent outbreaks of the aphid Cinara Curtis on Pinus spp. have been registered in southern Brazil, where it is causing significant losses to the forestry, lumbering, and paper mill industry. The genus Cinara is holarctic in origin, and includes 220 species, predominantly on Coniferae. The main symptoms are needle shedding, malformation of the branches, and tree stunting. Large colonies can be observed feeding on the branches, producing abundant honeydew, which allows extensive sooty mold development. A few predators have been collected, including Coccinellidae (Coleoptera), Syrphidae (Diptera), and Chrysopidae (Neuroptera). Green lacewing larvae are especially abundant and voracious. Laboratory tests were conducted in order to evaluate the impact of the larvae of the chrysopid Chrysoperla externa (Hagen) on Cinara spp. Batches of twenty larvae of each instar of C. externa were reared individually in plastic vials and fed with first to fourth instar Cinara pinivora (Wilson) and Cinara atlantica (Wilson) nymphs. Aphid consumption was studied under three temperatures: 15 °C, 20 °C .and 25°C, with 12L:12D photoperiod and 60% relative humidity. Feeding was evaluated every 24 hours. At 15 °C, the first instar larvae ate an average of 16.6 aphids; while the second consumed 44.9, and the third, 264.4 aphids. At 20 °C, the average consumption was 12.0; 28.8; and 183.2 aphids for the first, second, and third instar larvae, respectively. At 25 °C the consumption was 11.0; 21.6 and 108.3 aphids, respectively, for the first, second and third instar of C. externa larvae. The consumption of the third instar larvae represented about 80% of the total number of aphids predated at the three temperatures. At 15 °C the total consumption was greater because the time for the development was also significantly longer than at the other temperatures. The developmental period from egg hatching to the pupation was 63.0; 22.2; and 10.0 days at 15 °C, 20 °C, and 25 °C, respectively. The larval mortality was less than 10% at 20 and 25 °C, however it reached 40% at 15 °C, suggesting that this temperature, despite the high consumption, is not adequate for mass rearing. The best temperature for mass rearing in the laboratory is 25 °C, at which the development period is shorter and a smaller number of aphids is needed to feed the larvae. The results showed that C. externa can be a very efficient biological control agent for Cinara spp. on Pinus, especially due to its voracity and rearing easiness.

Index terms: Biological control; chrysopids; pine aphids; food consumption.

[0207] CHARACTERIZATION OF GREENBUG POPULATIONS COLLECTED IN ARGENTINA AND CHILE

<u>A.M.Castro¹</u>, A.A. Clúa¹, S. Ramos¹, D.O. Giménez¹ & H.O. Chidichimo^{2,3}, ¹Dept. of Biology and Ecology and ²Dept. of Production, Fac. of Agronomy, Univ. Nac. La Plata, CC 31, 1900-La Plata, Argentina ³ CICBA amcastro@isis.unlp.edu.ar

Greenbug, (Schizaphis graminum, Rond.) is one of the aphid pests that most seriously damages the cereal hosts and it is also one of the most important virus vector of sugarcane, potato, tomato, strawberry and pepper. Greenbug natural populations have been collected throughout Argentina and Chile during six years in order to establish the population dynamics for improving its control. Different traits economically important have been studied with these insects reared on susceptible barley and wheat plants. Ten maternal linages were isolated from every population. The host preference, the biotypic composition and their aggressiveness, the isozymes variability and the reproductive behaviour, were determine in 37 populations and in the derived clones. The aphids collected at low latitudes preferred S. halepensis as host, those ones collected on cereals significantly preferred barley and wheat, and insects collected on grasses preferred sorghums and oats. Three over 37 populations showed known biotypes being the most frequent biotypes B, C and F. Highly significant differences were determined between populations in greenbug aggressiveness in terms of coleoptile straight growth test of susceptible cultivars. Twenty different isozymes systems were analysed and it was found highly significant variability for estearases, phosphatases, and GOT. It was found no correlation between the population origin and the lapse required for sexuals differentiation. In two populations, (one from Argentina and the other from Chile), and in their derived clones there was not sexual induction. In another two Argentinean populations and derived clones only one sex was induced. The variability in host preference, aggressiveness, and isozymes systems could be explained by the reproductive behaviour. It is worth noticing that greenbug populations in Argentina and Chile have a different structure from those ones in the USA, since sexual reproduction is a common strategy of that aphid throughout very contrasting climates in our region.

Index terms: Greenbug, host-preference, biotypes, aggressiveness, reproductive behaviour

[0209] EVALUATION OF THE EFFICACY ON AN AGGREGATION PHEROMONE AS A MEANS OF CAPTURE AND PROTECTION AGAINST COSMOPOLITES SORDIDUS GERMAR (COLEOPTERA: CURCULIONIDAE) IN THE CANARY ISLANDS

A. Carnero¹, M. Montesdeoca² & J. Barquín³, ¹Inst. Canario de Investigaciones Agrarias, P.B. 60 - E38200 La Laguna, Tenerife, Canary Islands, Spain, ²Dept. Ciencias Agrarias, Univ. La Laguna, Tenerife, Canary Islands, 3Dept. Zoología, Univ. La Laguna, Tenerife, Canary Islands

The banana picudo, Cosmopolites sordidus was first cited for the island of Tenerife in 1986, after a century of banana cultivation free of this pest. It has spread rapidly constituting presently the most important pest for this crop due toits significant effect on yield. The assays have taken place on the north of the island of Tenerife, at a banana plantation located at sea level. The banana cultivar was Dwarf Cavendish, grown under drip irrigation. The pheromones were commercial origin. Pit-fall type traps were set up using a 3% detergent solution, located 20-m. apart and moved every week according to a pre-established statistical design. Treatments used were pheromone, pheromone + activator, activator and water control. The mixture pheromone+activator is the most effective treatment. The useful life of the pheromone was a 9 weeks. Using spatial analysis it was determined that the insect has focal distribution. Index term: Cosmopolites sordidus, pheromone,

[0210] EFFECT OF BLUE-YELLOW STRIPING ON STICKY TRAPS FOR THRIPS AND WHITEFLIES

<u>P. I. Carrizo</u>, Fac. Cs. Agr. y Ftales., Univ. Nac. La Plata. Calle 60 y 119, CC 31 (1900) La Plata. Argentina. e-mail: **Erro! Indicador não definido.**

It is possible to obtain an increase in total thrips caught on sticky traps, by putting them in front of a contrasting background colour, which result also attractive to the target species. If combined colour traps would produce a higher caught on trips by unit surface, and it does not affect other insect's behaviour, it may be an optimal choice. A possible advantage would be its potential use in mass trapping. The purpose of this study was to prove a combination of two different attractive colours - arranged as vertical striping - in order to improve thrips and whiteflies captures on greenhouse vegetable crops. Four trials were carried out in greenhouses, in tomato, pepper, cucumber and strawberry - the last one with onion as intercropping -. Thirty commercial sticky traps were placed on blossom, for one week. Colours were blue, yellow, and blue/yellow striping; adhesive surface was 10cm x 15cm, with striping 2 cm wide. Average captures/cm² were compared by mean of ANOVA and Tukey for thrips trials, and Kruskal-Wallis non parametric test for whiteflies trials (α =0.05). In pepper, trips caught were not different; Frankliniella occidentalis was the only species present. In strawberry there was not difference for thrips caught, because of a lower captures on yellow portions in striping traps; there were remarkable differences on F. occidentalis and Thrips tabaci presence, depending on that kind of trap involved. In tomato crop, there was highest caught for thrips on blue and lowest on yellow, while stripping trap was in the middle; F. occidentalis represented 75% and Thrips tabaci 25% of species caught. For cucumber trial, thrips caught on blue was the greatest, and clearly separated from yellow and striping ones; F. occidentalis being 90%, and T. tabaci 10% of species caught. Different thrips species composition might explain, at least in part, some apparent contradictions in colour tests - 'crop effect', as Mateus and Mexia named - and it is probably owing to mixture factors. Then, combined colours were not strong enough to overcame this crop effect, and enhance captures. For Trialeurodes vaporariorum, results were mostly negative, and were the same for every crop: yellow striping had very low captures by unit surface. Whiteflies seemed to reject yellow striping; the ratio (yellow striping / yellow pure) captures by unit surface were notably small: from 0.08 to 0.39. This is a negative non-expected consequence on whiteflies's behavior. No improving was attained because of two-coloured traps, because there was not evidence concerning an improvement in the thrips attraction, and there was some negative effect on white flies. Key words: Frankliniella occidentalis, Thrips tabaci, Trialeurodes vaporariorum, tomato, pepper, strawberry, cucumber

[0211] LEAST COUNTING SURFACE IN STICKY TRAPS FOR THYSANOPTERA AND ALERODOIDEA. L PRELIMINARY TESTS

<u>P. I. Carrizo</u>, Fac. Cs. Agr. y Ftales., Univ. Nac. La Plata. Calle 60 y 119, CC 31 (1900) La Plata. Argentina. e-mail: Erro! Indicador não definido..

Counting time for sticky traps might be reduced, by carrying out only on a portion of them; however, it should be examined how those insects arrange along trap surface. It was intended to prove the choice of carrying out countings in a smaller area of the traps - for a standard size -, taking two taxa, which currently are pests in greenhouse. Trials were carried out in cucumber; traps had an adhesive surface of 10cm x 13cm. Blue traps were used for thrips (9 trials, n=5), and yellow traps for thrips and whiteflies (5 trials, n=5). They were counted in the whole trap, and in 7 different arrangements, from 12 early created (see figure below). The expected capture was compared with actual ones on each arrangement, by means of G test, and paired t test was performed to settled down if caughts - by unit surface, of each arrangement - was higher or lower than average of the whole-trap counts (α =0.05). Frankliniella occidentalis represented more than 95% of trips species, and whitefly species was Trialeurodes vaporariorium. For trips, only 32% and 13% G tests adjusted to those expected values for yellow and blue traps, which shows a kind of cluster, especially on blue ones. According to t paired test, thrips caught on blue traps was meaningful higher than expected on: ii, iii, x, xii; meaningful lower than expected on: viii, ix. For yellow traps, it was meaningful higher than expected on: ii, iii, x, xii, meaningful lower than expected on: viii. Thrips behavior did not seem different because of color tested. For whiteflies, 96%~G tests adjusted to those expected, so these insects tended to be more uniformly distributed than the trips along the trap surface. Paired t test for whitefly shows that only caughts on viii and xii were meaningful different, higher than average. By counting two horizontal strips on top and bottom edges, 2 cm wide arrangement named i - it was obtained counts that were not significantly different from whole-trap counts, for both whiteflies and trips, in blue and yellow traps. That technique may reduce counting time by 70% compared with whole-trap counts, because only 30% of the total area are recorded.

Key words: Frankliniella occidentalis, Trialeurodes vaporariorium, counting time, cucumber

[0212] MULCH COLOR ATTRACTIVENESS FOR TRIPS AND WHITEFLIES BY MEANS OF STICKY TRAPS TRIALS

P. L Carrizo, Fac. Cs. Agr. y Ftales., Univ. Nac. La Plata. Calle 60 y 119, CC 31 (1900) La Plata. Argentina. e-mail: **Erro! Indicador não definido.**

The ideal trap should attract highest numbers of the pest populations; the ideal mulch should not. Blue or yellow - fairly most attractive - are not currently used on mulch color. About those currently used on La Plata horticultural belt - from more to less frequent: black, white, and orange - there is not information. Evaluations by means of true mulch may be costly, and a first approach might be obtained by means of sticky traps, in order to predict its behavior. In commercial greenhouses, there were carried out trials in tomato, cucumber and eggplant. Five colours were tested: yellow, blue, orange, white, and black; traps surface was 10cm x 13cm (n=10), and each trial was repeated twice. The traps were suspended on a wire; each one spaced 150 mm apart, and randomly distributed. Indeed, blue and yellow were used as witness for thrips and whiteflies populations. Total caught were compared, by means of ANOVA and Tukey tests; Kruskal-Wallis non-parametric test was used to compare eggplant results (α =0.05). Orange traps had meaningful lower caught for thrips, and meaningful higher for whiteflies; white ones were the opposite. Black ones had always the lowest caughts. A summary may be: blue ≥ white > orange = black for thrips, and yellow ≥ orange > white = black for whiteflies. Thrips species were different, depending on crop. Whitefly species was Trialeurodes vaporariorum. Both taxa had a divergent behavior, but their results should be not taken in an isolated manner. Even being not attractive to thrips, orange mulch might be a risk for whiteflies; a similar advice may be given for thrips and white mulch, so they should be not used. Thrips and whiteflies do attack together greenhouses crops, and every single cultural measure should be take account this. Table: thrips species on sticky traps, by color and crop.

Keywords: Frankliniella occidentalis, Thrips tabaci, Trialeurode's vaporariorum, tomato, eggplant, cucumber

[0213] AFRICANIZED HONEYBEE AND STINGLESS BEE AS POTENCIAL POLLINATORS OF SOME TROPICAL AND EXOTIC FRUITS IN BAILIA STATE, BRAZIL

M. S. de Castro¹ & F. F. de Oliveira², ¹Exp. Unit of Bahia Enterprise of Agric. Develop. EBDA, Salvador, Bahia and Dept. of Biology Sciense, State Univ. of Feira de Santana, Bahia. Dorival Caymi Av., 15.649 Itapuã Salvador, Bahia, Brazil 41.635-150. E-mail: marina@e-net.com.br; ²Dept. of Entomology, Federal Univ. of Paraná. Curitiba, Paraná, Brazil 81.531-970. E-mail: favizia@garoupa.bio.ufpr.br.

The bee community of a mixed orchard was studied at an experimental Station in the State of Bahia, Brazil. In this station, 20 species of native tropical and exotic fruits were observed. These ecological studies are important for the conservation of plants and bee fauna diversity. The pollinators play an important role on the reproductive success and gene flow of many agricultural and native plants and the plants are important food sources for the pollinators. A total of 14 highly eusocial bee species (Apidae) were recorded. The Africanized honeybee (*Apis mellifera scutelatta* L.) was the most abundant species at fruit flowers, representing 41.1% of all individuals or 51.7% of all Apidae. Of the stingless bees, 5 species can be considered as abundant fruit flower visitors, representing 1% or more of the sample and 8 species can be considered as rare. The analysis of the sampling shows the importance of the stingless bees (Apidae; Meliponinae) for some native tropical fruit trees as mainly potencial pollinators. Some patterns of bee species composition and relative abundance was studied.

Index Terms: Crop pollinators, bee community, highly eusocial bee, Bee Fauna

[0214] IMPACT OF CULTIVATION SYSTEMS ON *DICHELOPS MELACANTHUS* (HEMIPTERA: PENTATOMIDAE) ABUNDANCE AND ITS DAMAGE TO WHEAT IN SOUTHERN BRAZIL

V. R. Chocorosqui¹ & A. R. Panizzi², ¹Department of Zoology, Federal University of Paraná, P.O. Box 19020, Curitiba, Paraná 81531-990, Brazil. Email: viviane@cnpso.embrapa.br; ²Centro Nacional de Pesquisa de Soja (CNPSo), Empresa Brasileira de Pesquisa Agropecuária (Embrapa), Caixa Postal 231, Londrina, Paraná, 86001-970, Brazil. E-mail: panizzi@cnpso.embrapa.br.

The pentatomid *Dichelops melacanthus* (Dallas) was found as a new pest of wheat, *Triticum aestivum* L. in southern Brazil. Results of field evaluations indicated that this bug is associated with the no-tillage cultivation system, which favors its biology resulting in increase of the population. Adults and nymphs were found mostly on the soil, near the plant stems and underneath crop residues of the preceding summer crop, usually soybean, *Glycine max* (L.) Merrill or corn, *Zea mays* L. Wheat under conventional cultivation system was free of the bug attack. *D. melacanthus* caused substantial damage to wheat plants, particularly to seedlings. As a result of the bug attack, a reduction in the number of seed heads of up 34% was observed. Seed yield was reduced in 31% due to bugs attack, compared to plants free of damage. Weight of 1000 seeds was also reduced in approximately 5%. Management strategies to eliminate debris on the soil that offer shelter to stink bugs through plowing may mitigate the impact of D. melacanthus to wheat in southern Brazil.

Index terms: Hemiptera, Heteroptera, pentatomid, stinkbug, wheat, cultivation systems, pest management)

[0216] RESISTANCE TO GRAIN APHID IN WINTER TRITICALE CULTIVARS IN RELATION TO THE CONTENT OF MONO- AND OLIGOSACCHARIDES

<u>A. P. Ciepiela</u> & G. Chrzanowski, Dept. of Molecular Biology and Biophysics, Univ. of Podlasie, Prusa 12, 08-110 Siedlce, POLAND, e-mail: GrzegorzC@ap.siedlce.pl

Sugars are important nutrients for aphids, being their main energy source. Quantitative and qualitative sugar composition considerably affects choice of host plants by the aphids. Proportions of various sugars in the food determine aphid feeding activity, thus – amount of consumed and assimilated food. In present study soluble and reducing sugar content, and concentrations of saccharose, fructose and pentoses were evaluated in the cars of winter triticale cultivars of different resistance to grain aphid (*Sitobion avenae IF.J*). The results of entomological tests showed that Dagro cultivar was susceptible to grain aphid, and Malno – fairly resistant. Chemical analyzes revealed that aphid-free Dagro ears collected at the milk-maturity stage contained more soluble saccharides and saccharose, fructose and saccharose than Dagro plants. The differences of mono- and oligosaccharide content between the cultivars were statistically significant. The results indicate that high constitutive resistance of Malno winter triticale to the grain aphid is related to high content of reducing sugars, fructose, and pentoses in the areas.

Index terms: Sitobion avenae, winter triticale resistance, constitutive.

[0215] EFFECT OF THE GRAIN APHID FEEDING ON POLYSACCHARIDE CONTENT IN EARS OF WINTER TRITICALE CULTIVARS

A.P. Ciepiela, G. Chrzanowski & E. Radomyska, Dept. of Molecular Biology and Biophysics, Univ. of Podlasie, Prusa 12, 08-110 Siedlee, POLAND, e-mail: GrzegorzC@ap.siedlce.pl.

Grain resistance to aphids is closely related to structural polysaccharides of cell wall (cellulose, hemicelluloses, pectins). These compounds determine chemical structure of cell wall, and possibility of cell penetration by the aphids, acting as a mechanical barrier. Aphid saliva introduced into the host plant tissues during feeding affects the rate and direction of metabolic processes, e.g. synthesis of structural polysaccharides. In the present study the effect of feeding by grain aphid (Sitobion avenae /F./) on cellulose, hemicellulose, and pectin in ears of two triticale cultivars was evaluated. The cultivars differed in natural resistance to aphids – Dagro being more susceptible, and Malno – fairly resistant. Chemical analyzes revealed that non-infested by the aphids Dagro ears contained more hemicellulose, and less pectin and cellulose comparing to Malno plants. The differences of polysaccharide content in the non-infested plants of both cultivars were statistically significant. Aphid feeding on Dagro ears resulted in a significant decrease of content of all polysaccharides, comparing to the control. In Malno plants infested by grain aphid wingless females concentration of pectin and cellulose significantly increased, and content of hemicellulose dropped, comparing to the aphid-free plants. The results show that high resistance of Malno cultivar to the pest, constitutive and induced by S. avenae feeding, is related to the high pectin content, and low concentration of hemicellulose. The authors suggest that resistance of winter triticale to grain aphid is closely related to the structure and chemical composition of cell walls.

Index terms: Sitobion avenae, winter triticale resistance, constitutive, inducible.

[0217] EFFECT OF PYRIPROXYFEN ON WHITEFLY (BEMISIA ARGENTIFOLII) EGGS, IN THE EGGPLANT (SOLANUM MELOGENA), IN FIELD CONDITIONS

S.A.M.P. Coelho¹, M.H. Calafiori¹ & C.L. da Silva², Agronomic Engineering Course. CREUPI. Postal Box 05. 13990-000 - Espírito Santo do Pinhal – SP – Brazil. E-mail: cpagrpin@rantac.com.br. ²Hokko do Brasil. E-mail: issamu@hokko.com.br

B. argentifolii has caused great damage due to its aggressiveness and difficulty to control it. Trial was carried out, in field conditions, to applied pyriproxyfen on the eggplant culture, variety Napoli, in Estiva Gerbi county - SP, in April, 1999 and after in laboratory. Treatments were arranged in a completely randomized design with 10 replications. The treatments were: A- control; B- pyriproxifen (Cordial 100 - 75 ml/100 \Box). The plots were shaped by 4 plants being evaluated 1 cm²/eaf and 1 leaf/plant. Nymphs and adults were taken from leaves and only the eggs were left to observe the hatching. The leaves were maintained in BOD at 25°C. Evaluations were realized at the 3rd and 6th day after the first and second application of pyriproxyfen. Nymphs are counted after the emergence under binocular microscope and the percentage of hatching was established. The results allowed to conclude that pyriproxyfen applied in field conditions inhibit the nymph emergence after the second application with efficiency of 70,78% and 88,85% at the 3rd and 6th day, respectively. There wasn't phytotoxicity.

Index terms: ovicide, control, egg hatching.

[0218] DETERMINATION OF INJURY AND DAMAGE OF THE MEALYBUG DYSMICOCCUS BREVIPES (HEMIPTERA: PSEUDOCOCCIDAE) IN PINEAPPLE

K. G. F. Colen¹; J. C. Moraes¹; L. V. C. Santa-Cecília²; R. Zanetti¹ & A. B. Carnevale¹, ¹Dept² de Entomologia, Universidade Federal de Lavras 37200-000 Lavras Carnevale', 'Dept^a de Entomología, Universidade Federal de Lavras, 37200-000, Lavras, MG - Brazil. E-mail: jemoraes@ufla.br; ²Empresa de Pesquisa Agropecuária de Minas Gerais - EPAMIG, Campus da UFLA, 37200-000, Lavras, MG - Brazil.

Among the insects which are present on pineapple crop stands out the mealybug D. brevipes (Cockerell), which is spread in all the producing countries. Infestations under field conditions with the mealybug (0, 1, 5, 15, 30 mealybug per plant) on pineapple cuttings of the c.v. Smooth Cayenne potted in plastic pots were done. The objective was determining the injury and damage of that insect in terms of its density. The experimental design was completely randomized with four replicates and five treatments. The agronomic characteristics of the plants, population density of mealybug and wilt symptoms on pineapple plant through visual note scale were evaluated. The results showed that plant height, green matter weight of the root and aerial part were affected by the mealybug. A low population density of the mealybug was enough to transmit pineapple wilt. Index terms: IPM. Ananas comosus

[0220] FILTH IN FRUIT PRODUCTS MARKETED IN SÃO PAULO, BRAZIL

M. Correia & ²M.J. Roncada, Food Microscopy Division, Adolfo Lutz Institute, Avenida Dr. Arnaldo, 355, 01246-902, E-mail: mcorreia@ial.sp.gov.br; 2 Department of Nutrition, Public Health College from the University of São Paulo, Brazil. Financial support: FAPESP.

This survey was developed aiming the standardisation of the analytical methodology to the filth found in fruit jams, fruit pastes in sweets and in canned syrup fruits, and to determine the levels of filth contamination of such products. To isolate the filth found in the fruit jams, the method 16.10.06/950.89a of the Official Methods of Analysis of Association of Official Analytical Chemists International/1995 (AOAC International) was used; the same method was adapted to the fruit pastes in sweets, adding a new stage of sample boiling for dissolving. With the canned syrup fruits the methods 9L4a and 9L7a of the Macroanalytical Procedures Manual/1984 were adapted, which, with some modifications, allowed to carry out in one same sample the analysis of isolation of filth, of Howard mold count and Geotrichum mold count. To determine the levels of filth contamination, samples from the three products (fruit jams, fruit pastes in sweets and canned syrup fruits) were collected in supermarkets from São Paulo city. The analysis were carried out through the methods mentioned above. The results proved that the methods were appropriate, allowing a good visualisation of the light filth present in the filter paper. In relation to the levels of the contamination, it was found that 56.4% of the fruit jams, 54.4% of the fruit pastes in sweets and 31.6% of the canned syrup fruits were in disagreement with the Brazilian legislation for food which requires absence of extraneous materials, parasites or larvae in fruit products. The most contaminated products were: among the jams, the blackberry and raspberry ones; among the fruit pastes in sweets, the guava; and among the canned syrup fruits, the plums, mainly dead mites and insects and fragments of insects. Such results lead to the need of the alteration of the Bromatology legislation in force, establishing limits of toleration to strange materials such as fragments of insects.

[0219] COMPARISON OF DAMAGES CAUSED TO SOYBEAN BY DIFFERENT SPECIES OF STINK BUGS

B. S. Corrêa-Ferreira, Embrapa Soja, Caixa Postal 231, 86001-970 Londrina, PR, Brazil, E-mail beatriz@cnpso.embrapa.br

Damage caused by the three main species of stink bugs occuring on soybean were compared in field cages (1m x 1m) containing cultivar BR 37 soybean plants. Cages were infested with adults of Nezara viridula, Piezodorus guildinii and Euschistus heros, at a level of four stink bugs/m (8/cage), for 15 days, at pod filing stage (R5-R6). Evaluations were performed every two days when dead insects were replaced. After the infestation period the insects were eliminated by endossulfan aplication. Cages containing control plants remained free of stink bugs during all crop cycle. At harvesting, the number of healthy and damaged pods/plant and yield were evaluated. Seed quality from the control and infested plants were visually classified, as good, intermediate or bad seeds and also by tetrazoliun test (damaged seeds and non viable seeds). There was no difference in yield between infested and insect free plants, but damage on seed quality varied with stink bug species. For all cases, the seed quality was lower than for control plants. Results obtained by both visual and tetrazoliun evaluations showed that plants damaged by *P. guildinii* had the lowest quality seeds. From 50g seed samples, the average of the seeds classificated as good was 37.3g in plants infested with P. guildinii, compared to 41.8g, 44.2g and 46.6g in plants infested with *E. heros*, *N. viridula* and control, respectively. *P. guildinii* plants infested had about 18% of seed injuried and this value was higher than the 3.6% and 3.4% of plants infested with the two other species and 0.1% of the control plants. Similar results were obtained for the percentage of non viable seed due to stink bugs damage which was 5.7% for P. guildinii.

Index terms: Pentatomidae, Nezara viridula, Piezodorus guildinii, Euschistus heros. Glycine max

221] AGRONOMIC EFFICIENCY THE INSECTICIDES AND DOSES OF CONTROL TO TIBRACA LIMBATIVENTRIS IN IRRIGATED RICE

E. C. Costa¹, J.A.S. França¹ & R.C.Borin¹, ¹ Depto. de Defesa Fitossanitária, Centro de Ciências Rurais - Universidade Federal de Santa Maria, Campus Universitário, prédio 42, 1º andar, 3225 - CEP 97105-900 - Santa Maria - RS - Brasil e-mail: eccosta@ccr.ufsm.br.

A trial was carried out during 1998/99 season, in Santa Maria, RS-Brazil, in order to evaluated different inseticides and doses to control (Tibraca limbativentris) on El Passo L-144 irigated rice cultivar. The sampling of T. limbativentris was done with a sweeping trap into an experimental plot with 100m2. The area covered byy each sumpling was 3,8m2. The experimental field design was the complete random blocos with six treataments and four replications. The insecticides were Actara WG 25 (12,5g, 25g e 37,5g); Stron EC 60 (600g), Folidol 600 (270g) and a check. The insecticida was by a three, five and eight days after spraying. The insecticides were spraying by calibrated to 150 l/há. The evaluation were done three, five and eight days after the pre-spray, insecticides spraying. The treataments efficiency was calculate using Abbott (1925) formula and the two way analysis considerate the Duncan Test at probability of 5%. The result showed that Actara WG 25 (25 and 37,5 a.i.g/ha) controlled efficiently T. limbativentris despite the development stage.

[0222] THE USE OF ABOVE GROUND HEXAFLUMURON BAITS IN THE ELIMINATION OF A *COPTOTERMES HAVILANDI* COLONY LOCATED IN RIO CLARO, SP, BRAZIL (ISOPTERA, RHINOTERMITIDAE)

A. M. Costa-Leonardo¹, C. R. R. de Camargo-Dietrich¹ & S. L. Almeida², ¹Department of Biology, Universidade Estadual Paulista, Av. 24-A, 1515, 13506-900, Rio Claro, SP, Brazil, E-mail: amcl@rc.unesp.br; ² Dow AgroSciences Industrial Ltda. Rua Alexandre Dumas, 1671-4°C, 04717-903, São Paulo, SP, Brazil. E-mail: salmeida@dow.com

Coptotermes havilandi is an important termite pest in Brazil and its infestations are extremely difficult to control because of its large populations and satellite nests. In this study, the foraging population and foraging territory of a C. havilandi colony was determined and the action of hexaflumuron baits over the colony was investigated. Foraging population of a colony of C. havilandi was estimated at ca. 730,000 using two cycles of mark-release metodology with a weighted mean method. This colony was located in the campus of the University (UNESP, Rio Claro, SP) with termite activity spread into two buildings and a foraging territory that covered ca. 972 m². It was the single mature C. havilandi colony present in an area almost entirely occupied by the native subterranean termite Heterotermes tenuis. After characterizing the colony (estimating foraging population, foraging biomass and territory) through the use of both in-ground and above-ground stations, the hexaflumuron bait was introduced in only the above-ground stations. C. havilandi colony was eliminated in a period of 56 days through baits that had a matrix containing hexaflumuron, an insect growth regulator. The baiting procedure was initiated on February, 12, 1999 with the use of above ground stations only. Eleven bait stations were installed but only eight had consumption with termite activity (72.7% of hits). C. havilandi foraging ceased completely on April, 8, 1999 in the treated baits and on March, 3, 1999 in the untreated monitoring traps containing cardboard. Continuous monitoring through April, 22, 1999 showed an opportunistic invasion of H. tenuis termite in one bait station located within the original territory of C. havilandi. This H. tenuis infestation was controlled by June 1999. No termite activity was found in the foraging territory 10 months after control procedures were completed.

Index terms: subterranean termite, termite monitoring, mark-recapture technique.

[0223] OCCURRENCE AND DAMAGES OF ONCIDERES SAGA (COLEOPTERA, CERAMBYCIDAE) IN MIMOSA CAESALPINAEFOLIA (LEGUMINOSAE, CAESALPINOIDAE)

A. B. Coutinho¹, M. Scalise¹, C. R. S. Júnior¹ & A. G. Carvalho¹, ¹Depto. Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: acacio@ufrrj.br.

Mimosa caesalpinaefolia (Leguminosae, Caesalpinoidae), the popular "sabiá", happens in the northeast of Brasil. Its leaves are good as forage for the cattle and its wood for the production of stakes. Oncideres saga (Coleoptera, Cerambycidae), known by the name common of "sawyer", a menace has been considered for some botanical species. The work verified the occurrence and it evaluated the damages of O. saga in M. caesalpinaefolia in the period of February to June of 1998. It was made a research accomplished in the area of Fazenda do Viegas, in the city district of Bangu, RJ, to verify the occurrence of O. saga sawing branches of M. caesalpinaefolia, in plantation for recovery of degraded area. The inspection and it collects they were accomplished in an unit sample to verify the occurrence of sawed branches and with emergency holes, being measured the diameter, in centimeters, close to the base until the apex of the branch, and the length in meters. It was verified the occurrence and damages of the O. saga in just five copies of a unit of eighteen trees. The diameter measures and found medium length were of 1,33 cm (index of variation from 1,0 to 1,9) and 1,87m (1,22 to 2,98). The adults' of O. saga presence was observed, two females, accomplishing posture in a same branch. For the obtained results, it was verified that M. caesalpinaefolia is susceptible to O. saga when planted in degraded area causing alteration in the architecture of the crown, facilitating the organisms attack; it is necessary, therefore, a study of the flotation of O. saga, because through the same, they can be defined times for a cash it controls. Index terms: Degraded areas, "Sawyer".

[0224] SIMULATION OF THE TRI-TROPHIC SYSTEM COFFEE-BROCA-PARASITOIDS: POSSIBLE OUTCOMES FROM TWO DIFFERENT CLIMATIC REGIMES

J. R. Cure, Facultad de Ciencias. Departamento de Biologia Aplicada. Universidad Militar Nueva Granada.

As biologists we understand that life history traits affect the growth rates of populations. Numbers and size of the offspring, age distribution of reproduction and life span are all life history traits in which species differ (Futuyma, 1998). The problem has always been to have a consistent method that enables the practical use of this information, in terms of the useful application of laboratory data with field data and observations. When we talk about tri-trophic simulations we are referring to a very well structured system analysis for the simulation of ecological interactions and its outcomes. The system has been developed during the last 20 years, and although it has been extensively illustrated with biological control examples, it can also apply to basic ecology and applied biology in general (for a complete reference, see Gutierrez, 1996). Strengths of the system are: its ability to describe complex patterns using simple biological criteria as drivers of the models; the possibility of using available data to make initial assumptions; the capacity to incorporate new data as they are available; and its' modular approach, which permits the modification of functional relationships among variables as simulations suggest a new way for interpreting the data. In many countries of South America, coffee production is threatened by the introduced coffee berry borer, Hypothenemus hampei (Ferrari). There is a serious need to have a good method of control, which at the same time should be safe for the consumer. Several agencies in Latin America are currently looking for such a control and are introducing parasitoids and pathogens to deal with the problem (Hoyos and Aristizabal, 1996); however, there has not been a previous evaluation of the possible results of the introduced agents for the control of the borer. A tritrophic model was developed in order to have in advance, an estimate of the possible outcome of each parasitoid and their combination under different management strategies and climatic regimes (Gutierrez et al., 1998). Elements of behavior and life history of the borer and the parasitoids are incorporated into the model. The model is driven by climatic and management data (fertilization, pruning, etc.). What we are going to present is an example of the use of the approach to practical biological control. References:

[0225] EFFECT OF THE INSECT GROWTH REGULATOR DIFLUBENZURON ON REPRODUCTION OF EUSCHISTUS HEROS (HETEROPTERA: PENTATOMIDAE)

C. Czepak'; E. A. R. de Oliveira'; B. da S. Vieira'; H. G. Santana'; K. R. Kobus'; K. C. Albernaz'; A. L. da Silva'; P. M. Fernandes'; V.R.S. Veloso¹ & E. Moura², 'Universidade Federal de Goiás, Escola de Agronomia, c.p. 131, Cep: 74001-970, Goiânia-Go. ²Basf S. A

The effect of diflubenzuron (Dimilin), an insect growth regulator, on the fecundity and egg hatchability of *Euschistus heros* (Fabr.) (Hemiptera: Pentatomidae) was evaluated under controlled conditions. Newly-emerged adults from a stock culture were sexed and transferred to acrylic cages (1 couple/cage). Treatments were arranged in a completely randomized design with twenty replications, each couple/cage considered as a experimental unit. Treatments were: diflubenzuron 60 and 140 ml of the commercial product/100 L H₂O and control. The couples were fed with diflubenzuron-treated soybean legumes during 3 d. after emergence. Thereafter, they were fed on untreated soybean legumes during all period of observation. Adult fecundity and egg hatchability were evaluated daily. The averagee number of eggs laid/female (49,4 and 46,6) and egg hatchability (16,3 and 16,1) were lower when insects were fed on diflubenzuron seems to affect the embryonic development of *E. heros* by means of a transovarian action, thus avoiding larval eclosion. Results show the possibility of diflubenzuron application to reduce *E. heros* flipping production.

Index terms: diflubenzuron, Euschistus heros, soybean, transovarian action
[0226] BIO-CONTROL FOR NEW PESTS INVASIONS IN CALIFORNIA VINEYARDS: OBSCURE MEALYBUG AS A CASE EXAMPLE

K. M. Daane¹, A. Jani¹, M. Bianchi² & K. M. Weir¹, ¹Div. Insect Biology, Univ. of California, Berkeley, CA 94706, USA, daane@uckac.edu; ² Univ. of California Cooperative Extension, 2156 Sierra Way, San Luis Obispo, CA 93401, USA.

During the past two decades, a number of new insect pests have disrupted well-established IPM programs California vineyards. These include the variegated leafhopper (Erythroneura variabilis), obscure mealybug (Pseudococcus viburni), vine mealybug (Planococcus ficus), and glassy-winged sharpshooter (Homalodisca coagulata), Chemical controls for any one of these pests can disrupt the well-established biological control of other pests. Here, we present research on the bio-control of the obscure mealybug, and discuss regional IPM practices needed to curtail future pest problems. During the 1990s, obscure mealybug pest status increased dramatically in the Central Coast wine grape regions, requiring 2-4 applications of synthetic insecticides. Fruit infestation rates of 70-90% were recorded. Initial research indicated (1) there were no effective natural enemies and (2) ant populations were significantly correlated to mealybug populations. In 1996, two encyrtid parasitoids were imported from Chile: Leptomastix epona and Pseudaphycus flavidulus. These parasitoid were released at five vineyard sites and, in 1996 and 1997, recoveries of both species were made after winter no-release periods. However, mealybug densities remained high at all study sites and percentage parasitism was low. Field observations indicated that bio-control would not be effective until ant populations were reduced. In 1998 and 1999, laboratory and field studies investigated the role of anttending on obscure mealybug and its parasitoids. Laboratory studies showed ants interfere with parasitoid oviposition and remove parasitized mummies. Ants are most disruptive against L. epona, which has a slower oviposition time, compared with P. flavidulus, and lays eggs singly. In commercial vineyards, plots were established to test releases of imported parasitoids into ant-tended and ant-excluded plots. Results show that mealybug densities dropped significantly in ant-excluded plots. Parasitism levels were low in all but one vineyard where there was good ant control, where percentage parasitism climbed to over 75% and remained there throughout the season. When ants were present, percentage parasitism was <25% and mealybug abundance remained high. Predatory beetles were found both in ant-tended and ant-excluded plots. Results suggest that to improve biological control of obscure mealybug, insecticide treatments must first be made for ant control. A comparison is made of the obscure mealybug pest status with other new pest associations in vineyards and, through this comparison, a call is made for more regionwide IPM programs to reduce the spread of current pests to new vine-growing regions in California and the introduction of new pests.

Index terms: Pseudaphycus, Leptomastix, Pseudococcus, ant-tending.

[0227] AVERMECTINS VS DORAMECTIN: WHATS IN IT FOR DUNG BEETLES

I. R. Dadour¹ & D. F. Cook², ¹Zoology Dept. Univ. of Western Australia, Nedlands, 6009; ²Entomology Section, Agriculture Western Australia, South Perth, 6151, Western Australia.

Two groups of 50 cattle were given a subcutaneous injection of either abamectin (Avomec) or doramectin (Dectomax) at a dose rate of 200 µg/kg liveweight. A third group of 50 cattle remained untreated. Dung samples were collected on 1, 3, 6, 9, 18, 24, 34 and 42 days post-injection and excreted residues were bioassayed using the dung beetle Onthophagus binodis Thunberg. Abamectin residues excreted at 3 and 6 days postinjection and doramectin residues excreted at 9 days post-injection caused significant mortality in newly-emerged adults of O. binodis. Both compounds induced a range of sub-lethal effects on O.binodis, however, abamectin residues excreted in dung up to 42 days post-injection had a deleterious impact on ovarian condition, brood mass (egg) production, and larval survival. Doramectin residues only had a deleterious effect on these parameters at 3 and 6 days post-injection relative to dung from control cattle. Analysis of the dung collected at each date post-injection indicated that moisture content, pH, and %nitrogen were not different from other physico-chemical profiles conducted on cattle dung. The bioassay data indicated that doramectin concentrations of < 60 (g/kg have minimal impact on the mortality and reproductive potential of O. binodis and that deleterious effects to this species will be evident for only 1-2 weeks following administration of the drug to cattle. The potential ecotoxic effects of these compounds are discussed in terms of dung beetle activity and strategies for parasite control of cattle in the Australian.

[0228] EFFECT OF PREVENTIVE INSECTICIDES ON SITOPHILUS SPP (COLEOPTERA: CURCULIONIDAE)

L.R. Descamps¹, M.E. Reviriego¹ & <u>A.A. Suarez</u>², ¹Univ. Nac. Del Sur. San Andres S/N. (8000), Bahía Blanca, Argentina. e-mail Errol Indicador não definido. ²E.E.A.INTA Anguil, Ruta Nac. N°5 Km 580, C.C. 11, (6326) Anguil, La Pampa, Argentina; e-mail asuarez@anguil.inta.gov.ar.

Application of preventive insecticides is the most common practice to control insect pests in grain storage facilities. Treatment efficacy and residuality depend on the pesticide used. The objective of this study was to determine the effectiveness of different insecticides to control Sitophilus spp. Insects were collected from wheat storage places in the Bahia Blanca aerea and reared in laboratory at 25° C temperature and 70% relative humidity. The experiment design was a randomized complete block with four replications. Wheat grain was treated with the following insecticides: DDVP (100% EC) 10 cc/tn, Fenitrotion (100% EC) 6 cc/tn, Clorpirofos metil (48% EC) 10 cc/tn and Deltametrin + Piperonil Butoxide (2.5%+20% EC) 20 cc/tn. Fifty grams of treated grain were infested at 1, 30, 60, 90, 120, 150 and 180 days with 30 adult insects without sex determination. Dead insects were counted 5-7 d after infestation. Mortality was ajusted using Abbott's formula. The data obteined were analized using PROC ANOVA and means were separated using MEANS / LSD test (P=0.05) (SAS Institute, 1988). Signifficant differences were observed among treatments. Clorpirifos and Fenitrotion showed 100% mortality when grain infestation was done at 1, 30, 60, 90, 120 and 150 d. At 180 d mortality was 98% for Fenitrotion and 86% for Clorpirifos. DDVP mortality was 100% at 1,30,60,90 d, 98.7% at 120 d, 79.7% at 150 d and 69% at 180 d. Deltametrin + Piperonyl Butoxide mortality was 98% at 1 d, 79% at 30 d, 42.5% at 60 d, 82.7% at 90 d, 98.7% at 120 d, 99% at 150 d and 91.5% at 180 d. We conclude that all treatments, except DDVP, were effective to control *Sitophilus spp.* in stored wheat for up to 180 d.

Index words: Sitophilus spp., insecticides, stored wheat.

[0229] DAMAGE LEVEL EFFECT TO A NUMBER OF GRAINS PER SPIKE AND WEIGHT PER HEAD CAUSED BY CEREAL LEAF BEETLE (CLB) OF WHEAT AND BARLEY

B. Dimitrijevic, Agricultural research institute "Serbia", Center for small grains, Yugoslavia, 34000 Kragujevac, Save Kovacevica 31, tel +381 34 33 36 63, mail: bvd@uis0.uis.kg.ac.yu, or ddimitrijevic@ptt.yu.

Lema melanopus L. (Coleoptera, Chrysomelidae) is the most important pest on small grains of Yugoslavia. The damages CLB causes are frequent and in some years very significant. Research concludes of eight genotypes of winter wheat (Dicna, NS Rana 5, Proteinka, Jugoslavija, Studenica, KG 56-S, Levcanka, Ravanica) and winter barley (Partizan) on Center for small grains experimental fields in Kragujevac during 1996/97, and 1997/98, years. The experiment was concluded in controlled conditions (the plants were in cages) and in field conditions (control plants) also. After the cages were set adults of CLB were inserted (45 females and 45 males) manualy. Those adults were collected during copulation period. After the larvae feeding the damages were registered using the numbered scale (0-5). Analysis of quantitative traits of wheat and barley included number of grains per spike and weight per head. Plants under cages (treatment) were exposed to severe attack of CLB and had a less number of grains per spike then those outside cages (control), except from barley (Partizan). This genotype had 2.35 higher average number of grains per spike compared to control. The highest influence to a number of grains per spike was concluded on genotype Dicna where the difference between the average number of grains per spike of treatment and control was 13.68. The Studenica, Ravanica and Jugoslavija had 9.32, 9.12 and 8.65 respectively. Lowest damage effect for this trait was registered on NS Rana 5 genotype (3.40). Except from that, the small differences were obtained for Proteinka (3.65) and KG 56-S (4.05). This leads to conclusion that the damage effects of those genotypes were less than the damage effects obtained for Studenica, Ravanica and Jugoslavija. Weight per head in all investigated genotypes, observed in average numbers for both experimental years, was less for damaged plants The highest difference in average weight per head compared to control was obtained for genotype Diena (0.86 g). The Jugoslavija and Studenica, Ravanica, NS Rana 5 and KG 56-S had 0.59g, 0.49g and 0.46g respectively. The least influence of treatment compared to control plants was obtained for genotypes Levennka (0.33g) and Proteinka (0.39g). Statistical significance exists in all differences. The correlation factor between the damage effect of treatment and the weight per head was -0.505 which represents strong negative dependence.

Index terms: Cereal Leaf Beetle, small grains, quantitative traits.

[0230] ANNIHILATION OF FOUR FRUIT FLY PEST SPECIES ON THE PACIFIC ISLAND OF NAURU USING FIPRONIL IN PASSIVE BAITING SYSTEMS

R. A. I. Drew¹, A. J. Allwood² & <u>R. M. Bull³</u>, ¹Australian School of Environmental Studies, Griffith Uni., Nathan Campus, Q4111, Australia; ²South Pacific Commission, Private Mail Bag, Suva, Fiji; ³Aventis CropScience Australia P/L, 261 Tingira St., Pinkenba, Brisbane Q4008, Australia

An experimental programme using male annihilation and feeding attractant techniques to eradicate exotic fruit flies from Nauru Island was commenced in October 1998 targeting Bactrocera dorsalis, B. xanthodes, B. frauenfeldi and B. cucurbitae. Male annihilation methods used 40x40mm caneite blocks impregnated with methyl eugenol (ME)/0.1% fipronil (B. dorsalis and B. xanthodes) and Cue-lure (CL) /0.1% fipronil (B. frauenfeldi and cucurbitae) attached to trees at 300-700/km² and replaced at approximately 6 weekly intervals for 3 successive treatments. Protein autolysate feeding attractant containing 0.005% fipronil was also sprayed on host tree foliage to provide additional mortality of adult breeding populations. Fruit fly populations were monitored by rearing adults from fallen fruit and collecting flies in modified Steiner traps at 22 sites on the island. major reductions of B. dorasalis and B xanthodes were recorded within 9 days of commencement of ME/fipronil block distribution and trapping and fruit rearing data indicated both species were close to extinction by May 1999. CL /fipronil block treatment commenced in February 1999 but produced less dramatic reductions of B. frauenfeldi than ME attracted species. Mortality responses increased when a modified formulation of protein autolysate/fipronil gel spray was adopted in August in conjunction with CL blocks. In December 1999, the island was declared free of *B. dorsalis* and *B. cucurbitae*, but traps continued to record occasional incidence of B. frauenfeldi and B. xanthodes.

[0332] SUSCEPTIBILITY OF DIFFERENT ONION HYBRIDS AND VARIETIES TO THE ATTACK OF ONION MAGGOT DELIA ANTIQUA (DIPTERA: ANTHOMYIDAE)

A. C. Dughetti & C. D. García, National Institute Technology Agriculture (INTA), Agric. Hilario Ascasubi Exp. Station, Hilario Ascasubi, Bs. As.- 8142, Argentina, E-mail adughetti@inta.gov.ar

The onion maggot Delia antiqua is the principal pest of onion crop and the others liliaceous related to her in world's regions of temperate climate. At 1997, this insect was registered to make important damage at the irrigation area of bonaerense valley Colorado River, Province of Buenos Aires, Argentina. Damage was made at onion's seedling and crops, in direct sowing, in early date (last days of april to beginning may) and used varieties of long days (Valcatorce INTA and Australian Brown). The use of resistance varieties to the attack of these maggots is an interesting crop management by reducing or eliminating the use of insecticides because of contamination the soils and environment and increased the cost. The objective of this research was to evaluate susceptibility of different hybrid's onion and varieties to the attack of Delia antiqua, measured in the percentage of damaged plants. The experiment was done at field plots to the Experimental Station INTA Hilario Ascasubi, Argentina, in 1999. Plots were 2.40 m² and treatments were randomized in complete block design replicated four times. Onion was direct seeded in double rows (0.8 m row spacing). Hybrid onions and varieties were 24 and all the cases of short days. The onion plants damaged by Delia antiqua were evaluated by visually inspected of the plot's rows. The data's percentage damage plants from each plot were transformed to arc sin $\sqrt{\{x (\%) / 100\}} + 0.5$ and they were subjected to analysis of variance. Treatment means were separated using Tukey's Multiple Range Test (α = 0.05). "Caballero" had the smallest onion plants damaged by Delia antiqua. Hybrids "XPH67772" and "Valle F1 RS" were different to number damaged plant's by onion maggot from "Caballero" (α = 0.05).

Index terms: onion maggot, Delia antiqua, damage, onion, hybrid & varieties.

[0231] EVALUATION OF THE DAMAGE PRODUCED BY CLOVER SEED CHALCID BRUCHOPHAGUS GIBBUS (HYMENOPTERA: EURYTOMIDAE) IN RED CLOVER, IN THE COLORADO RIVER BONAERENSE VALLEY

<u>A. C. Dughetti</u>, National Institute Technology Agriculture (INTA), Agric. Hilario Ascasubi Exp. Station, Hilario Ascasubi, Bs. As.- 8142, Argentina, E-mail adughetti@inta.gov.ar

The clover seed chalcid is a microhymenopterous that cause damage of variable intensity in other lands of the world where produce seeds of this leguminous. The seed red clover is damaged by the larvas of this chalcid. They feed inside the seed and therefore it remains empty. It consumes all of the contents and pupates inside the hollow seed coat. The farmer doesn't known the loss that produced this chalcid because the infested seed is lighter than healthy seed. During the harvest most of the chalcid-bearing seed are removed during the mill cleaning operation since they are lighter weight than the good seed. Therefore, the seed with the wasp is a source of chalcid infestation in the field. The objective of this research was evaluated the damage produced by this chalcid in different red clover fields of seed production, in the Colorado River bonaerense valley. The experiment was done in red clover fields of seed production in the area during the years 1988, 1990, 1991 y 1992. Damage was evaluated by infestation percentage. It was tacked of the total seeds of the every head. From every field, 500 heads were harvested at random and they were kept paper bag. In 1988, were harvested 200 heads; and in 1992, were harvested 400.At the laboratory, the heads were thrashed by hand, helped with forceps (medium point) separating seeds of vegetal cover (sepals and receptacle). The healthy seeds were separated of infested and holed seeds by the chalcid. The doubtful seeds were pressed by a forceps. If they exuded a white creme liquid, they were considered the larvas inside the seeds. The percentage of infestation was get using the total number of seed and the damage seed by head. The sample of every field was a great number of heads, for this reason the dates was resumed in a frequency table. Using this table was calculated the means, the mode, the modal class, the standard deviation and the variation coefficient. The infestation percentage of this chalcid in the years 1988, 1990, 1991 and 1992 changes of the 6.3 % to the 44.7 % of damage, with a mean of the 24.9 %.

[0233] OVO-LARVICIDAL EFFECTS OF LUFENURON TO POTATO TUBER MOTH, PHTHORIMAEA OPERCULELLA (ZELLER) (LEPIDOPTERA: GELECHIIDAE)

E O. Edomwande,¹ A. S. Schoeman,¹* J. A. Brits,² & M. van der Merwe¹, ¹Dept. of Zoology & Entomology, Univ. of Pretoria, Pretoria 0002, South Africa. ²Crop Protection Sector, Novartis SA, P.O.Box 92, Isando 1600, South Africa.

The effects of the chitin synthesis inhibitor, lufenuron against potato tuber moth *Phthorimaea operculella* (Lepidoptera: Gelechiidae) eggs, were assayde by topically exposing different egg age groups (1-, 2-, 3- and 4-d- old) to treated potato tubers under laboratory conditions. Two concentrations (4 and 12 g a.i. litre⁴ respectively) of lufenuron were used and the controls were treated in distilled water. Each concentration glus its control was replicated four times and kept at a constant temperature of $28 \pm 1^{\circ}$ C and 12L: 12D photoperiod. Hatched first instar harvae were further reared to the adult stage on the treated tubers, while the controls were fed untreated tubers. Egg hatch from both treated and untreated tubers was very high (>95%), but mortality (>90%) of the first instar larvae were unable to penetrate or cause any noticeable damage to the potato tubers. At the higher concentration (12 g a.i. litre⁴) tested, adult emergence was less than 2% and this is a good indication that lufenuron may significantly reduce the amount of damage caused by the potato tuber moth when used in IPM programs.

Index terms: Chitin-synthesis inhibitor, lufenuron

[0234] FIRST REPORT ON THE PRESENCE OF MULBERRY THRIPS PSEUDODENDROTHRIPS MORI (THYS., THRIPIDAE) AS A NEW SPECIES FOR INSECT FAUNA OF MULBERRY FIELD OF NORTH OF IRAN

K. Etebari¹, J. Jalali¹ & M. Tak sokhan², 1.Dept. of Plant Protection, College of Agriculture, Univ. of Guilan. IRAN, 41335-3179; ²Research unit of silkworm rearing Co. IRAN, Rasht, P.O.Box 41635-1538.

The mulberry thrips *Psuedodendrothrips mori* NIWA is introduced as a dominant species in the insect fauna of mulberry field of Guilan province. The insect sucks the sap of the plant thus reducing the protein content of the leaves by 17.8% and the moisture by 3.57%, therefore have a negative impact on the quality of the leaves consumed by silkworm. The insect has 6-8 generations in a year and enjoys 3 highest peaks in summer season. The highest peak being the second week of august recorded 206.8 numbers in 100 cm² of leaf surface. The duration of each generation in summer ranges from 15-25 days. This insect hibernates as an adult. Two other thrips species (*Thrips tabaci* and *Heliothrips haemorrhodalis*) have also been collected from mulberry field of the area. However, their population stands next to *P. mori*. The collected species were confirmed by Prof. R. Zur Strassen of Frankfurt museum. The predator (*Orius minutus*) seens to control the thrips population in the area.

[0235] THE BIOLOGICAL STUDY OF WHEAT LEAF MINER SYRINGOPAIS TEMPERATELLA (*LEPIDOPTERA ELACHISTIDAE*) IN KHUZESTAN PROVINCE

<u>P. A. Fard¹</u>, Entomology Dept. College of Agriculture Univ. of Tehran, Karaj Iran 31584 E-mail:pafard@chamran.ut.ac.ir.

A study was carried out during 1993-1995 to investigate the biology of wheat leaf miner at two different areas: Shushtar (irrigated wheat field) and Izeh both at field and lab conditions. The results obtained during two years of studies reaveled that: 1) Duration of larval stage in the soil is about 233-250 days (aestivation); 2) Feeding period of larvae on the plant is about 75-100 days; 3) The prepupation and pupation duration is about 12-15 days; 4) The adult life time is 9-13 days; and 5) Incubation time of egg is between 10-12 days. The adults appear late February and feed of nectars from flowers of various plants for two days and mating periods take about 2-3 days. A female lays 29-56 eggs in the soil cracks around plant's base. Hatched larvae (neonate) enter the soil such as a soil chamber in which they pass hot and dry spring and summer as aestivation. The appearance of larvae in next growing season is dependent on environmental conditions. If the autumnal rain occurs early, the activity of hibernated larvae will start early too. Index terms: Leaf miner-Pupation-Hibernated

[0236] POPULATIONAL COMPOSITION AND SOIL MOBILITY OF SCAPTOCORIS CASTANEA (HETEROPTERA:CYDNIDAE) IN GOIÁS, BRAZIL

P. M. Fornandes¹; I. R. O. Cruvinel¹; K. Kobus¹; C. Czepak¹A.C. Oliveira¹; E. Almeida¹ & G. Ottoni¹¹, ¹Universidade Federal de Goiás, Escola de Agronomia, c.p. 131, Cep. 74001-970, Goiânia – Go. Pmarta@terra.com.br.

High S. castanea populations are becoming frequent in savanna crops. During the year crops 97/98 and 98/99, the average population reached more than 1000 adults and nymphs/m3 soil in soybean, cotton, rice and mayze crops. The knowledge of insect stational behavior in the soil is a requirement for the adoption of efficacious control methods. From august/99 to february/00 monthly sampling were conduced on infested fields in Acreúna_GO. Five spots were sampled every time using a 20cm diameter trade to obtain soil at 0 and 100cm. The first evaluations in 08/27 and 09/23 showed that although the soil was extremely dry up to more than 3.0m deep, about 90% of insects were found between 0 and 60cm. More than 50% were 1st and 2nd instar nymphs with normal appearence sheltered inside small round chambers in the soil. Living plants were taken during the raining season, with increased soil humidity and soybean plantation. The insects migrated to the surface, mainly between 0 to 40cm. First and second-instar nymph populations decreased after 11/25. Adults were only found after 10/29 and their frequency increased afterwards. It was evident that they probably present annual cycle.

[0237] PEST-INSECTS ASSOCIATED WITH CITRUS IN BOM JESUS DO ITABAPOANA, RJ, BRAZIL

E. A. A. Ferrara¹, P. R. R. Silva² & P. C. R. Cassino², ¹CTAIBB, Univ. Fed. Fluminense, Bom Jesus do Itabapoana, RJ 28360-000, Brazil, E-mail fernando@lutarc.com.br; ²Depto. de Entomologia e Fitopatologia, CIMP "CRG" '/ UFRRJ, BR 465 - km 7, Seropédica, RJ 23890-000, Brazil, E-mail: pramalho@fst.com.br; E-mail pr.cassino@uol.com.br.

Bom Jesus do Itabapoana is located in the northwest of the state of Rio de Janeiro with the coordinates of 21° 08'09"S of latitude and 41° 40' 08"W of longitude, at an elevation of 114 m above sea level. Presently, this region focuses the irrigated fruit crops. The citrus crop, mainly "Tahiti" true lime (*Citrus latifolia*) takes part of the potential exploration of the agriculture in this region due to its geomorphology and suitable conditions of soil and climate. Aiming to identify pests and regulator biotic organisms associated with the cultivar "Tahiti", a technical visit was made in some commercial orchards throughout the city and surroundings in January 2000. Seven true limes were selected and inspected. Infestation rates were registered by the presence and absence of insects on each quadrant of the canopy, and expressed in percentage of presence. Seven species were recovered: *Selenaspidus articulatus* (55%), *Pinnaspis aspidistrae* (70%) (Homoptera, Diaspididae), *Aleurothricus floccosus* (75%), *Dialeurodes citrifolii* (90%), *Paraleyrodes bondari* (50%), *Lleurotachelus cruzi* (30%) (Homoptera, Aleyrodidae), *Phylloenistis citrella* (75%) (Lepidoptera, Gracillaridae). We recorded 3 species of predators: *Pentilia egena* (5%), *Cycloneda sanguinea* (5%) (Coleoptera, Coccinellidae) and *Chrysoperla* sp. (5%)

Index terms: Diaspididae, Aleyrodidae, Gracillariidae, Coccinellidae, Chrysopidae, citrus

[0238] PRELIMINARY SURVEY OF TEPHRITID FRUIT FLIES IN THE NORTHWEST OF THE RIO DE JANEIRO STATE, BRAZIL

F. A. A. Ferrera¹, E. L. Aguiar-Menezes² & P. C. R. Cassino³, ¹CTAIBB, Univ. Fed. Fluminense, Bom Jesus do Itabapoana, RJ 28360-000, Brazil, E-mail fernando@lutarc.com.br; ²Embrapa Agrobiologia, Caixa Postal 74505, Seropédica, RJ 23890-000, Brazil, E-mail menezes@cnpab.embrapa.br; ³Depto. de Entomologia e Fitopatologia, CIMP "CRG"/ UFRRJ, BR 465 – km 7, Seropédica, RJ 23890-000, Brazil, E-mail pr.cassino@uol.com.br.

Irrigated fruit crops have been stimulated in the northwest of Rio de Janeiro state, such as mango, citrus, guava and passion fruit. Tephritid fruit flies are considered one of the most important pests of commercially grown fruits in Brazil. Aiming to survey the species of tephritid flies that may occur in the northwest of Rio de Janeiro, we installed McPhail traps in orchards in six cities of this region (Bom Jesus do Itabapoana, Natividade, Italva, Porciúncula, Itaperuna, Varre-Sai). Traps were baited with hydrolyzed protein plus borax as preservative. They were serviced every 7 days and all insect captured were taken to the laboratory where the flies were separated from the other insects and placed in vials containing 70% alcohol for conserving until the identification. In our first collection, we identified a total of 4 Anastrepha species (A. amita, A. fraterculus, A. grandis and A. obliqua) and Ceratitis capitata. New record for the state of Rio de Janeiro from the present study includes A. amita.

Index terms: Tephritidae, Anastrepha spp., Ceratitis capitata, survey

[0239] EFFECT OF RATES, VOLUMES AND APPLICATIONS METHODS ON THE CONTROL OF SPODOPTERA FRUGIPERDA IN MAIZE BY METHOMYL

M.C. Ferreira¹ & J. Belasque Júnior², ¹Dept. Fitossanidade, Univ. Estadual Paulista-Campus de Jaboticabal, Via de Acesso Paulo Donato Castellane s/n, 14870-000, São Paulo/Brazil, E-mail: mdacosta@fcav.unesp.br; ²Dept. Produção Vegetal, Univ. Estadual Paulista-Campus de Jaboticabal, E-mail: belasque@hotmail.com.

The control of fall armyworm - FAW - (Spodoptera frugiperda) in Brazil usually accomplished by spraying insecticides when plant damages is visible. Transgenic plants is the most developed technique for FAW control, but it is not used to Brazilian conditions yct. Thus, the chemical control is still used nearly as the unique alternative. Therefore, studies for optimisation of rates, volumes, and application methods, are very important to reduce economic and environmental impacts. Taking in account the aforementioned this work was developed aiming to evaluate the effect of methomyl applied by two application methods (band and broadcast), in two rates (0.6 and 0.3 Uha), and in two volumes (300 and 150 Uha), on the FAW control, in maize (hybrid Agromen 2010). The field trial was carried out as a randomised block with three replications, and analysed as a factorial $2^3 + 1$ control, on the university farm of Faculdade de Ciências Agrárias e Veterinárias/UNESP – at Jaboticabal, SP - Brazil, starting on 20-april-99. Evaluations were performed 1, 3, 5, and 9 days after applications (daa), by collecting 5 plants per plot, to numeric quantification of alive FAW. There were no difference between rates or applications volumes on the FAW control. Band showed better effect than broadcast application on 3 and 5 daa, but no difference was verified on 1 and 9 daa. The control plots presented higher numbers of living FAW per plant on all evaluation times studied, compared to other treatments.

Index terms: fall armyworm, chemical control, application technology

[0240] ABUNDANCE OF MESO AND MACROFAUNA IN PAMPEAN HAPLUDOLLS AND ARGIUDOLLS: THE INFLUENCE OF TOPSOIL MACROPOROSITY

A.M. Folcia¹; M.T. Taboada² & D.J. Consentino², ¹Catedra Zoologia Agricola, ²Catedra de Fertilidad y Fertilizantes. Facultad de Agronomia-UBA. Ave. San Martin 4453 (1417) Bs. As. Argentina. Email: afolcia@mail.agro.uba.ar

Soil pores have different size and functionality. Those > 30 Im in diameter are the habitat for meso- (100 [m - 2 mm) and macro-fauna (> 2 mm). This was studied in sandy loams (Hapludolls) and silty loams (Argiudolls). These soils are presumed to have high and low macroporosity in their top horizons respectively. We hypothesized that this different macroporosity determines different abundance of meso- and macro-fauna in each site. Topsoil undisturbed samples (0-20 cm) were taken in July 1999 in four sites in Bs. As. province: a) Alberti, sandy loam Typic Hapludoll (pastures grazed by cattle); b) Bragado, sandy loam T. Hapludoll (park); c) Perez Millan, silty clay loam Vertic Argiodoll (pasture grazed by cattle); and d) Rafael Obligado, silty loam Typic Argiudoll (forest, Eucalytus sp.). In each site we determined (direct observation) the abundance of macrofauna (Oligochaeta, Arthropoda[Insecta, Myriapoda, Crustacea, Arachnida] and saprophytic Nematoda), and the abundance of mesofauna (Enchytreidae, Colembolla and Acarina) by the Berlese method. The volumen of soil macropores (> 30 m) was determined from the difference between water volumes retained at 0 - 10 kPa matric potential (pressure apparatus) times soil bulk density. Soil macroporosity was correlated (Pearson) to the abundance of the whole meso and macrofauna and of each taxon. Soil macroporosity varied greatly among sites (5-35% total porosity), but this variation did not explain differences observed in taxon abundance (r= -0.14 to 0.42; FD = 9). This rejects our hypothesis. The abundance of meso- and macrofauna was not related to the amount of habitable space. Unlike, the abundance of macrofauna was rather related to land use, regardless topsoil texture. Both pastures (Alberdi and P. Millan) showed great abundance while the park (Bragado) and forest (R. Obligado), sites showed low abundance of macrofauna. The latter showed no presence of Oligochaeta. Soil mesofauna showed erratic differences between sites. About the factors causing different abundance of macrofauna can be thought that cattle grazing determines a greater recycling of residues from excreta and thus a greater availability of food. This would affect trophic chains, and so, the density of the different groups. Index terms: Arthropoda, Oligochaeta, Nematoda.

[0241] ROOTWORM EMERGENCE FROM Cry3Bb HYBRIDS COMPARED TO THAT OBSERVED WITH INSECTICIDE-TREATED MAISE

B.W. Fuller¹, M.A. Boetel², L.D. Chandler³ & P.M. Davis⁴, ¹Plant Science Dept., South Dakota State Univ., 248-C NPB, Brookings, SD 57007, USA, E-mail Billy Fuller@sdstate.edu; ²Dept of Entomology, P.O. Box 5346, Hultz Hall, North Dakota State Univ., Fargo, ND, 58105, USA. ³USDA, ARS, Red River Valley Ag. Res. Ctr., Fargo, ND 58105, USA; ⁴Monsanto Co., 3302 SE Convenience Blvd., Ankeny, IA 50021. USA.

Rootworms in the genus *Diabrotica* are typically the most economically important maize pest in North America. Consequently, to combat this serious pest, maize producers often use insecticide in a prophylactic manner. Currently under the Food Quality Protection Act, many of these insecticides are under intense review. Efforts by Monsanto Co. and other major seed producers has sought to investigate a more environmentally-sound alternative to insecticides by use of hybrids expressing a Cry3Bb protein derived form Bacillus thuringiensis. This inserted protein is believed to offer maize producers superior options by allowing reduced contact from handling synthetic insecticide, prevents misapplication or calibrations problems, and increased safety toward non-target organisms. Resistance management is possibly the most pressing issue to safeguard this valuable technology for its long-term sustainability. Therefore, our experiment was initiated to established baseline data on general efficacy and rootworm survivability as it relates to resistance management. Adult rootworms were collected from pyramid-shaped emergence cages using methods according to Boetel & Fuller (1997). Seven treatments including four transgenic events (code named: Event-A, -B, -C, and -D), three insecticides (Counter, Force, Lorsban) and untreated maize were use in this evaluation. These treatments were arranged in a randomized block design with four replications near Cavour, South Dakota, USA. Emergence and root rating data were analyzed using the SAS GLM procedure and an LSD test was used to compare treatment means. A 4.2 root rating mean was derived from the untreated check plots using the root damage scale by Hill and Peters (1971). All transgenic events provided sufficient root protection to prevent damage from reaching a 3.0 economic injury level (EIL). Counter, Force, and Lorsban all performed equally well from this perspective. Event D was outstanding in preventing damage and averaged a perfect 1.0 with no observable rootworm feeding scars present. All emergence data by species and sex will be review in the actual presentation. However, one key finding was that Event D showed very little survival in addition to its excellent role in damage reduction. These data represent an early assessment and many factors (inbred & hybrid yield, stacking compatibility, insertion related factors, and potential to develop resistance) may ultimately decide which event(s) are chosen by industry for release.

Index terms: Diabrotica virgifera, Diabrotica barberi, resistance.

[0242] ENTROPY OF ADULT WASPS OF POLISTES LANIO MISCHOCYTTARUS CERBERUS (HYMENOPTERA, VESPIDAE) F AND (HYMENOPTERA, VESPIDAE) FROM COLONIES STUDIED IN FIELD CONDITIONS

E. Giannotti^{1, 2} & C.J. Von Zuben^{1, 3}, ¹Dept. of Zoology, Universidade. Estadual Paulista, P.O. Box 199, Rio Claro, SP, 13506-900, Brazil. ²E-mail edilgian@rc.unesp.br; ³E-mail vonzuben@rc.unesp.br.

The entropy is a measure of heterogeneity in the distribution of deaths by age in a insect population. The formula for this measure using life table notation is $H = \left\{ \sum_{x=0}^{\omega} e_x d_x \right\} e_0 \text{ The numerator (i.e., the sum of the products } e_x d_x \text{ can be}$

interpreted as the average days of future life that are lost by the observed deaths and ω represents the last day of possible life from the initial age (x = 0). The denominator is the expectation of life at birth (e0). The entropy serves as a quantitative characterization of survival pattern and can be interpreted as the number of days lost owing to death per number of days lived. If H = 0, then all deaths occur at the same age, and if H = 1, then the I_x schedule is exponentially declining. The intermediate value, H = 0.5, indicates a linear I_x schedule (Carey, 1993). The adult wasps of 12 nests of Polistes lanio (n = 1,803) and 14 nests of Mischocyttarus cerberus (N = 345) were marked on the thorax for determining their life-span. It was assumed that an adult was dead when it disappeared from the nest. The life tables of these wasp populations were made according to Carey's (1993) method described as follow: the proportion of wasps surviving from birth to exact age x is lx; the proportion of wasps alive at age x that survive through the interval x to x + 1, is calculated

as: $p_x = l_{x+1}/l_x$; the proportion of wasps alive at age x that die through the

interval x to x + 1, is calculated as: $q_x = 1 - p_x$; the difference in number of

survivors from successive ages x and x+1, is calculated as: $d_x = l_x - l_{x+1}$; the per capita fraction of interval lived in the age interval x to x + 1, is evaluated as: $L_x = l_x (d_x/2)$; the total number of days lived beyond age x, is obtained from:

 $T_x = \sum\nolimits_v^\omega L_x$; and the expectation of life at age x, is calculated as: $e_x = T_x \left/ l_x \right.$.

The values for P. lanio were: $e_0 = 28.8$ days, $\omega = 230$ days and H = 0.869; and M. cerberus $e_0 = 14.4$ days, $\omega = 95$ days and H = 0.767. These high values of entropy in both species (that are primitively eusocial wasps, with small colonies) were due to the deaths that occurred during the first days of life, probably because of the beginning of foraging activities. Thus, foraging has a critical importance on the survival of Polistes and Mischocyttarus populations.

[0243] DAMAGE LEVELS AND EVALUATION OF COTTON YIELD LOSSES CAUSED BY ANTHONOMUS GRANDIS (COLEOPTERA: CURCULIONIDAE)

F. S. Gielfi¹ & A. C. Busoli², ¹Faculdade de Ciências Agrarias, Univ. Camilo Castelo Branco, Estrada Projetada F-1, Fazenda Santa Rita. ZIP: 15600-000, Fernandópolis, São Paulo State, Brazil. E-mail gielfi@fcav.unesp.br, ²Faculdade de Ciências Agrárias e Veterinárias, Univ. Estadual Paulista, Campus de Jaboticabal. Via de Acesso Prof. Paulo Donato Castelanne, km 05, ZIP:14870-000, Jaboticabal, São Paulo State, Brazil.

The Boll Weevil, Anthonomus grandis, is considered the major of the cotton pest in America. The determination of the damage level and evaluation of losses caused by insects are fundamentals to sucess of IPM programs. The objeticve of this research was to study different infestation levels and cotton losses caused by Boll Weevil. The experiments was carried out during 1995/96 growing season. The experimental design used was the randomized blocks (RCB), with five treatments ("check", 5, 10, 15, 20% damaged squares) and four replications. A hundred squares were sampled randomly (1 square/plant) from each plot at intervals from of 3 to 7 days. A square was damaged when it presented oviposition or feeding puncture. When the average damaged squares was equaled to the specified infestation level, the plots were sprayed. There was differences in the cotton yield (fiber plus seeds) for the several infestation levels. The results indicate that infestation levels between 5% and 10% are suitable for Boll Weevil control control and each 1% damaged squares the cotton yield decreases 33,1 kg/ha. Index terms: IPM, sampling, infestation level.

[0244] INCIDENCE OF THE DAMAGE OF PLATYPUS SULCATUS CHAPUIS (COLEOPTERA, PLATYPODIDAE) IN THE QUALITY OF POPULUS DELTOIDES WOODS

R. A. Giménez¹, A. E. Etiennot², R. Frank³ & G. Alvarez⁴, Proyecto UBACyT, TG16.¹ ^{2,4} Cátedra de Terapéutica Vegetal, Facultad de Agronomía, Univ. de Buenos Aires. Av. San Martín 4453, (1417), Buenos Aires, Argentina. E-mail: rgimenez@agro.uba.ar; ³ Cátedra de Administración Rural, ditto.

Platypus sulcatus Chapuis, ambrosia beetle, cause loses in Populus deltoides Marshall production, Caroline poplar, showed as the reduction of growth, breaking down of weakened trees and the loose of quality in the wood. This pest attack healthy trees. After the cut down of the orchard, the wood goes drying and the mycelium of the fungi ambrosia, which recovers the walls of the tunnels produced by P. sulcatus, turns in a brownish colour. The wood pieces or boards appeared with perforations with dark borders that restring the destiny of the production and difficult the commercialisation. The production of sawed wood of poplar clones Catfish 5 and I-72/51 from the Delta of Paraná nd section was evaluated. From 370 logs analysed we obtained 2049 boards 8 feet long, with different thickness from which only 28.039% had not damage. The board's attack by P. sulcatus did not present a clear special pattern of distribution because the dispersed attacks (30%), the concentrated ones (25.5%) and the combinated ones (16.7%) did not differed statistically. Neither difference between the location of damage was observed along the boards: 29.07% were attacked at the extremes, 43% at the proximal areas and 25% at the central area (ANOVA $\alpha = 0.05$). Between the tables with concentrated damage a great frequency of boards with less than 10 holes (43.15%) was observed, 17.81% with 11 - 20 holes, 4.9% with 21 - 30 and 5.8% with more that 30 ones were found. Between the tables with disperse attack a major frequency of the first class with less account of holes, was found. The damages presented an aleatory distribution along the boards with a predominance of few holes, being concentrated or dispersed, and the incidence of damage was of 72% of the boards.

Index terms: ambrosia beetle, wood borer, forestry products, damage

[0245] STUDIES ON INFECTION MECHANISMS OF THE FUNGI BEAUVERIA BASSIANA AND METARHIZIUM ANISOPLIAE ON HYPOTHENEMUS HAMPEI USING FLUORESCENCE MICROSCOPY AND SCANNING ELECTRON MICROSCOPY

F. Delgado¹, P.E. Vélez¹, E. M. Giraldo¹ & Y. López¹, ¹Disciplina de Entomología. Centro Nacional de Investigaciones de Café (Cenicafé). Chinchina, Caldas, Colombia. Email fefdelb@cafedecolombia.com Fax: 0968-506630. A.A 2427.Manizales. Caldas. Colombia.

Among the several pests that attack coffee crop (Coffea arabica), the most serious for colombian coffee growers is the coffee berry borer (Hypothenemus hampei). So far the use of entomopathogenic fungi B. bassiana and M. anisopliae are considered to control this insect pest of economic importance. We have studied infection mechanisms of both B. bassiana and M. anisopliae on adults of H. hampei and cuticle fragments by light fluorescence microscopy and scanning electron microscopy (SEM). The infection seems to involve the following events: (1) adherence of the spores to the cuticle (2) germination of spores and growth of the mycelium on cuticle surface (3) penetration of germinative tubes into the cuticle (4) extensive lateral development of hyphae followed by strong degradation of the cuticle layers. Labelling with Calcofluor White suggests that cuticle penetration and colonization mechanisms by both B. bassiana and M. anisopliae are closely related to enzymatic hydrolisis and mechanical pressure. Germinative tubes of B. bassiana and M. anisopliae can penetrate at any place of the H. hampei cuticle, although the most frequently penetration site is the insect abdomen close to the adherence site of the spores. A fissure is produced on the cuticle surface after penetration of the germinative tube into the insect. These observations bring further insights into the infection mechanisms of both fungi on H. hampei and on the localization of fungal spores and their penetration site on the insect cuticle. Spores localization, germination, mycelium growth and development of these fungi were observed from 48 h to 12 days after inoculation on growing media containing fragments of *H. hampei* cuticle using fluorescence microscopy and SEM.

Index terms: Entomopathogenic fungi, Coffee herry borer, conidial attachment, microscopy

[0246] *DIGLYPHUS* SP. COMPLEX IN OESTE REGION OF PORTUGAL AND ITS ROLE AS NATURAL CONTROL AGENTS IN GREENHOUSE VEGETABLES

<u>M. C. Godinho¹</u> & A. Mexia², ¹Escola Superior Agrária de Viseu,, Campus Politécnico, 2500 Viseu ceugodinho@isa.utl.pt ; ²Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras, amexia@isa.utl.pt

Leafminers (Liriomyzn sp.) have been referred as key-pests of greenhouse vegetables mostly on greenbeans, tomato, lettuce and cucumber. Liriomyza trifolii, Liriomyza bryoniae, and Liriomyza huidobrensis, this last species after 1991, were the species responsible for damages. Growers in Portugal spray mostly abamectine, imidaclopride and ciromazine against leafminers and other active ingredients against whiteflies and thrips can disrupt equilibrium between leafminers and their parasitoids, resulting in leafminers outbreaks. Studies were carried out during three years in order to assess population densities of Liriomyza adults and larvae at six greenhouses located 50 km Northwest from Lisbon. Insect and plant samples were collected fortnightly and observed at the laboratory. Data about active, dead and parasitised larvae with ectoparasitoids were recorded endoparasitoids presents were recorded after emergence. Ectoparasitoids adults obtained in laboratory were identified. Levels of parasitised leafminers larvae and levels of dead larvae, presented important differences related with crop protection practices followed in each greenhouses. In fact, growers have different attitudes towards control of leafminer's populations and, consequently, they chose different active ingredients with very distinct secondary effects on beneficials naturally occurring. In the present study is referred: (i) L. huidobrensis as the unique species found at present in the Oeste region; (ii) Diglyphus crassinervis, Diglyphus isaen and Diglyphus popoea as the most important ectoparasitoid species and their different external morphological aspects and (iii) the reasons that can explain the differences found on species diversity and abundance.

Index terms: leafminers, protected crops, Diglyphus crassinervis, Diglyphus isaea, Diglyphus popoea

[0247] IS WOLBACHIA INFECTION RESPONSIBLE FOR REPRODUCTIVE INCOMPATIBILITY IN THE SPIDER MITE, TETRANYCHUS KANZAWAI (ACARI: TETRANYCHIDAE)?

T. Gotoh, Lab. of Appl. Entomol. & Zool., Faculty of Agriculture, Ibaraki University, Ami, Ibaraki 300-0393, JAPAN, E-mail: gotoh@msv.ipc.ibaraki.ac.jp.

The Kanzawa spider mite, Tetranychus kanzawai Kishida, is a serious pest threatening many agricultural crops in Japan and China. It is known to occur in two strains, T and K (Gomi & Gotoh, 1996; Gotoh et al., 1999). There is a reproductive incompatibility between the two strains: no females appeared from a cross between females of the K strain and males of the T strain, whereas the reciprocal cross produced female offspring but the proportion of females was lower in comparison with the intra-strain crosses. *Wolbachia* are maternally inherited bacteria that mediate cytoplasmic incompatibility (CI), thelytokous parthenogenesis and feminization in animal hosts such as insects and terrestrial isopods (O'Neill et al., 1997). CI manipulated by Wolbachia has been observed in crosses between uninfected females and infected males, and resulted in no production of offspring in diplodiploids or in only male progeny in haplodiploids. The presence of Wolbachia has also been detected in T. kanzawai (Gomi et al., 1997). The current study was undertaken in order to discriminate *T. kanzawai* populations collected from different localities into either the K strain or the T strain and to survey local populations for the presence or absence of Wolbachia endosymbionts by PCR of ftsZ gene. Of 74 local populations tested, eleven belonged to the K strain and the others the T strain. Wolbachia infection occurred in local populations belonging to both the T and K strains. As all of the infected populations harbored a Wolbachia strain which does not influence compatibility of the host (i.e., modification negative), Wolhachia is not responsible for the incompatibility between the T and K strains.

Index terms: Tetranychus kanzawai, Wolbachia, reproductive incompatibility, ftsZ

[0248] EFFICIENCY OF THE INSECTICIDE ACTARA (THIAMETOXAN) ON CONTROL OF SHARPSHOOTER VECTORS OF XYLELLA FASTIDIOSA ON CITRUS

<u>S. Gravena</u>⁴, S.R. Benvenga¹, P.E.B. Paiva¹, J.L. Silva¹& L.C.S. Amorin¹, ¹Gravena ManEcol Ltda, Rua Monteiro Lobato 856, 14870-000, Jaboticabal/SP, Brazil. E-mail gravena@asbyte.com.br

The Citrus Variegated Chlorosis (CVC) is a serious citrus disease caused by the xylem limited bacterium Xylella fastidiosa that has been transmitted by the sharpshooters Acrogonia sp., Dilobapterus costalimai and Oncometopia facialis which have been controlled on young citrus orchards. The efficiency of Actara in two formulations 250 WG and 10 GR in different dosagens was compared to a standard insecticide Winner (imidacloprid). A four years old citrus orchard (*Citrus sinensis*) variety Pera was used for the study. The insecticide Actara 250 WG was applied on trunk and soil at 0.5 g of thiametoxan per plant, Actara 10 GR was applied on soil at 0.5 and 1.0 g of thiametoxan per plant and Winner applied on trunk at 1.5 g of imidacloprid per plant. The treatments were replicated 3 times where sharpshooter adults were released in voil cages weekly and evaluated up to 7 days. The insecticide Actara 250 WG (0.5g) and Winner (1.5g) applied on trunk, Actara 10 GR (1g) applied on soil controlled the sharpshooter vectors for 76 days, with mortality up to 80%.

Index Terms: Acrogonia sp., Dilobopterus costalimai, Oncometopia facialis, Chemical Control

[0249] EFFICIENCY OF THE INSECTICIDE TEMIK 150 (ALDICARB) ON CONTROL OF SHARPSHOOTER VECTORS OF XYLELLA FASTIDIOSA ON CITRUS

S. Gravena¹, S.R. Benvenga¹, J.L. Silva¹, N. Araújo¹ & R.D. Martíns¹, ¹Gravena ManEcol Ltda, Rua Monteiro Lobato , 856, 14870-000, Jaboticabal/SP, Brazil. E-mail gravena@asbyte.com.br

The Citrus Variegated Chlorosis (CVC) has affected all sweet orange varieties in Brazil. The CVC is caused by the bacterium *Xylella fastidiosa* which has been transmitted by the sharpshooters *Acrogonia* sp., *Dilobopterus costalimai* and *Oncometopia facialis*. The efficiency of the granulated insecticide Temik 150 with systemic action on control these insects was evaluated on a 2 years old citrus orchard variety Natal, during March to June of 1999. This insecticide was applied on soil at 10, 15, 20 and 25 g per plant. The treatments were replicated 3 times, where insect adults were released weekly in voil cagos and evaluated up to 7 days after that. The insecticide Temik 150 at 20 and 25g per plant was effective for 76 days against these insects, with mortality higher than 80%, at 7 days after the insects were released. The dosages 10 and 15g resulted 30 and 48 days of effective control, respectively.

Index Terms: Acrogonia sp., Dilobopterus costalimai, Oncometopia facialis, Chemical Control

[0250] EFFICIENCY OF THE INSECTICIDE WINNER (IMIDACLOPRID) ON CONTROL OF SOME CITRUS PESTS AND SELECTIVITY TO NATURAL ENEMIES

S. Gravena¹, S.R. Benvenga¹, P.E.B. Paiva¹& J.L. Silva¹, ¹Gravena ManEcol Ltda, Rua Monteiro Lobato 856, 14870-000, Jaboticabal/SP, Brazil. E-mail gravena@asbyte.com.br

The continuous leaf flushes on young citrus trees have predisposed these plants to particular pests such as the sharpshooters *Acrogonia* sp. *Dilobopterus costalimai* and *Oncometopia facialis*, the citrus leafminer *Phyllocnistis citrella* and the brown citrus aphid *Toxoptera citricidus*. The efficiency of the sistemic insecticide Winner on control of these pests and the effect on predators was compared to a conventional strategy where insecticides were sprayed. An one year old citrus orchard with two plots of 2.5 hectares was used for the trial. The insecticide Winner was applied on trunk four times a year at 0.5 g of imidaeloprid per plant in January, 0.5 g. in April, 0.6 g in June and 1.0 g. in September, according to the pest infestations and the conventional area was sprayed monthly with Decis 25 CE(deltamethrine) at 25 ml per hectolitre or Dimetoato 400CE (dimetoathe) at 100 ml, both mixed with Vertimee 18 CE (abameetin) at 5 ml and Natural oil (soybean oil) at 0.25%. At fortnightly frequency, 20 plants were evaluated randomly and the sharpshooters were collected in 8 yellow traps(15X5cm) per plot during one year vectors of *Xyllela fastidiosa, Acrogonia* sp., *D. costalimai* and *O. facialis* in winter and spring season when compared to the conventional strategy. The mean infested branches by *P. citrella* was 12.9 and 29.2% on Winner and conventional strategy. respectively. *T. citricidus* was reduced more significantly on Winner strategy. The higger abundances of the insect predators *Pentilia egena* and *Coccidophilus citricidus* and predatory mites *Euseius citrifolius* and *Iphiseiodes zuluagai* were observed on Winner strategy.

Index terms: Acrogonia sp., Dilobopterus costalimai, Oncometopia facialis, Phyllocnistis citrella, Toxoptera citricidus

[0252] DEVELOPING PRACTICAL RECOMMENDATIONS FOR MANAGING INSECT RESISTANCE TO BT TRANSGENIC MAIZE

R. L. Hellmich¹, **R. A. Higgins²**, **& E. C. Ortman³**, ¹USDA-ARS, Corn Insects and Crop Genetics Research Unit and Dept. of Entomology, 109 Genetics Laboratory, c/o Insectary, Iowa State University, Ames, IA 50011, USA, E-mail rlhellmi@iastate.edu; ²Dept. of Entomology, Waters Hall, Kansas State University, Manhattan, KS 66506, USA; ³Agricultural Research Programs, 1140 Agriculture Administration Building, Purdue University, West Lafayette, IN 47907, USA.

Managing resistance of insects to Bacillus thuringiensis (Bt) transgenic maize is necessary because Bt maize is valuable and all stakeholders want to preserve its efficacy. Currently, the high-dose/refuge strategy is the resistance management strategy of choice. There are potential problems with this strategy, yet research is underway to try to better define these problems and to offer solutions. A Regional Research Committee has fostered dialouge between industry, producers, academics and regulators. The NC205 committee formally addresses research on the AEcology and Management of European Corn Borer and Other Stalk-Boring Lepidoptera.@ For the past six years this committee has sponsored several meetings and symposia with industry and the Environmental Protection Agency to discuss insect resistance management issues. The NC205 Resistance Management meeting provides a forum for all parties to discuss general and specific issues concerning managing the resistance of European corn borer, Ostrinia nubilalis. The meetings have provided opportunities for sharing information, fine-tuning programs, establishing research priorities, reducing redundancies, and building understanding among participants. dialogue has allowed the committee to identify science-based practical resistance management strategies. The importance of resistance management strategies that are practical cannot be overemphasized because NC205 recognizes that the ultimate stewards of the Bt technology are the growers. So the committee has tried, whenever possible and without compromising the scientific integrity of resistance management, to consider grower realities. Topics discussed include monitoring for insect resistance, education, extension, grower surveys, managing resistance of other insects (especially rootworm), ongoing research, and future needs for research.

Index terms: Ostrinia nubilalis, resistance management, NC205 committee.

ALEYRODIDAE) OF THE CANARY ISLANDS (SPAIN)

[0251] CROP ROTATION COLLAPSES AS A VIABLE PEST MANAGEMENT STRATEGY FOR WESTERN CORN ROOTWORMS, *DIABROTICA VIRGIFERA VIRGIFERA*, IN THE EASTERN CORN BELT OF THE USA

M. E. Gray¹, S.T. Ratcliffe¹, J.L. Spencer², E. Levine² & K.L. Steffey¹, ¹Dept. of Crop Sciences, Univ. of Illinois, S-320 Turner Hall, 1102 S. Goodwin Ave., Urbana, IL 61801, USA, E-mail m-gray4@uiuc.edu; Center for Economic Entomology, Illinois Natural History Survey, 607 E. Peabody Drive, Champaign, IL 61820, USA.

Western and northern corn rootworms, Diabrotica virgifera virgifera LeConte and Diabotica barberi Smith & Lawrence, respectively, inflict severe economic damage to maize, Zea mays (L.), throughout much of the USA Corn Belt as well as some regions of Canada. Both species have a univoltine life cycle and a narrow host range that includes primarily maize and a few other grass species (Setaria spp.). For decades, the annual rotation of maize with soybeans, Glycine max, has proven an excellent pest management strategy because corn rootworm larvae are unable to survive on the roots of soybean plants. In the mid-1980s, it was widely reported that some rotated cornfields in Illinois, Iowa, Minnesota, and South Dakota had root injury caused by northern corn rootworms that prolonged their embryonic diapause through two consecutive winters. In 1987, agronomists reported corn rootworm larval injury in several rotated maize seed-production fields in east-central Illinois. Entomologists collected larvae and returned them to the laboratory where they completed their development as western corn rootworms. Explanations for the western corn rootworm larval injury to rotated maize were not lucid. Since 1987, crop rotation has continued to fail as a pest management strategy for western corn rootworms across an expanding geographical region of the eastern Corn Belt of the USA. Rather than prolonging their embryonic diapause, western corn rootworms have seemingly adapted to crop rotation by laying at least a portion of their eggs directly into soybean fields. Oviposition into other crops such as alfalfa, Medicago sativa L., also has been confirmed. Our current hypothesis suggests that the intensive selection pressure of an annual rotation of maize with soybeans has selected for a new western corn rootworm strain that does not restrict its oviposition to maize. The consequence of this novel adaptation to a cultural pest management strategy has been an impressive escalation of soil insecticide use in rotated maize fields in Illinois, Indiana, southern Michigan, and western Ohio. Designing effective resistance management plans for transgenic cultivars for corn rootworms will be a challenge because producers are likely to plant these varieties on both rotated and non-rotated maize acres.

[0253] CURRENT STUDIES ON THE WHITEFLY FAUNA (HOMOPTERA:

Whiteflies (Hemiptera: Aleyrodidae) are a group of sap-sucking insects of undisputed economic importance, which can cause significant direct damage to plants. Until very recently, whiteflies were an insect group that had been almost completely unstudied in the Canary Islands. Nevertheless, in a relatively few years several species have become major pests, and nowadays whiteflies are among the most serious agricultural pests in the archipelago. For this reason, whiteflies are the subject of a current research programme being carried out in the Canaries. Emphasis has been given to systematics, and thus a recent survey has resulted in six new additions to the Canarian whitefly species list, and three probable new species are under investigation. However, various taxonomic problems still exist and await solutions. These mainly include members of Bemisia afer and Bemisia tabaci species-groups, the larval stages of which show great morphological differences when developing on different host plants. The whitefly fauna of the Canaries presents a complex and scientifically interesting mixture of endemic and introduced species. While endemic species are mainly associated to the so-called "Macaronesian Laurel Forest" and the "Macaronesian Succulent Shrub" floras, several introduced species have caused serious economic problems in the archipelago. In particular, Aleurodicus dispersus and Lecanoideus floccissimus (both of them Neotropical members of the subfamily Aleurodicinae) can be considered the most important pests of ornamentals and shade trees in the Canaries, and have caused serious losses in tropical fruit tree plantations. Aleurothrixus floccosus and Parabemisia myricae are important pest in Citrus orchards, but Aleyrodes proletella and Siphoninus phillyreae are only considered of minor economic significance in these islands. Several cosmopolitan whitefly pests are also present through the Canaries, particularly Trialeurodes vaporariorum and Bemisia tabaci (biotypes "B" and "Q"). Besides causing direct damage, phytotoxic disorders and whitefly-transmitted virus outbreaks have been occurring recently, and are correlated with these species. Solutions are being sought to this new, and continuing, whitefly problems and, thus, research efforts have been also focused on whitefly biology, IPM management strategies and classical biological control. The authors aim to present an update overview of the whitefly problems occurring in the Canary Islands, combined with data on host plants, distribution, biological, and taxonomic aspects.

Index terms: Aleyrodidae, whiteflies, Canary Islands.

[0254] SOYBEAN STEM BORER IN KANSAS: LIFE HISTORY, SAMPLING, AND SEVERITY OF RECENT INFESTATIONS

R. A. Higgins¹, P. E. Sloderbeck¹, L. L. Buschman¹, S. B. Ramaswamy¹, C. Daves¹, H. Li¹ & W. Schapaugh², ¹Dept. of Entomology, Kansas State Univ., Waters Hall, Manhattan, KS 66506, USA, E-mail thiggins@oznet.ksu.edu; ²Dept. of Agronomy, Kansas State Univ., Throckmorton Hall, Manhattan, KS 66506.

Annually, for at least 15 years, specialists with Kansas State University have received scattered inquiries about the soybean stem borer (Dectes texanus) from growers and consultants. Only rarely did these reports evoke more than limited interest because most infestations were of insignificant occurrence. Late in 1998, multiple telephone calls indicated that areas thought to be relatively free of this pest were experiencing heavy infestations in some fields. Growers, consultants, and university employees reported that several North-Central Kansas soybean fields exceeded 50% infestation, with dramatic lodging developing as untimely rains delayed the completion of harvest. Some 1998 plantings of rotated fields unexpectedly approached 100% infestation. The 1999 growing season was the first year we devoted serious research effort to this pest in Kansas. Infestations again proved to be unexpectedly severe in several locations, damaging 90 to 100% of plants in several rotated fields. Our year 2000 sampling program will include holding infested soften studied in outdoor cages to establish when overwintering larvae change stages, first to pupae, then to adults. This research will establish when adults emerge and, thus when sampling may yield results and when the insect first becomes vulnerable to insecticides. Adult soybean stem borer populations will continue to be monitored through weekly sweep net sampling during our growing season of June, July and August to better define the seasonal occurrence of the egg laying stage. Sampling of adults will be expanded beyond known heavily infested areas to understand the magnitude of the problem across the state. Data on field history and year 2000 infestation levels at selected sites will be compared to determine if obvious correlations among cropping practices (crop rotations, neighboring vegetation, planting dates, maturity groups, etc.) and soybean stem borer infestations exist. Work also is being initiated to identify a usable synthetic sex pheromone as part of a project to provide soybean growers, consultants, and researchers with less labor-intensive approaches for assessing adult activity and possibly abundance. Replicated variety and limited insecticide screening trials also are being planned. Information on the progression of larval tunneling within the plant petioles and stems, plus timing of first signs of girdling and percentage of lodged plants also will be acquired as resources permit. Collecting this type of multidisciplinary information should help us determine whether soybean growers have practical, management options beyond avoiding serious lodging through timely harvesting of heavily infested fields.

[0255] FIRST RECORD OF OCCURRENCE OF APHIS SPIRAECOLA (HEMIPTERA: APHIDIDAE) ON IXORA COCCINEA AND I. COCCINEA VAR, COMPACTA (RUBIACEAE)

S. D. L. Imenes¹, E. C. Bergmann¹, A. L. B. G. Peronti² & <u>S. Ide¹</u>, ¹Centro de Sanidade Vegetal, Instituto Biológico, Av. Cons. Rodrigues Alves, 1252, São Paulo SP 04014-900, Brasil, E-mail imenes@biologico.br; ²Depto. de Ecologia e Biologia Evolutiva, Centro de Ciências Biológicas e da Saúde, Universidade Federal de São Carlos, Rod. Washington Luiz km 235, São Carlos SP 13565-905, Brasil.

Aphis spiraecola is a polyphagous species that colonizes young twigs and inflorescences of host plants belonging to several families such as Compositae, Rosaceae, Solanaceae, Curcubitaceae, Apocinaceae, among others. Native from Far East now it is widely distributed in all zoogeographical regions. The apterae are light green, except for the siphunculi, antennae and cauda that are black, contrasting with the rest of the body. The alatae are black, with green abdomen and pale tibiae. In October/1999, the incidence of alatae and apterae forms of A. spiraecola was verified in home gardens in São José do Rio Preto, North São Paulo, Brazil. It was colonizing plants of Ixora coccinea var. compacta (Rubiaceae) growing on beds exposed to sunlight. The insects were found feeding on young shoots of the hosts. The plants were highly infested and their leaves were completely curled. Some aphid specimens were parasited by the microhymenopteran Aplelinus gossypii (Hymenoptera: Aphelinidae). In November of the same year the presence of this same aphid species was detected in Porto Seguro, South Bahia, Brazil, feeding mainly on inflorescences of *l. coccinea*. The aphid was identified by Dr. Carlos R. Sousa-Silva (UFSCar) and the aphelinid by Dr. Marcelo T. Tavares (UNIARA). Ixora has high ornamental and economic values, being largely used in parks and gardens, for growing in edgings, rows, along walls and pots. I. coccinea is a woody, erect, few branched shrub, with leathery, light-green leaves; the inflorescences are large, terminal, long, with flowers orange, pink or yellow. The var. compacta is a small-branched shrub with small, thick, dark-green leaves; the inflorescences are dense and globose, with pink, yellow or red-orange colored flowers.

Index terms: Aphelinus gossypii, Aphelinidae, ornamental plants, Brazil.

[0256] PERFORMANCE OF CERATITIS CAPITATA (DIPTERA, TEPHRITIDAE) ON FRUITS: COMPARISON OF TWO LABORATORY POPULATIONS

I.S. Joachim-Bravo¹, A. N. Guimarñes¹, T. C. Magalhñes¹ & A. S. Nascimento², ¹Inst. of Biology, Univ. Federal of Bahia, Ave. Barão de Geremoabo s/n, Campus Universitário de Ondina, Salvador, Bahia, 40.170-290, Brazil, E-mail ibravo@ufba.br; ²CNPMF/EMBRAPA, Cruz-das-Almas, Bahia, 44.380-000, Brazil.

The mediterranean fruit fly, Ceratitis capitata, in the imature phase, feed on countless fruit species, causing serious losses to world fruit culture. Rearing these flies in the laboratory permits attempts at biological control; furthermore, laboratory-reared populations can be used for basic research in different areas. Literature data show that artificial fruit fly rearing for many generations in the laboratory causes deleterious changes in behavior compared to wild populations. In general, laboratory-reared populations mature more rapidly, with an increased reproductive rate and a reduced ability to fly. Regarding the feeding behavior and the oviposition behavior studies show that flies do not show preference for artificial diets or natural hosts. Among others cares, a constant wild flies introduction in the laboratory flies colonies has been being a practice used to the variability genetics maintenance and for the decreesing of deleterious effects caused by the artificial rearing. Experiments were carried out to test the performance of two C. capitata laboratory-reared populations (a population reared with artificial diet for 18 years without the wild flies introduction - pop. A - and other reared with artificial diet for 10 years with individuals' wild periodic introduction - pop. B), when imatures fed on three natural hosts: papaya (Carica papaya), mango (Mangifera indica) and orange (Citrus sinensis). The performance parameters tested were percent emergence, time to emergence, adult female size, egg production during the pre-oviposition phase (first five days of adult life), longevity of adults, fecundity along the female adult life and pre-oviposition period. The data were analyzed statistically by the Mann- Whitney and Kruskal-Wallis tests at the 5% of significance. Considering the parameters, time to emergence, percent emergence, adult female size, egg production during pre-oviposition phase and fecundity along the life, the performance of both the populations were superior when the flies fed on papava and mango compared to orange. Comparing both populations to each other, the data show that the time to emergency was longer and the females longevity was shorter for population A compared to the population B, independent of the fruit host. However, the population A females had a larger fecundity along life regarding population B, with all the fruits tested. Comparing the others parameters the performance of the two populations was similar. The implications of these results for the practices used to the variability genetics maintenance of fruit flies laboratory-reared populations will be discussed.

Index terms: Ceratitis capitata, feeding behavior, laboratory rearing

[0257] FACTORS AFFECTING COTTON BOLL WEEVIL SURVIVAL IN VARIOUS OVERWINTERING HABITAT IN THE MIDDLE SOUTH REGION OF THE UNITED STATES

<u>D. R. Johnson</u>¹ & G. M. Lorenz¹, ¹Univ. of Arkansas Cooperative Extension Serv., P. O. Box 391, Little Rock, AR 73303, USA, E-mail djohnson@uaex.edu, and glorenz@uaex.edu.

Boll weevil (Anthonomus grandis) survives the winter in the mid-south cotton production region of the United States by movement during the fall into various types of vegetation surrounding cotton fields. The most favorable overwintering habitat in Arkansas is forested areas with deciduous trees. Forested areas with deep deposits of leaves and other organic materials were the most favorable for the survival of boll weevil. Areas that involve grass as a major portion of the habitat composition were the least favorable for survival. The effect of temperature and moisture in these deciduous habitats directly affects survival of boll weevil. Colder weather and high humidity conditions were the least favorable for the survival of boll weevil. Survival of boll weevil declines when the micro-habitat temperature drops below a minus 2.5 degrees centigrade coupled with high moisture conditions.

Index terms: Anthonomus grandis, vegetation, environment

[0258] GIANT BLACK BARK PEACH APHID PTEROCHLOROIDES PERSICAE (HOMOPTERA: LACNIDAE)

S. Kacic¹, K. Zanic¹, J. Igre-Barcic² & M. Katalinic¹, ¹ Inst. for Adriatic Crops and Karst Reclamation, Put Duilova 11, Split 21000, Croatia; E-mail: sonja@stijena.krs.hr, ² Faculty of Agriculture, Svetosimumska 25, Zagreb 10000, Croatia

Giant black bark aphid Pterochloroides persicae was observed at the end of seventies in Croatia and since then it has been a constant member of our entomofauna. Aphid colonies are easily visible on peach shady branches and trunk parts. The great infestation causes branch decline because of aphid colonies sucking. A few years infestation induces tree decline. Aphids excrete honeydew in abundant quantity that covers plant parts and soil under attacked tree. The presence of honeydew stimulates sooty mould growth and finally flacks like petroleum appear, separately under the tree. In the most cases, this pest habits and attacks a peach (Prunus persica), although it has been determined on other prunoideae. Pterochloroides persicae characteristics had not been investigated in our region before, so we did researches including: morphology, host plants, damages, location spots, biology, ecology and posibilities of its control. Field investigations were conducted from Zadar to Dubrovnik, coast and island region, to record the pest distribution and host plants in period 1996-1998. Bioecology of *Pterochloroides persicae* was investigated in selected peach orchard in Split region. Infested trees were observed twice a week during spring - autumn period and twice a month during the winter. Aphid colonies life duration was observed on peach woody cuttings in the laboratory. Other than peach, colonies of Pterochloroides persicae were found on these plant species: Prunus armeniaca, P. amygdali, P. mahaleb, Mespilus germanica and on sedlings G. F. root stock. Only on the peach aphid was presented all the year. Number and size of colonies varied through the year. The type of aphid reproduction was only parthenogenesis. It overwintered at all development stages except the egg. Otherwise, the egg stage of this aphid was not noted in our conditions during our study. Aphid colonies survived up to three months on woody cuttings in the laboratory, depending on air temperature and humidity.

[0260] FACTORS INFLUENCING DEVELOPMENTAL VELOCITY IN CHRYSOPERLA CARNEA

T. Kubota¹, ¹Kitakarasuyama 6-31-2, Setagaya, Tokyo 157-0061, Japan, E-mail: tkubota@mtd.biglobe.ne.jp

Environmental and genetic factors underlying developmental velocities in *Chrysoperla* carnea were explored. In this study, a strain of *Chrysoperla curnea* was propagated from a field-collected female (generation (gen) 0) and acclimatized to the insectary environment (chamber-a: temperature, ca. 26 °C; RH, 60%; photoperiod, 16L8D) and subdivided into 3 strains at gen 11. Each of these strains was then assigned to one of the 3 environments: chamber-a as described above, chamber-b (temperature, ca. 23°C; with same RH and photoperiod as chamber-a) and chamber-c (ca. 21°C; with same RH and photoperiod as chamber-a). The animals were reared successively through gen 27 and larvae of these strains were examined at each generation to see whether their developmental velocities (LDV) were different due to chambers they were reared and/or due to sibs they belong to ('sib' refers to offspring sharing the same parent and nests within each 'chamber'). First, the author found significant (at 5% level) seasonal fluctuation in generational LDV: highest in summer and lowest in winter for all 3 strains at each of 3 immediate temperature levels. Also, the generational mean LDV's were, in the order of chamber-a > chamber-b > chamber-c for most of generations except at gen 18 in which the order was chamber-a > chamber-to is most of generations except a gen to in which the order was chamber-a / chamber-b. Second, throughout the majority of generation, the LDV was higher in chamber-b and chamber-b. The differentiation in LDV due to chamber environment was significant at gen 17, 18, 24, 25 and 27 at 26 °C immediate temperature level, at gen 15, 17, (18), (23), 24 and 27 at 23°C immediate temperature level and at gen 17, 20, 26 and 27 at 21°C immediate temperature. Significant differentiation due only to sib was also observed, often in generations preceding these generations. The author employed thorough statistical analyses on various experimental data such as theritability, accidental selection, inbreeding, survival rates, reproductive performance in these strain and meteorological record to further deduce the factors influencing LDV. The author concludes that the environmental factor is the major determinant of LDV suggesting that the developmental velocity of chrysopid stock in insectaries is different from those in natural environment.

Index terms: environmental factor, heritability, founder effect, inbreeding, acclimatization.

[0259] STICKY NET CYLINDER TRAP FOR THE RICE LEAF BUG, TRIGONOTYLUS CAELESTIALIUM (HETEROPTERA: MIRIDAE)

M. Kakizaki¹ & H. Sugie², ¹ Hokkaido Ornamental Plants and Vegetables Research Center, Higashi-Takikawa 735, Takikawa, Hokkaido 073-0026, Japan, E-mail kakizams@agri.pref.hokkaido.jp² National Institute of Agro-Environmental Sciences

The rice leaf bug, *Trigonotylus caelestialium* (Kirkaldy) (Miridae), is distributed in China, Europe, Russian, North America and Japan. It is one of the major pests causing a pecky rice, and injures wheats, maize and forage grasses. It was reported that *T. caelestialium* females attract conspecific males (Kakizaki and Sugie, 1997), and that the female has a sex attractant pheromone. Although they are able to be captured by water pan trap, not by the horizontal sticky board trap with a roof and two entrances. Then, we made 'the sticky net cylinder trap' (1-mm mesh, 5 - 6 cm diam., 30 - 40 cm length, coated with the sticky material 'KINRYU Spray', vertically set on the ground and baited with pheromone lure at 25 - 30 cm in height), which captured more males than any of the other sticky type trap. The numbers of males captured at 0 - 10 cm and 11 - 20 cm in height by this trap, which was 40 cm long and set with the lure at height of 30 cm, were greater than at 21 - 30 cm und 31 - 40 cm, respectively; this trap captured more males than a trap 80 cm long set with he lure at a height of 70 cm. A 10-cm diameter trap captured smaller males than a 5-cm fiameter trap. The 5-mm mesh trap captured more males than the 1-mm mesh trap without a drop in the sticky efficiency. This trap is useful for investigation of trap design. index terms: sticky net cylinder trap, trap design, Miridae, rice leaf bug, *Trigonotylus* scalestialium [0261] USE OF THIAMETHOXAN IN BEAN PEST CONTROL

<u>A.M. Labinas</u>¹ & W. B. Crocomo², ¹Dept. of Ciências Agrárias - Univ. of Taubaté - 432 Quatro de março St. Taubaté - SP - Brazil, 12020-270, E-mail <adianal@tecsat.com.br>; ² Dept. of Vegetable Production - FCA - UNESP - P. O. Box 237, Botucatu - SP - Brazil, 18603-970, E-mail <wcrocomo@fca.unesp.br >

With the aim to evaluate the losses caused by different pests that occur in bean crops and analyze the economic gains of the control with Thiamethoxan insecticide. Two experiments, using 'carioca' bean, were conducted in two different seedling season. These experiments were conducted on the Pilot Farm of Taubaté University - SP - Brazil. The water season crop was realized from October to December of 1998 and the dry season crop from February to May of 1999. Both experiments followed the experimental design of 14 treatments with 4 repetitions, with 50 m² plot (10 rows distant 0,5 m with 10 m length and 5 plants per meter). Three treatments (1,2 and 3) with ACTARA 250 WG, in the dosage of 150,0g a.i. Ana applied in intervals of 7, 14 and 21 days; one treatment (4) with CRUISER 700 WS, in the dosage of 1,5g a.i. /kg applied in seeds treatment; three treatments (5, 6 and 7) with CRUISER 700 WS, in the dosage of 1,5g a.i../kg applied in seeds treatment plus ACTARA 250 WG, in the doage of 150,0 g i. a. /ha applied in intervals of 7, 14 and 21 days; three treatments (8, 9 and 10) with TAMARON BR, in the dosage of 600,0 g a.i./ha applied in intervals of 7, 14 and 21 days; three treatments (11, 12 and 13) with CRUISER 700 WS in the dosage of 1,5g a.i./kg applied in seeds treatment and a b) with extended the state of the stat indicative such as height, leaves number, leaf area, flowers number, pods number and the pests population of each insect species present in the plants and quantified their damage; in the end of the culture, the productivity parameters indicatives were evaluated such as grains number per pods, weight of 100 grains and production in Kg/ha. In the dry season crop occurred more insect species than in water season, however, the data got showed the populational level reached by different insect pest species, in both tests, did not cause significant losses that justified the use of chemical control. The treatments that applied both insecticides Cruiser and Actara caused a better vegetative development. No difference was detected in the production either because of insecticide treatments or because of cultive season.

Index terms: Thiamethoxan, Phaseolus vulgaris, chemical control, chemical treatment schedule

Symposium and Poster Session

[0262] CONTROL OF *DIABROTICA SPECIOSA* (COLEOPTERA, CHRYSOMELIDAE) NA CULTURA DA BATATA

C. A Lacerda¹, A M. C. de Lyra Netto², V. F. dos Santos², M. C. L. da Silva², Caixa postal 157, 37200-000 Lavras - MG, Brasil, E-mail cynthia@ufla.br; ² Empresa Pernambucana de Pesquisa Agropecuária - IPA, Ay. Gal. San Martin 1371, Bongi, 50761-000 Recife - Pe, Brasil.

It wish to control *Diabrotica speciosa* populations on potato crop and to reduce the crop damages, makes this research. It was studied the Deltamethrin 25 CE dosage effect: 0; 1; 8 and 16 ml/20 | of water only and with the presence (pg) and absence (ag) of trap crop small pigeon pea (*Cajanus cajan*) precursor of the cultivate IAPAR-43-Aratā on *Diabrotica speciosa* larva damage in Baraka potato roots. Planted in two times: begining june of 1995, 1996 and 1997 (e₁) and middle/final of june of 1995 and 1996 (e₂) in waste are in Caruaru, Pernambuco state, Brazil. The experimental delineation was chance blocks with four treatments and five repetitions. In (e₁) and in (e₂) planted one area with potato (b) and another area with potato and pigeon pea (bg). Counted the damage *D. speciosa* larva on roots and used Abbott to calculate the treatments efficience. Got untill 36,4 % efficience on number of commercial damaged roots from plants of (e₁), weekly powdered with Deltamethrin 25 CE on subdosage of 1 ml of the control of the damage of *D. speciosa* larva to Baraka potato roots in waste area of Caruaru, Pernambucos state, in Brazil. The crops of june middle and of june end were completely unfavorable to the control of the damage of *D. speciosa* larvae to Baraka potato roots in waste area of Caruaru, Pernambucos state, in Brazil. The crops of june middle and of june end were completely unfavorable to the control of the damage of *D. speciosa* larvae to Baraka potato roots in waste area of Caruaru, Pernambuco state, in Brazil.

Index terms: Diabrotica speciosa, damage, trap crop, pigeon pea, deltamethrin

[0263] A KAOLIN-BASED PARTICLE FILM DETERS FEEDING AND OVIPOSITION BY THE WEEVIL DIAPREPES ABBREVIATUS

S. L. Lapointe, USDA-ARS, U.S. Horticultural Research Laboratory, 2001 South Rock Road, Ft. Pierce, FL 34945, USA, E-mail slapointe@ushrl.ars.usda.gov

Broad-nosed weevils are pests of citrus and ornamentals throughout the Caribbean and peninsular Florida in the USA. Most notable of these is Diaprepes abbreviatus (L.), first discovered on the mainland U.S. at Apopka, FL in 1964. This species most probably originated on Puerto Rico where is causes considerable damage to citrus and other crops Females of this group place their eggs with an adhesive in a single layer in a niche most often fabricated by juxtaposing leaves. The options currently available to citrus growers in Florida for control of root weevils include entomopathogenic nematodes, oil sprays, and adulticides, none of which provide reliable, economically viable control. Recent interest in particle films for control of plant pathogens and insect pests has led to the development of experimental formulations of kaolin, an inert silicate, for foliar applications. A hydrophilic formulation of kaolin was tested in a screenhouse for its effect on the behavior of D. abbreviatus. Feeding by adults on treated foliage was reduced by 75 - 84% compared with adults fed untreated foliage. No direct insecticidal activity was detected. Oviposition was completely suppressed on treated foliage. While females oviposited >19,000 eggs during 2 trials on untreated foliage, no egg masses were found on foliage treated with the kaolin formulation. Studies under greenhouse conditions have determined a dose-response function that quantifies the amount of kaolin residue on leaves required to elicit the behavioral avoidance by D. abbreviatus. These data indicate potential for kaolin as a barrier to oviposition in citrus groves and may prove to be an economically viable and environmentally sound component of an integrated approach to control of D. abbreviatus and related root weevils.

Index terms: Diaprepes abbreviatus, kaolin, particle film, ovipostion, citrus.

[0264] APPLICATION OF BIODEGRADABLE, SUGAR-STARCH SPHERES TREATED WITH REDUCED-RISK INSECTICIDES FOR MANAGEMENT OF KEY *RHAGOLETIS* SPECIES

O.E. Liburd, L.S. Stelinski, & M. R. McGuire¹, Department of Entomology, Center for Integrated Plant Systems B-9, Michigan State University, East Lansing, MI 48824, USA-¹National Center for Agriculture Utilization Research, Bioactive Agents Research Unit, Agricultural Research Service, USDA, Peoria, IL 61604, USA.

The apple maggot, *Rhagoletis pomonella* (Walsh), and the blueberry maggot, *Rhagoletis mendax* Curran, are the key late-season pests of apples, *Malus domestica* Borkhausen, and blueberries *Vaccinium* spp. in northeastern and mid-western United States and southeastern Canada. Current methods of control involve 3-5 applications of insecticides, primarily organophosphates. In an attempt to develop nonorganophosphate alternatives for control of apple maggot and blueberry maggot, the effectiveness of baited, biodegradable, sugar-starch spheres treated with 7.4 (Al) indecloprid (Provado® 1.6 F) [Bayer, Kansas, City, MO] and (2) an untreated (control) sphere, were evaluated in several unsprayed apple orchards and blueberry plantings. In 1999, in addition to evaluating sphere effectiveness, three potential sphere deployment strategies were evaluated for efficacy in suppressing apple maggot and blueberry maggot files. These included (1) perimeter deployment of single spheres, (2) perimeter deployment of sphere clusters and (3) uniformed, grid, deployment strategy. Our standard inidacloprid treatment (evaluated in 1998) was also compared with a "new" neo-nicotinoid insecticide, thiomethoxam (Actara®) [Novartiis Crop Protection Iuc., Greensboro, NC] 2 % (Al) in 1999. *Rhagoletis* files were sampled twice per week on stickly plexi-glas panes placed horizontally 30 cm beneath biodegradable spheres. Our 1998 results indicated that significantly (P < 0.05) more *R. pomonella* and *R. mendax* flies were tecorded on plexi-glas panes placed unterated spheres. Also, the mean time *Rhagoletis* flies spent alighting on inidacloprid treated spheres was significantly longer than the time spent on untreated spheres sequent with panes placed under treated with our sphere deployment trails and there were no significant differences among the treatments evaluated. In our study of reduced risk insecticides, significantily more *R. pomonella* flies were caught on plexi-glas panes placed beneath inidacloprid-treated spheres compare

[0265] A GASOLINE-DRIVEN SUCTION APPARATUS FOR SAMPLING BLISSUS ANTILLUS (HEMIPTERA: LYGAEIDAE) AND OTHER ARTHROPODS IN PASTURES

J. O. G. de Lima¹ & N. L. Mendes², ¹Laboratório de Proteção de Plantas e ²Laboratório de Materiais Avançados, Univ. Estadual do Norte Fluminense, Av. Alberto Lamego 2000, 28.015-620 - Campos dos Goytacazes, RJ, Brazil. E-mail joscar@uenf.br.

In 1999, chinch bugs collected in pastures in several areas of Brazil were identified and confirmed as *Blissus antillus*. Previously, they had been identified as *Blissus leucopterus*. Since 1980 these chinch bugs have been damaging the pastures of *Brachiaria arrecta* and *B. purpuracens* growing in soils with high moisture content in the state of Rio de Janeiro. In a study regarding the preference of this insect for pastures, we employed a plastic tray and the "D-VAC" for sampling the bugs, and both methods presented several difficulties. Bending and shaking the plants over the tray cannot be done in low grasses (<20 cm), and is not so efficient and as fast as the sampling done with the "D-VAC". On the other hand, the "D-VAC" machine has considerable weight, is difficult to carry, is expensive, and presents frequent mechanical problems. In search of a more efficient cupument, we converted a grass-cutting machine (carried over the shoulder, when in operation), manufactured by Still, in a suction equipment for sampling *B. antillus* and other arthropods. In a field test, in a pasture of *B. arrecta* (height <25 cm) we compared its capture efficiency with that of the "D-VAC" (a motorized knapsack sprayer, manufactured by Hatsuta and converted into a suction sampler, with the general design of the American "D-VAC"). With the new equipment, we captured significantly larger numbers of arthropods, belonging to seven groups separated according to their size, number and capture frequency: I. *B. antillus*, 2. Hymenoptera (mainly Fornicide), 3. Acari, 4. Coleoptera, 5. Hemiptera (mainly Auchenorrhyncha), 6. Collembola, and 7. Araneae. It became evident that the new equipment has excellent potential for sampling arthropods in pastures, and may be an appropriate alternative for the traditional "D-VAC", because of its efficiency, low cost and lightness.

Index terms: Suction sampler, D-VAC, grassland

[0266] CHEMICAL CONTROL OF THE TOBACCO FLEA BEETLE

D. Link, Centro de Ciencias Rurais -UFSM. Predio 42. Santa Maria, RS. 97105-900 Brazil. E-mail: <dlink@ccr.ufsm.br>

The tobacco flea beetle, *Epitrix fasciata* (Coleoptera: Chrysomelidae) damage the tobacco leaves, decreasing the commercial value. The efficiency of chemical control of this pest on tobacco plants was studied in Vera Cruz county, State of Rio Grande do Sul, Brazil, during 1998/99 growing crop season. Lambdacyalothrin at 5.0g and 7.5g a.i./ha, CS and EC formulations; Acephate PS at 750g a.i./ha, and Imidacloprid WG at 70g a.i./ha, were sprayed on tobacco plants. Lambdacyalothrin, at two dosages and formulations, was efficient to control the tobacco flea beetle, reducing more than 82% the population until three weeks. Acephate and Imidacloprid reduced more than 64% until two weeks. Index therms: cultivated plant, pest control, *Epitrix fasciata*, efficave.

V. S. Lins & H. R. Santos, N.C.A, CEUD, Univ. Federal de Mato Grosso de Sul, C. Postal 533. Dourados - MS - BR, CEP 79825-070, E-mail: vilins@hotmail.com

IN GRAINS OF FIVE CULTIVATE OF CORN

[0267] NATURAL AND ARTIFICIAL INFESTATION OF THE SITOPHILUS SPP

The present work has as objective evaluates the damages provoked by the *Sitophilus* spp, in 5 corn varieties (AG612, AG5011, AG8012, AG1051 and Br473) in laboratory conditions, with the temperature accompaniment and humidity relative atmosphere. The research was constituted of 2 tests: Natural Infestation, represented by the 5 varieties supra mentioned, slightly infested in field; constituted of 5 treatments of 4 repetitions, totaling 20 portions. In the Artificial Infestation was used AG612 and AG5011, being established 4 treatments of 4 repetitions, being 2 of these treatments infested with 2 weevils and the other ones 2, with 8 weevils, totaling 16 portions. For each portion 200g of corn were placed in glass flasks (500ml) with mouth it releases, drained cover and prohibited with screen of steel with mesh 5mm to avoid the escape of the insects. All the treatments were them cultivate more infested; and AG5011 and AG8012 the fewer infested, therefore the most resistant. Test-2, it was verified that there was not significant difference among the two varieties. Humidity and temperature didn't influence in the population growth of the weevils.

Key - Words: Curculionidae, Maize Weevil, Plague, Zea Mays, Stored Products.

[0268] CONTROL OF ORTHEZIA PRAELONGA IN WEST INDIAN CHERRY, MALPIGHIA GLABRA USING FORMULATIONS AND THREE APPLICATION METHODS OF THIAMETHOXAM

R. Barros¹, **M. D. R. O. Silva¹ & S. Araújo¹**, ¹Fitossanidade, Univ. Fed. Rural de Pernambuco, Av. Dom Manoel de Medeiros S/N, Dois Irmãos 52171-900 Recife, PE. E-mail: rbarros@nelore.npde.ufrpe.br.

The scale Orthezia praelonga (Homoptera: Orthezidae) had been recorded recently as a serious pest in West Indian Cherry (WIC) Malpighia glabra growing area in Brazil. In Pernambuco, Brazil WIC population has been verified seasonally from July to November. The lack of insecticides registered by Agricultural Minister for WIC has impeded the use of this method for *O. praelonga* and others insects pests attacking WIC. Thus, this work aimed to evaluate the efficacy of Thiamethoxam for O. praelonga control in WIC. The experiments were set up in a WIC orchard five years old, spaced 3.5 x 3.5 m between and within line. The experiment was carried out in a randomized complete block with 8 treatments and 4 replications composed by two plants each. The treatments consisted by: I - Control; II - Foliar spray (Actara 250 WG) 1g/1.2 L water/plant; III - Foliar spray (Actara 250 WG) 2 g/1.2 L water/planta; IV - Stem spray (Actara 250 WG) 1 g/0.5 L water/planta; V - Stem spray (Actara 250 WG) 2 g/0.5 L water/plant; VI - Soil placement (Cruiser 700 WS) 2 g/plant; VII - Soil placement (Cruiser 700 WS) 4 g/plant and, VIII -Soil placement (Cruiser 700 WS) 6 g/plant. For foliar and stem treatments were used a costal sprayer 40 lbs/pol² and a trigger-pump 1.0 L volume, respectively. Thiamethoxam soil placement was applied by distributing granules in a semi-circle furrow 5.0-cm depth distant = 50% plant canopy projection from plant base. The evaluations were carried out at 9, 18, 27, and 36 days after application for all treatments. Each evaluation consisted of 16 leaves per replication-plant. The samples were took up to laboratory and the number of scale alive/leaf was counted using a stereo microscope and recorded. Application of Actara 250 WG 2 g/1.2 L water/plant through foliar spraying promoted efficiency of 60.7% in the first evaluation and maintained inferior to 45% in following evaluations. The treatment through stem application and soil placement showed efficacy inferior to 52% and only 27 days after application. Based on our results Thiamethoxam applied by foliar spraying, stem application and soil placement did not show an efficient control of O. praelonga in WIC orchard. However, investigation with higher Thiamethoxam doses than those used in this study should be carried to determine an efficient control method for this important pest in WIC

[0269] EGYPTIAN ALFALFA WEEVIL (IIYPERA BRUNNEIPENNIS) CONTROL AND WATER QUALITY

<u>R. F. Long</u>, Univ. of CA Cooperative Extension, 70 Cottonwood St., Woodland, CA 95695 Email: rflong@ucdavis.edu

The organophosphate insecticides Chlorpyrifos (Lorsban® and Lock-On®) and Imidan® (Phosmet) moved offsite from alfalfa fields via irrigation runoff at levels high enough to kill the aquatic test invertebrate *Ceriodaphnia*. The Pyrethroids (Warrior® and Baythroid® were not detected in the alfalfa irrigation tailwater samples (as measured by toxicity to *Ceriodaphnia*). Efficacy trials for pest control showed that the pyrethroids controlled the Egyptian alfalfa weevil *Hypera brunneipennis* as well as the standard organophosphate treatments; however, they may cause aphid outbreaks. Costs for the pyrethroids are the same or lower than the organophosphates.

Index terms: Pest control, organophosphates, pyrethroids, aquatic toxicity

[0270] OCCURENCE OF THRIPS ON NIAGARA TABLE GRAPE AND ITS CONTROL WITH THE INSECTICIDES THIACLOPRID AND METHIOCARB ASSOCIATED WITH *METARIHIZIUM ANISOPLIAE*

<u>R.B. Lopes¹</u>, M.A. Tamai¹, S.B. Alves¹, S. Silveira Neto¹, & S. Salvo², ¹Dept. Entomologia, Fitopatologia e Zoologia Agrícola, ESALQ/USP, Pádua Dias Ave., 11, P.O. Box 9, Piracicaba, SP, 13418-900, Brazil, E-mail rblopes@carpa.ciagri.usp.br; ²Bayer S.A., Domingos Jorge St., 1100, São Paulo, SP, 04779-900, Brazil.

Thrips are reported as important pests on table grapes in United States and several countries of Europe. Damage caused by thrips was observed in table grape (Niagara) crop in Limeira-SP, and a sample was send for identification to D.S. R.C.Monteiro in USA. This specie probably belows in genus Frankliniella. During the blooming period, high populations were observed feeding on pollen and small berries. The symptoms of the attack are more visible after the development of the berries and are characterized by dark scars and suberized surface on berries, sometimes causing the berry to crack of seed to prolapse. The effect on thrips population of one application of the insecticides Calypso 480SC (thiacloprid) or Mesurol (methiocarb) associated or not with the entomopathogenic fungus Metarhizium anisopliae was evaluated during the blooming period. For evaluation of thrips damage on fruits, the treatments were applied three additional times, 7, 14 and 21 days after the first application. The treatments were: a) M. anisopliae (strain 1037) 1x107 conidia/ml; b) Calypso 20ml/1001; c-d) Mesurol 100 and 150ml/100 l; e) Mesurol 100 ml/100 l + M. anisopliae 1×10^7 conidia/ml. Only Mesurol, associated or not with the fungus was effective in reducing thrips infestation, and no phytotoxic damage was observed. The efficiency of Mesurol 150ml/100l and the insecticide associated with the fungus for the control of the thrips population was 84.2 and 95.5%, respectively. In both cases, there was a reduction of approximately 70% in the number of berries with scars symptoms. For control of thrips on table grapes, chemical insecticides associated or not with M. anisopliae should be applied during at the blooming period of the crop. Index terms: chemical control, fungi, microbial control, thrips.

Symposium and Poster Session

[0272] COMPARATIVE PARASITOID GUILD ANALYSIS OF *RACHIPLUSIA NU* (LEPIDOPTERA: NOCTUIDAE) LARVAE IN DIFFERENT PLANT HABITATS

M.G. Luna¹ & <u>N.E. Sánchez²</u>, ¹Dept. Ecol. & Evol. Biol., UCI, 321 Steinhaus Hall, Irvine CA 92697-2525, USA; ²Centro de Estudios Parasitológicos y de Vectores, Univ. Nacional de La Plata-CONICET, 2 Nº 584 (1900) La Plata, Argentina, E-mail cepave@museo.fcnym.unlp.edu.ar

Rachiplusia nu is a pest of crops and it is also found on non-crop vegetation in Argentina. The objective of this study was to examine the structure of parasitoid guilds of R. nu larvae in 4 pesticide-free crops (soybean, sunflower, and mixed clover and alfalfa pastures) and in 2 non-agricultural legume patches (Melilotus alba and Galega officinalis) in the Pampean region. Through larvae sampling, from 1992 to 1998, and laboratory data plus the known biology of the species recorded during the study, host abundance. parasitoid species composition and richness, number of parasitoid guilds per plant species, and levels of parasitism, were determined. Highest R. nu population abundances were found in crops. All parasitoid species were primary endoparasitoids, except for 2 secondary endoparasitoid species registered in sunflower crops, and they belonged to Hymenoptera and Diptera orders. R. nu larvae hosted the highest number of parasitoid species in soybean (11) and the smallest in non-crops (3). Also, differences were found in the representation of parasitoid guilds among the six plant habitats. The number of parasitoid guilds ranged from 4 in sunflower and soybean crops (egg-prepupal endoparasitoid, early larval endoparasitoid, late larval endoparasitoid, and larval-pupal endoparasitoid) to 2 for G. officinalis patches (early larval endoparasitoid and late larval endoparasitoid). Levels of parasitism of R. nu were higher in crop than in non-crop habitats. Finally, it was observed that, in general, parasitoid species belonging to guilds that attack earlier host stages had higher percent of parasitism than those attacking later developmental stages. Results of this study are consistent with the host abundance hypothesis, which is among the key ecological variables determining parasitoid community structure.

Index terms: hymenopteran parasitoids, dipteran parasitoids, parasitoid community structure, agricultural habitats, natural habitats.

[0271] DEVELOPMENT OF AN EXTENSION-BASED SAMPLING SERVICE FOR COTTON APHID FUNGUS, *NEOZYGITES FRESENII*

<u>G. M. Lorenz¹</u>, D. C. Steinkraus², G. O. Boys² & D. R. Johnson¹, ¹Cooperative Extension Serv., Univ. of Arkansas, P.O. Box 391, Little Rock, AR 72203, USA, E-mail glorenz@uaex.edu, ²Dept. of Entomology, Univ. of Arkansas, Fayetteville, AR 72701, USA.

The cotton aphid, Aphis gosypii, has become a major pest of cotton in recent years due to insecticide resistance and behavioral changes. The cotton aphid fungus, *Neozygites fresenii*, is the most important natural enemy of the cotton aphid. Frequently in late-June through mid-August, the aphid fungus is very effective in reducing aphid populations. Since 1993 the cotton aphid fungus has been utilized in an IPM program in Arkansas and has since expanded to Louisiana and Mississippi since 1997. The objective of the program has been to sample aphid populations throughout the season, determine the percentage of the natural control provided by the fungus. The information is provided to consultants, growers, and Extension personnel to help make decisions on whether or not additional control tactics are necessary. Research in Arkansas has shown that declines in cotton aphid populations due to the cotton aphid fungus are widespread and somewhat predictable, and often result in rapid aphid population reductions. Generally, once 15% of the aphid population is infected a decline will occur in about seven days. When this level of infection is reached it is more economical and advantageous for growers to let the fungus reduce the aphid population than to apply an insecticide. With this in mind a service to diagnose field-collected aphids was developed where sample results can be communicated via internet, fax, or telephone within 24 hours of sampling. The objective of this project has been to provide cotton growers, consultants, and Extension personnel with timely information on the status of this valuable natural enemy that can be used to improve cotton IPM programs.

Index terms: Aphis gosypii, IPM, natural enemy

[0273] LIFE-TIME ACTIVITY BUDGET OF MANGO (MARULA) FRUIT FLY, CERATITIS COSYRA, AND ITS RESPONSE TO ATTRACTANTS

<u>S. A. Lux¹, N. Zenz¹ & P. Nemeye¹, ¹ International Centre of Insect Physiology and Ecology, Nairobi, Kenya, P.O. Box 30 772, s.a.lux@icipe.org, Nzenz@icipe.org, Pnemeye@icipe.org</u>

Based on our surveys conducted in many African countries, C. cosyra has been found to be one of the major mango pests throughout Sub-Saharan Africa. This very little known fruit fly, indigenous to Africa, does not respond to most standard commercially available attractants, hence is difficult to manage. Over 100 males and females were observed in laboratory conditions from 5:00 AM till 11:00 every day, starting from their emergence till death. Their longevity and dynamics of life-time behaviours were described. In addition, response of males and females to the standard, commercially available attractants, as well as several other non-commercial attractants was evaluated. Differences in the response, according to the sex, age, maturity and mating status were described.

[0274] THIAMETHOXAM ON THE CONTROL OF SUGARCANE BORER DIATRAEA SACCHARALIS (LEP., CRAMBIDAE)

N. Macedo & M.B.S. Campos, Centro de Ciências Agrárias/UFSCar, Araras, SP.cx.p.153, CEP 13600-970. E-mail: newmac@cca.ufscar.br.

This experiment aim to evaluate in field conditions the effects of different dosages of Thiamethoxam (commercial product ACTARA 10 G) on larvae of sugarcane borer, *Diatraea saccharalis*, in the plant infestation phase. The experiment was installed at Araras, (SP), in 20.01.99, on plant cane 9 months aged, RB 855453 variety. The parcels were infested by hand with 2^{nd} and 3^{rd} larval instars reared in laboratory. The treatments were: $T^1 = 150$ g a i./ha; $T^2 = 200$ g a i./ha; $T^3 = 250$ g a i./ha and T^4 = check, installed in bands, split plot design, each sub-parcel (a and b) constituted of one stool with 5 stalls, 6 replicates. Chemical was applied by hand, on the soil surface, by side of sugarcane row. Six weeks after infested stalls were collected, longitudinally opened and the damage of the pest was evaluated by means of a note scale as follows: small (S) = 1; medium (M) = 2 and great (G) = 3. The smallest damage occurred on infested stalls with 2^{nd} larval instar, treated with 200 and 250 g ai./ha (T^2a e T^3a) and 3^{rd} larval instar treated with 250 g, ai./ha (T^3b). It was concluded that Thiamethoxam applied on the soil, in the dosage of 250 g ai. or ormore/ha can control infesting first larval instars of *D. saccharalis* on sugarcane. Index terms: *Diatraea saccharalis*, sugarcane borer, control, Thiamethoxam

[0275] OCCURRENCE OF DEFOLIATOR CATTERPILARS (LEPIDOPTERA) ON EUCALYPTUS IN THE REGION OF LAVRAS-MG, BRAZIL

W. J. M. S. Maia¹ & V. H. P. Bueno¹, 1. Depto. de Entomologia, Univ. Fed. de Lavras, Caixa Postal 37, Lavras, MG, 37.200-000, Brasil, E-mail wimsmaia@ufla

The forest system of *Eucalyptus* spp. stands out as one of the main factors of increase of the planted area, about 60%, of reforestation in Brazil. In Minas Gerais (southest region of Brazil), this ratio reach 88%. But in parallel with that, there was also an increase in the number of insects associated with the eucalyptus trees in the country. In this context, the defoliator catterpillars, which along the last three decades have been taking over increased importance due their persistence and increase of the damage. This work was designed to determine the occurrence of lepidopterous associated with *Eucalyptus* spp. in the region of Lavras, Minas Gerais State. A number of 187 weekly collections were accomplished over the area (about 10 ha) from August 1995 to March 1999, with the use of a "Luiz de Queiroz" model light trap, placed at 2.0 meters height over the soil level, and working from 17 to 07 h. The occurrence of the species *Eupseudosoma aberrans* Schaus, 1905 (Arctiidae); *Apatelodes sericea* Schaus, 1896 (Eupterotidae); *Sabulodes caberata caberata* Guenée, 1857 (Geometridae); *Sarsina violascens* Herrich-Schaeffer, 1856 (Lymantriidae); *Adeloneivaia subangulata* (Herrich-Schaeffer, 1855) Travassos, 1940; Automeris illustris Walker, 1855; *Dirphia albolinea; Dirphia triangulatum* e *Eacles imperialis magnifica* Walker, 1855; November/95, March/97, June/97, October/96, March/98, March/96 and October/96, respectively for these species collected.

[0276] RESULTS FROM 3 YEARS OF BWACT USE IN THE NATIONAL BOLL WEEVIL SUPRESSION PROGRAM OF PARAGUAY

O. G. Manessi, Plato Industries, Inc., Ttc. Alfredo Nuñez 250, Asunción, Paraguay Email: platopy@highway.com.py.

Cotton in Paraguay is the main "cash" crop for more than 100,000 small family farms. The Paraguayan system of cotton production is unique and currently provides employment for approximately 1,000,000 people (20% of the country's population); it generates an annual "cash flow" of US\$ 400,000,000. Even with the social and economic importance of this crop, from 1990/91 to 1996/97 the planting decreased 80%. One of the main reasons for this reduction was the arrival of the boll weevil (Anthonomus grandis); it entered from Brazil and quickly established in 90% of the production zones, causing an average increase in the production cost of 35% and an average decrease in the cotton production of 40%. In the 1997/1998 cotton crop, the Ministry of Agriculture designed and started a "NATIONAL PLAN TO REACTIVATE COTTON" (NPRC); as an integral part of the NPRC, the boll weevil program was established and was based on the installation of Boll Weevil Attract and Control Tubes (BWACT or TMP or TMB) and stalk destruction. The objectives were, with a low cost per hectare to reduce the boll weevil population and avoid economic damage during the cotton crop cycle and to increase cotton production with lower production costs. The Program of BWACTs is "preventive" in approach and is based on the behavior and biology of the boll weevil in Paraguay. The use of the BWACT at planting protects the crop for about 50 days without spraying and this provides for a build-up of parasites and predators that normally continue to provide for boll weevil control during the remainder of the critical fruiting cycle. The "end of crop" BWACT installation drives the population to a low level and subsequent natural mortality forces the weevils to a lower level for the benefit of a next crop. The methodology of use at the end of the cotton crop is the destruction of stalks and the installation of 1 BWACT per hectare and at cotton planting, the installation of 1 BWACT per hectare. The use of BWACTs is very adaptable to the production system of small producers and it is not harmful for the environment or the small grower. The Program has a low cost of about US\$22/ hectare/ year. After 3 years of the BWACT Program, the boll weevil population has been decreased by more than 85% and there has been a decrease in the quantity of insecticide for boll weevils from 6-8 applications per crop to less than 1 in the cotton crops of 1998/99 and 1999/2000. Equally important, there was a decrease in production losses from boll weevil damage of about 40% in the 1996/1997 crop to damage levels of no economic importance in the 1998/99 and 1999/2000 crops. Results from the 3 year program will be presented in detail.

Index terms: Anthonomus grandis, boll weevil control, cotton

[0277] EVALUATION OF SYSTEMIC INSECTICIDE THIAMETHOXAN ON THE VEGETATIVE GROWTH OF DRY BEAN PLANTS

D. S. Martins¹ & M. J. Fornazier¹, ¹EMCAPER- Empresa Capixaba de Pesquisa, Assistência Técnica e Extensão Rural-Rua Afonso Sarlo, 160, Bento Ferreira, Vitória/ES, CEP 29052-010, Brazil, E-mail davidmartins@emcaper.com.br.

Different insect pests are associated to bean crop with the main importance for the happening in early stages, that cause directly losses on the plants development and growth or indirects losses as virus vectors with reduction the crop yield. The period from bean seed germination until flowering is the most susceptible to the crops needing keep plants free of the pests or maintain pests populations in acceptable level. The plant metabolism can be altered by some systemic insecticides that cause benefic or detrimetal effects on plants when used on the control of the pests. The effect of systemic insecticide thiamethoxan on the growth of dry bean plants of cv. Xamego (black bean) was studied under field conditions. A randomized complet block design experiment with 7 treatments and 4 replications was carried out during the rain season on the highland Region of Espírito Santo State. Each plot was formed by 6 rows of 3.0m apart and 0.5m into row, with 12 seeds/m. Thiamethoxan treatments were: Actara 250 WG at 100, 125 and 150g a.i./ha, spouted in the soil on botton the plants 3 days after seeds germination, and irrigated immediately; Cruiser 700 WS at 70, 140 and 210g a.i./100kg seeds as seed treatment; and untreated control. At 10, 17, 24 and 38 days after germination were evaluated: number of leaves; plant height; dry weight of leaves, stems and roots; number of Rhizobium nodules; and number of pods, of 5 plants harvested by plot. The experiment was irrigated and sprayed with methamidophos insecticide and tebuconozole fungicide to uniformize and avoid pests and diseases interference at the experimental area. There were no significant differences to the numbers of leaves, Rhizobium nodules and pods. Plants treated with the two thiamethoxan formulations had greater in dry weight and plant height, comparatively to the untreated plants, showing a benefic effect caused by the thiamethoxan, that was more evident with Cruiser 700 WG formulation on the early stages of plant development. With the growth of plants, the difference of this effect, among the two formulations, was decreasing until to same value. At flowering stage, excluding the plant height, was not observed significantly difference on treated and untreated plants. All doses of the both formulations, in growth early stages, were superior to the untreated plants, but the best plant growing and development was observed on the intermediate and highest doses recomended (Cruiser 700 WS at 140 and 210 g a.i./100kg of seeds and for Actara 250 WG at 125 and 150 g a.i./ha.)

Index terms: Phaseolus vulgaris, development, tonic effect

[0278] EVALUATION OF TWO COFFEE SPECIES AS HOST OF FRUIT FLIES (DIPTERA: TEPHRITIDAE) IN THE ESPÍRITO SANTO STATE, BRAZIL

D. S. Martins¹, M. M. Teixeira¹ & A. Malavasi², ¹EMCAPER-Empresa Capixaba de Pesquisa, Assistência Técnica e Extensão Rural - Rua Afonso Sarlo, 160, Bento Ferreira, Vitória/ES, CEP 29052-010, Brazil, E-mail davidmartins@emcaper.com.br; ²Departamento de Biologia, Instituto de Biociências-USP, Cx. Postal 11.461, São Paulo/SP, CEP 05422-970, Brazil.

The coffee cultive in the Espírito Santo State is realized with two coffee species: Coffea arabica, developped in the region with cold weather temperature, ranging from 19 to 21°C, and altitude more than 400 m over level sea, where there is culture of temperate and subtropical fruit plants too; and Coffea canephora (robusta) cultivated in warm weather conditions, ranging from 22 to 26°C, and altitude lowest that 400m, where are planted the tropical fruit plants. The coffee is host to different insect species; of this, there is the flies Ceratitis capitata and Anastrepha fraterculus, the most important and damage brazilian fruits. Despite this flies didn't cause direct damages to the coffee berry, because they eat fruit mesocarp only, the coffee plant is important to host sucession, that is the great process for the maitainance and development of fly populations. The objective of this research was to evaluate C. arabica and C. canephora as host and as natural repository of populations of th fruit flies. The data were obtained from may to june/1998, in 120 farms (60 of C. arabica and 60 of C. canephora), from 22 counties, seven of them cultivate only the C. arabica, nine only the C. canephora and six cultivate both species. The fruit samples of 0,51 "berry" in post harvest stage were immediately transported for laboratory; the flies emerged were identificated at Biology Departament of Bioscience Institute/University of São Paulo-USP. 19,5 kg (13.669 fruits) of arabica coffee and 18,3 kg (26.067 fruits) of robusta were observed. All C. arabica counties were infested with fruit flies and 98,3% of the farms had fruits infested, that originated 2.612 pupae. The C. *canephora* had 11,7% of the farms infested, originating only 9 pupae. The infestation index in *C. arabica* was 0,19 pupae/fruit and 131,23 pupae/kg of berry. In *C. canephora* was 0,0004 pupac/fruit and 0,49 pupae/kg of berry, respectively 475 and 268 less than C. arabica. From the 1.273 fruit flies obtained, 99,3% were originated of the 'arabica', being 76,6% C. capitata and 26,3% A. fraterculus. It was obtained also, an example of A. serpentina in C. canephora. So, it is concluded that: C. arabica had a major predominance as host of fruit flies, being of this C. capitata more frequent than A. fraterculus; C. canephora, on the contrary of C. arabica, for host succession, was showed very unfavorable to the fruit flies, so, less important as natural repose place of tephritid populations, at regions where this coffee specie is cultivated.

Index terms: Coffea arabica, Coffea canephora, hosts, Ceratitis capitata, Anastrepha fraterculus, Anastrepha serpentina

[0279] HOST PLANTS OF FRUIT FLIES (DIPTERA: TEPHRITIDAE) IN THE STATE OF ESPÍRITO SANTO, BRAZIL

D. S. Martins¹, K. Uramoto² & A. Malavasi², ¹EMCAPER-Empresa Capixaba de Pesquisa, Assistência Técnica e Extensão Rural - Rua Afonso Sarlo, 160, Bento Ferreira, Vitória/ES, CEP 29052-010, Brazil, E-mail davidmartins@emcaper.com.br; ²Departamento de Biologia, Instituto de Biociências-USP, CX. Postal 11.461, São Paulo/SP, CEP 05422-970, Brazil.

Trapping surveys of tephritid fruit flies have been systematically conducted since 1993 in the state of Espfrito Santo, resulting in 25 species of Anastrepha reported as well as Ceratiis capitata. Nevertheless, there is a lack of knowledge regarding the host plants of most species as well as the species that attack cultivated fruits. To fill this gap, native and introduced plant species were collected in several locations. Samples of freshly fallen fruits and fruits randomly picked from the trees were taken. A total of 29 plant species, belonging to 18 genera and 12 families were infested by fruit flies. Nine species of the family Myrtaceae were infested by seven species of Tephritidae. Anastrepha fraterculus, C. capitata, and A. obliqua had the broadest host range, infesting fruits of 19, 16, and 12 species. A total of six tephritid species were found associated to guava (*Psidium guajava*, Myrtaceae), and four to *Pouteria caimito* (Sapotaceae). The data obtained in this survey supplement the host plant list published by Zucchi (2000): the family Caricaceae is reported as a host for Anastrepha fraterculus in Brazil and 19 new records of host fruit tephritid associations are provided:

Index terms: Anastrepha spp., Ceratitis capitata, hosts, survey

[0280] SPATIAL DISTRIBUTION OF ACROGONIA SP., DILOBOPTERUS COSTALIMAI AND ONCOMETOPIA FACIALIS IN BRAZILIAN CITRUS

W. I. Maruyama¹ & J. C. Barbosa², ¹Depto: Fitossanidade - ²Depto Ciências Exatas, Univ. Estadual Paulista (UNESP), Via de Acesso Prof. Dr. Paulo Donato Castellane, s/n. Jaboticabal, São Paulo State, Brazil, 14870-000. E-mail: maruyama@fcav.unesp.br, jbarbosa@fcav.unesp.br. ¹Studentship and financial support from Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP).

Around 22% of orange tree in São Paulo State are infected by Xyllela fastidiosa bacterium, responsable for disease CitrusVariegated Chlorosis (CVC), transmited by Cicadellidae. The objetive of this work was to determine the spatial distribution the vectors Acrogonia sp., Dilobopterus costalimai and Oncometopia facialis. The capture of this insects was performed in orange area with yellow sticky traps, that were located at each plant and ordered in a grade sampling of 100 points in aproximaly 1 ha, at heigth 1,5 m under soil. It was realized sampling on 06/11, 20/11 and 04/12/1999. The statistical analysis was done by using 3 insect vectors and processing the total number of them in one tree (sum 4 traps/plant), total among line (sum 2 traps turn to line), and total among trees (sum 2 traps turn among trees). Vectors average collected at traps were in first, second and third sampling 1.85, 1.76 and 3.03 to total on plant, 0.77, 0.89 and 1.39 total among line, 1.08, 0.87 and 1.64 total among plants. Only the total on plants in the first sampling and total in line second sampling showed random distribution, with Morisita index 1.105 and 1.096 respectively, and showed agreement on Poisson's distribution. The other results are in agreement with negative binomial distribution, with Morisita's index among 1.160 to 1.504, with second sampling in the line (k=4.0) and the total on third sampling (k=1.30)showed behavior aggregation, and the others aggregation was moderate (k>5) with tendency to aleatory. Also we have observed that as the average population improved occourred a tendency to improve aggregation.

Index terms: Cicadellidae, Morisita-index, Citrus-Variegated-Chlorosis.

[0281] PHYTOPHAGOUS PENTATOMIDS ASSOCIATED WITH DIFFERENT LEGUMINOSAE IN PROVINCE OF BUENOS AIRES, ARGENTINA

G. E. Marzorati & G. Liljesthröm, CEPAVE Calle 2 Nº 584 (1900) La Plata. Argentina. E-mail cepave@museo. fcnym. unlp. edu. Ar.

Certain pentatomids are serious pests on different leguminosae cultures. In agroecosystems in the localities of Magdalena and La Plata, cultivated (Medicago sativa, Glycine max and Trifolium repens) and pure patches of spontaneous (Melilotus sp. and Galega officinalis) leguminosae are present. In this study, the densities and spatial distribution of phytophagous pentatomids on different leguminosae patches were analysed between October 1997 and January 2000. Every fifteen days 3 transects (100 m each) were distributed randomly in the 5 leguminosae, and the number of insects recorded. The Shannon index of diversity H, and the Levins niche amplitude index B, were calculated seasonally. M. sativa and T. repens were cut 3 times during the year and fundamentally remained in vegetative stage; G. max was in vegetative stage in summer and reproductive stage in autumn and Melilotus sp. and G. officinalis were in vegetative stage in early spring and in vegetative and reproductive in summer and autumn. All pentatomids were found on the different leguminosae in all seasons and the total number and percentage were: Nezara viridula (n=624; 57.3%), Piezodorus guildinii (n=301; 27.6%), Dichelops furcatus (n=104; 9.5%) and Edessa meditabunda (n=60; 5.5%). In stping H was higher on M. sativa (H=1.24) and Melilotus sp. (H=1.09); in summer on M. sativa (H=1.25) and T. repens (H=1.21), and in autumn in G. officinalis (H=0.88) and T. repens (H=0.79). N. viridula was concentrated on G. officinalis in the spring, and during the summer and autumn, it had a similar relative density on all leguminosae. P. guildinii and E. meditabanda were concentrated on M. sativa during the spring and on T. repens in summer and autumn. D. furcatus was concentrated on G. officinalis and M. sativa in spring, on T. repens in summer and on T. repens and G. officinalis in autumn. B was maximal for D. furcatus in summer (B=3.03) and spring (B=2.25) and for N. viridula in autumn (B=2.63). Results from these experiments show that pentatomid spatial concentration changes seasonally with M. sativa, T. repens and G. officinalis being the 3 most densely populated by the insects, the first one in spring, the second one in spring and summer and the third one in summer and autumn.

Index terms: Phithophagous pentatomids, pest, leguminosae

[0282] THE COMMON PISTACHIO PSYLLA, THE MAJOR PISTACHIO PEST IN IRAN

M.R. Mehrneiad, Pistachio Research Institute, P. O. Box 77175.435, Rafsanjan, Iran.

The common pistachio psylla, Agonoscena pistaciae is the most serious insect pest of cultivated pistachio trees and is distributed throughout all the pistachio-producing regions in Iran Usually the population rapidly increases from early spring. However, the presence of high population densities of psyllid nymphs and adults causes severe problems in kernel development and subsequently bud drop and defoliation occurs, therefore it causes significant economic losses. The common pistachio psylla has two seasonal forms. The winter-form psyllids appear in early October and emigrate towards the overwintering shelters. They are larger with generally darker forewings with brown shading in the cells and pigmented veins. The female ovaries are undeveloped at the time of emergence. The winter-forms appear in the late winter and attack pistachio trees in the early spring, feed on swollen buds, young leaves and shoots and establish the summer-form generation. The insect lays her eggs mainly on the upper surface of the pistachio leaves, but egg laying on the petiole of soft leaves and young succulent plant shoots was observed as well. Eggs are embedded in plant tissue by a very delicate pedicel. Feeding and ovipositing of the psyllids, either winter- or summer-forms, on the stem's tissues or on the base of buds of pistachio trees has not yet been observed. Both stages (nymphs and adults) produce huge amounts of a paste-consistency honeydew that turns to white solid granules immediately after secretion. This species develops and reproduces in the wide range of temperature, and produces several generations during the growth seasons. Natural control is exhibited by several species of parasitoids and predators including; Encyrtidae, Coccinellidae, Chrysopidae, Anthocoridae, Phytoseiidae, Anistidae and Erythreidae in the pistachio orchards

[0284] CHEMICAL CONTROL OF *THIPS TABACI* (THYSANOPTERA: THRIPIDAE) WITH INSECTICIDE CONFIDOR (IMIDACLOPRID), IN POTATO CROP, *SOLANUM TUBEROSUM*

R.S. de Mendonca¹, A.C. Silva², L.O. Salgado², E.C. Teixeira³ & A.P. Botelho⁴, ¹Inst. de Ciências Agrárias, Universidade de Alfenas/UNIFENAS, P.O. Box 23, Alfenas, MG, Brazil, Zip Code 37.130-000, E-mail: fileni@artefinal.com.br; ² Agroteste-Pesquisa e Consultoria, P.O.Box 201, Lavras, MG, Brazil, Zip Code 37.200-000, E-mail: agrotest@ufla.br; ³Trainee of the Univ. de Alfenas/UNIFENAS, Trainee in Machado City.

The focus of this paper was evaluate the efficiency of the insecticide Confidor (Imidacloprid) in the control of Thrips tabaci in potato crop. The trial was set up in Minas Gerais State, Brazil, Machado City, with geographical position defined by the coordinates 21° 40° 40" South latitude, 45° 55' 45" West longitude and altitude of 1096 meters, in South area of Minas Gerais. The potatoes seeds were planted on March 20, 1999, being used the variety Achat. It was used the spacing of 0.80 m X 0.30 m and sowed 15 cm depth. The experiment design used was randomized blocks, with 6 treatments and 4 replications. The treatments in commercial products/ha were 1. Confidor 700 GRDA (20) g); 2. Confidor 700 GRDA (350 g); 3. Confidor 200Sc (700 ml); 4. Confidor 480 SC (300 ml); 5. Temik (15 kg), check; and 6. Control. The Confidor insecticides were applied in spray method with volume of 270 L/ha, and was utilized tlat nozzle number 110-02 driven to the basis of the stem, very close of the soil. The Temik insecticide was applied in the day of the plantation. The evaluations were accomplished with 1, 5, 10, 15, and 30 days after the treatment (DAT). It was collected 10 leaflets by parcels and counted the total numbers of thrips alive with a glass magnifying (20 X). The means were analyzed by the Tukey test (p<0.05) and the efficiency established with Abbott formula. The results showed an efficiency of 100% from the third to the last evaluation for all doses and formulations of the insecticide Confidor, indicating that the treatments 1 to 4 can be recommende for the thrips control in the potatoes crops Index terms: Thysanoptera, Thripidae, insecticide, thrips

[0283] A DOSE RECOMENDATION AND AN EVALUATION OF THE EFFICIENCY OF THE FARM CHEMICAL CONFIDOR (IMIDACLOPRID) TO CONTROL MYZUS PERSICAE (HOMOPTERA: APHIDIDAE) IN THE POTATO CROP SOLANUM TUBEROSUM

R.S. de Mendonca¹, A.C. Silva², L.O. Salgado², D.H. Fileni¹ & E.C. Teixeira³, ¹ Inst. de Ciências Agrárias, Univ. de Alfenas/UNIFENAS, P.O. Box 23, Alfenas, MG, Brazil, Zip Code 37.130-000, E-mail: fileni@artefinal.com.br; ² Agroteste-Pesquisa e Consultoria, P.O.Box 201, Lavras, MG, Brazil, Zip Code 37.200-000, E-mail: agrotest@ufla.br; ³Estagiária da Univ. de Alfenas/UNIFENAS

The aphids have great importance as a viruses vector in the potato crop, being the *Myzus* persicae a vector of large number of virus species, specially the Pumpkin Mosaic Virus (PMV). These phitoviroses are responsible for an important looses in quality and quantity in potato crop. The focus of this study was to evaluate the efficiency and the recommended dose for differents formulations of the farm chemical Confidor (Imidacloprid) to control *Myzus persicae* in the potato crop. The test was set up in Carmo do Rio Claro City, Minas Gerais State, Brazil, during March up to June, 1999. The experimental design was the randomized block experiment with six treatments and four replications. The efficiency of the treatments was evaluated according to the numbers of alive aphids in sample of 10 foliols. It was used the Abbott formula as measure of efficiency and means were separated by Duncan test (p<0.05). It was made six evaluation during the observed period, the results from first, fourth and sixth.

[0285] THE SIBERT TECHNOLOGY DIGITAL MICROPROBE (DMP) AND ITS USES IN DETECTING TERMITE GALLERIES, CAVITIES, AND DECAYED WOOD IN TREES, STRUCTURAL LUMBER, AND TRANSMISSION POLES

M. T. Messenger & E. D. Freytag, City of New Orleans Mosquito and Termite Control Board, 6601 S. Shore Harbor Blvd., New Orleans, LA 70126-8012, USA.

The Formosan subterranean termite, Coptotermes formosanus Shiraki (Isoptera: Rhinotermitidae), is one of the most destructive pests of structural lumber in New Orleans and other sub-tropical areas of the southern U.S., including Hawaii. They are also found in trees but their damage potential against living trees is unknown. Locating termite galleries inside trees, structural lumber, and transmission poles can be difficult because of the cryptic nature of termites. Using the Sibert Technology Digital microProbe (DmP), investigators can assess the structural integrity of trees and lumber by locating termite galleries, cavities, and areas of wood decay. The DmP penetrates wood using a 350 mm long, 1.5 mm diameter probe at a constant rate of 7000 revolutions per minute, and with attachments, can penetrate up to one meter. The DmP measures the resistance in the wood, in addition to the pressure required to penetrate the wood. The results from each drilling are recorded using Sibert Technology software and can be graphically displayed in a spreadsheet program using a connected computer. The graph generated by the spreadsheet program shows the state of the wood, including growth rings, which are indicated by peaks of harder wood and troughs of softer wood. Termite galleries and cavities in the wood are indicated by horizontal lines of zero resistance along with a drastic drop in the amount of pressure required. The exact location and width of the termite gallery or cavity can also be determined. The DmP is effective in locating termite galleries inside trees and lumber and is less destructive than other methods. Results from each drilling can be of assistance in legal proceedings over liability of fallen trees, structural lumber, and transmission poles. Treating termite-infested trees, structural lumber, and transmission poles with termiticides becomes an easier task once the location and extent of termite activity is known. Data from using the DmP in New Orleans to locate termite galleries in trees and structural lumber will be discussed. Index terms: decay detecting device, termite detection, termite inspection

[0286] COMPARATIVE STUDY OF BUMBLEBEES AND HONEYBEES EFFICIENCY IN GREENHOUSE MUSKMELON CROPS

A. Mexia¹, S. Albano² & <u>E. Salvado²</u>, ¹Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras amexia@isa.utl.pt; ²Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal.

In Portugal, honeybees are the pollinators commonly used in muskmelon crop. The application of bumblebee (Bombus terrestris) hives is a practice recently adopted in the pollination of this crop. The daily activity pattern of each pollinator, in this crop, was studied, as well as quantitative aspects of the visits (time per flower, interflower time and number of visits per minute) and qualitative aspects (frequency of foreleg scraping movement of the mouthparts). The honeybee activity pattern, in the studied conditions, demonstrates some advantages in relation to bumblebees: greater number of visits to the staminate and hermaphroditic flowers and in the last ones during the period of higher stigma receptivity. It was also verified that the honeybees presented significantly longer visits. However, the biggest frequency of scraping movement of the mouthparts and the greater number of visits per minute shown by bumblebees demonstrated that those also could be efficient for muskmelon pollination. If muskmelon plants seem to have benefits from the bumblebee visits in qualitative aspects, on the other hand, honeybees did compensate their performance through the high intensity of pollination that provide to the flowers. However this study suggest that the patterns of activity and foraging behaviour, exibited by each pollinator, are flexible to greenhouses conditions and can influence their effectiveness as pollinators.

Index terms: Apis mellifera, Bombus terrestris, foraging behaviour, Cucumis melo

[0288] DAMAGE EVALUATION OF HELICOVERPA ZEA ON THREE CORN HYBRIDS IN DIFFERENT PLANTING TIMES

J. M. Milanez¹ & L. A. Chiaradia¹, ¹Centro de Pesquisas para Pequenas Propriedades -Epagri, 89801-970, Chapecó-SC, Brasil, E-mail milanez@epagri.rct-sc.br

The corn earworm Helicoverpa zea (Lepidoptera: Noctuidae), is reported as one of the main pest on corn crop. The occurence is restricted to the last period of corn crop's development with technological difficulties in controlling the pest, even using chemical products. This study evaluated the number of damaged plants in three commercial hybrid corn, in nine different planting times in 1997/98. The experiment was conducted in the Research Center of Experimental Station for Small Properties - Epagri, located in Chapecó-SC, Brazil. Plants were arranged in a randomised block desing with nine treatments (planting times) and four replicates. The block areas were 27 m² with 0,90 cm between lines and a population of 55.000 plants/ha. The corn hybrids evaluated were: Agroceres 1051 (normal cycle), Cargill 901 (super precocious) and Pionner 3099 (precocious). The evaluation was conducted on the harvest, by counting the number of damaged spike. The results showed that there were significant statistical differences between the percentage of damaged plants and the different planting times for hybrid Agroceres 1051 and Cargill 90. Rates of the damaged spike for Cargill 90, Agroceres 1051 and Pionner 3099 was 17%, 11% and 10%, respectively. The lowest number of damaged spike, for the three hybrid studied, was observed in the first planting time, in August. In the result analysis, the hybrids did not differ significantly with respect to earworm damage, although it was verified that Pionner 3099 was less damaged, while Cargill 90 was the most damaged.

Index terms: corn earworm, hybrid corn

[0287] POLLINATION OF GREENHOUSE TOMATO CROP BY BUMBLEBEES

A. Mexia¹, E. Salvado² & <u>S. Albano²</u>, ¹Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras amexia@isa.utl.pt ; ²Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal.

In Portugal, the use of bumblebees' hives (Bombus terrestris) for pollination in greenhouse tomato crops is already routine, but little it is known concerning the pollinator activity under these conditions. General aspects of the colony activity at the hive (tunneltraffic) and foraging activity on the crop have been analysed. The guard bee activity was also observed_at the hive entrance. The activity daily pattern at the hive showed a higher activity of the foragers at the beginning and end of the day, which did correspond respectively to the periods of crop flowers aperture and closing in the day. The main registered variations in hive activity, during the study period, were related to different colony developmental phases, reflected by the variation of forager's total population and pollen demands of the colony. The presence of the guard bee in the hive's entrance diminished during the study period, demonstrating a gradual loss of investment in the colony defence, probably because of resources abundance in the crop (pollen) and the little aggressive environment in the greenhouse. The reduction of visit number in the afternoon was related with the intense decrease of pollen amount in the flowers as a result of the high intensity of visits in the morning period. Despite pollination intensity not been equal in the different phases of the study period, the percentage of flowers with visit marks of bumblebees was very high, mainly from 2^{nd} week after the hive installation. At 3^{tu} generation emergency a systematic exit of bumblebees from the greenhouse was registered. These individuals did not carry pollen baskets to the hive. This occurrence revealed that limitations of another resource existed that could not be satisfied inside greenhouse. They exit period of these individuals did not affect pollination activity of bumblebees on the crop since it was in the highest phase. Index terms: Bombus terrestris, pollinator activity

[0289] DO INVERSIONS INCREASE SPRAY DRIFT

D.R. Miller¹, T.E. Stoughton¹, W.E. Steinke², <u>E.W. Huddleston³</u> & J.B. Ross³, ¹Univ. Ct., ²UCD, CA., ³NMSU, NM.

Single spray runs were conducted in a mature pecan orchard with orchard airblast sprayer. Sprays were made 54 m from the downwind edge. Drift was measured 33, 66, 132 and 198 m downwind, using ground plates, high volume air samplers and string. Atmospheric stability was the primary determinant drift on (ground) and above (1.2m) the adjacent field. Drift was approximately double in stable compared with unstable conditions. Drift decreased with higher intensity instability. There was little relationship between the intensity of stability and drift. Wind speed appeared less important than stability. Most of the drift was deposited within 66 m of the orchard edge. Measurable amounts drifted farther. Compared with the amount collected at 33 m and averaged over nine replications, 2.6% of the material on ground plates, 4.2% by high volume samplers and 17.1% by string samplers drifted farther than 198 m.

0290] HF-ENERGY INFLUENCE ON GRANARY PESTS

A.A. Mishchenko*, O.A. Malinin*, I.A. Mashkey*, <u>V.M. Rashkovan</u>**, Y.P. Mazalov***, *Institute of Experimental and Clinical Velerinary Medicine under Ukrainian Academy of Agricultural Sciences, **Kharkov Aviation Institute, ***National Scientific Center" Kharkov Institute of Technical physics".

Ecological and entomological investigations carried out at feed stuff plants, elevators and other grain processing enterprises of Ukraine and South of Russia have shown over 100 kinds of granary pests were found in the researched objects. The most wide-spread insects are representatives of families as Curculionidae, Tenebrionidae Dermestidae, Anobiidae and Cucujidae. Besides, grain and grain products are infected to a great extent with spores of microscopic fungi and bacteria. HF-irradiation influence on Sitophilus granarius L., S. Oryzae L., Tenebrio molitor L., Alphitobius diaporium Pz. Were carried out on devices of Kharkov Institute of Physics and Technics and State Aerospace University "KhAI". Several ranges of wavelength with different power values of the generator were investigated. Grain contamination intensity has reached near 100 pests per 1 kg. Experiments were conducted in 5-6 repeats in a stationary regime. With the usage of generator operating in an impulse regime (frequency 47-48 MGz) the biological influential effect was connected with amplitude of field intensity in the zone of sample. Exposition time doesn't practically influence on increasing of mortality rate of insects. Raising a voltage in a region of sample the mortality rate of insects was being expanded. During the effecting of HF-irradiation with frequency 900-2450 MHz the mortality rate of insects immediately was correlating with exposition and temperature factor. Exposition increasing of grain processing from 5 to 45-60 seconds facilitated the raising of dead insect quantity from 68% to 100%. Grain temperature during this process didn't exceed 45-50°C. The obtained data witness about the fact that in a presence of plasma discharge insects begin to lapse into a shock state /nock-dawn/, and than sometimes after several days their depth occurs. In a case of plasma discharge it was succeeded to obtain entire depth of insects for 3-8 seconds. So, the conducted researches allowed defining new parameters of physical influential factors on insects not connected with heating effect. Authors thank to the Scientific Technical Center of Ukraine for the support in the limits of the project 447 "Grain-Crops Microwave Protection at Agricultural Enterprises of Ukraine"

[0292] NEW TRAPPING METHOD FOR PENTATOMIDAE, COREIDAE AND OTHER HETEROPTERA

<u>R. F. Mizell</u>, NFREC-Monticello, University of Florida, Rt 4, Box 4092, Monticello, FL 32344., USA, E-mail rfm@gnv.ifas.ufl.edu.

Stink bugs (Pentatomidae) and plant bugs (Coreidae) are important pests of a myriad of fruit, nut, vegetable and seed crops throughout the world. Sweep nets, light traps and baits are often used to collect these species. Monitoring methods for this pest group suitable for estimation of population parameters are limited to labor-intensive sampling methods such as limb jarring, sweep net or chemical knock-down using volatile insecticides. New methods are needed to facilitate pest management decision-making. Several recent breakthroughs have led to development of a more promising and efficient monitoring method for stink and plant bugs. The Florida stink bug trap was invented as a modification of the pyramidal (Tedders) trap now used for monitoring many Curculionidae. The trap bottom is pyramidal in shape, 1.22 m in height, and made from 4 mm Masonite sheeting. The pyramidal bottom is painted bright yellow (Glidden 4540 Safety Yellow) which is visually attractive to the bugs. The trap top which serves as the collection device is made of fine wire-mesh window screen and is designed similar in shape and size to the top (collector) portion of the Helicoverpa spp. pheromone trap. The top differs from the Helicoverpa trap top in that it has a flared skirt about 5-8 cm in width around the bottom of the funnel. The entry hole in the screen funnel fits over the trap bottom at its top and enables the bugs to walk into the collection device and traps them. While the trap functions by visually attracting bugs, a pheromone of Euschistus spp. is available and greatly increases trap efficiency for monitoring this genera. Traps baited with pheromone also collect selected parasites (Tachinidae) of stink bugs. In addition to about 15-20 species of phytophagous and predacious Pentatomidae and Coreidae, many species of Reduvidae, and Miridae are also collected in the trap. The trap's design, use and limitations along with some results from monitoring stink bugs in a variety of crops will he discussed.

[0291] INSECT PESTS ON MACADAMIANUT TREES IN COLONIA SAN JUAN DE YAPACANI, SANTA CRUZ DISTRICT, BOLIVIA

<u>V. Miyasato</u>, O. Mochida, I. Guaman, Y. Hatta & T. Mori, ¹CETABOL, Casilla # 555, Santa Cruz, Bolivia: cetabol@daitec.scz.com

Some seeds of macadamia nut trees (Macadamia integrifolia) were introduced from Hawaii into the Colony in 1965, 1967, & 1971, respectively. CAISY (Cooperativa Agropecuaria Integral San Juan de Yapacani) has commercialized the seedlings to its member farmers since 1989. As of the end of 1999, fiftysix farmers grew the nut trees in 315ha of the colonial area. One of the biggest constraints is insect pests. Some 10-50% nuts were damaged by the sucking of Coreid (Leptoglossus spp., & Sphyctyrtus stral) & Pentatomid bugs (Loxa, Antiteuchus, etc.) in fields. The eggs and nymphs of both Loxa & Sphyctyrtus were found on leaves of macadamia nut trees. However, adults of all these bugs suck on not only the nut seeds of macadamia but also seeds of other plants and survive for longer than one month. They seem to have some host plants other than macadamia. Leptoglossus and Loxa adults attack even mature nuts with hard shells but Sphyctyrtus ones appear to prefer flowers or soft and young seeds. Sphyctyrtus is observed from flowering through harvest, while Leptoglossus is frequently found in seed maturity period. Many seeds damaged by bugs fall in earlier stages before harvesting time (Table 1). Additionally, some species belonging to Isop., Homop. (Aphididae, Coccidae, Diaspididae, Membracidae), Coleop. (Scarabaeidae, Ipidae, Platypodidae, Curculionidae, Cerambycidae, Bupresidae, Chrysomelidae), Hymenop. (Meliponidae), & Lepidop. (Pyralidae, Lycaenidae) were recorded as minor pests. Ants & paper wasps (Vespidae, Polistinae) are frequently troublesome in operation.

IN CENTRAL KALIMANTAN, BORNEO, INDONESIA IN WET SEASON 1997/98 O. Mochida^{1,2}, K. Nakasono¹, Arif R¹, & K. Ueda¹, ¹JALDA, Syuuwa-Siba Paaku-Bldg B 13F., Siba-Kouen 1-2-4, Minato-ku, Tokyo-To, Japan, 105-0011 ² Present address:

102931 YIELD LOSS ASSESSMENT OF UPLAND RICE DUE TO INSECT PESTS

Field trials were conducted at JALDA (Japan Agricultural Land Development Agency) farm (3°58'50''S and 114°53'46''E) at Jorong, C. Kalimantan. The cultivar, Dodokan, was seeded in plots (7.5x5.75m each) with 4 replications under randomized block design Dec 16, 1997 & harvested Apr 7, 1998. Cultural practice was followed to the usual ways carried out at the farm for last 4 years; N, P2O5, & K2O of 69; 46; & 30kg/ha except for insecticide applications. All the experimental plots were covered with nets for preventing bird damages. Heading & maturity were on Mar 18 & Apr 18, \Box 1998, respectively. Four insecticide treatments were tested: no application as untreated check (U), & other three treatments (T1-3) with carbofuran 3G (34 kg/ha) together with or without bensultap 50WP (0.5 kg/ha) for foliar spray certain days after sowing (DAS) as shown in Table 1. When the yield of T3 (maximal protection plots) was 1.84 t/ha or 100 in relative value, that of U plots was only 1.01 t/ha or 54.9. It means that 54.9% of the potential yield was harvested but the other or 45.1% was lost by insect pests, when no insecticide applications, fluctuating between 1.01 & 1.84 t/ha or 54-100% in relative values. Otherwise, yield losses were assessed to be 0 to 44%. Nezara viridula (Het., Pentatomidae) & Sesamia inferens (Lep., Nuctuidae) were major pest species. Leptocorisa oratorius (Het., Alydidae), Conocephalus longipennis (Ort., Tettigonidae), Hysteroneura starine (Hom., Aphididae), Megymenus spinosum (Het., Dinidoridae), etc. were collected as minor pests.

[0294] EFFICIENCY OF SOME CHEMICALS TO CONTROL WHITE FLY, BEMISIA ARGENTIFOLII IN PUMPKIN CUCURBITA MOSCHATA, IN SAN FRANCISCO VALLEY – BRAZIL

J.O.T. Moreira¹ & M. R. Lavorenti², ¹ Dept. de Tecnol. e Ciências Sociais/Univ. do Est. da Bahia, C. Postal 171, CEP 48900-000 Juazeiro-BA-Brasil, E-mail: osmateles@bol.com.br, ² Dept. Técnico da Novartis Biociências S.A. – R. Domingos Ferreira, 222 - sala 101 CEP 51.020-030 Recife-PE-Brasil. E-mail: cleber-oliveira@cp.novartis.com.

The white fly, from Bemisia complex is one of the worst pests in the 20th century. Its spread, in the world, have been happening very fast. Today more than 700 plant hosts are known and the damage are around some billion dollars and Bemisia argentifolii causes the most serious damages in Northeast Brazil. One of the most damaged plant families are the cucurbitaceae, and the pumpkin the most sensible specie, with serious direct and indirect damages. To evaluate some chemicals efficiency in B. argentifilii control in the pumpkin crop Cucurbita moschata, ev. "jacarezinho" a trial was done in an experimental area in Bahia State University in Juazeiro – BA – Brazil. The chemicals were Thiametoxan (ACTARA 250 WG) 400 g/ha squirted; Pyridaphenthion (OFUNACK 400 CE) 150 ml/100 1 H2O; Acethamiprid (SAUROS PS) 50 g/100 1 H2O and 25 g/100 H2O; Imidacloprid (CONFIDOR 700 GRDA) 360 g/ha squirted; Mineral oil (ASSIST) 1.000 ml/100 H2O; Thiametoxan (ACTARA 250 WG) 400 g/ha squirted, followed by weekly aplications intercalating the chemicals: Acephate (ORTHENE 750 BR) 100 g/100 i H₂O; Buprofesin (APPLAUD 250) 150 g/100 i H₂O; Fenpropathrin (MEOTHRIN 300) 30 ml/100 i H₂O and Pyriproxifen (CORDIAL 100 CE) 75 g/100 i H₂O and Carbosulfan (MARSHAL 200 SC) 200 ml/100 | H2O mixed with Bifenthrin (TALSTAR 110 CE) 20 ml/100 1 H2O and a control. There were weekly evaluations, examinating 10 leaves/plot, registering white fly eggs, nynphs and pupae numbers. From the results, was concluded that ACTARA 250 WG a single aplication followed by weekly aplications alternating the cited products was the most efficient treatment to control the white fly, and in the second place CONFIDOR 700 GRDA, ACTARA 250 WG applied each 20 days showed the same efficiency and SAUROS PS in the highest rate. Index terms: pumpkin, Cucurbita, white fly, Bemisia

[0296] EFFICACY EVALUATION OF KARATE ZEON 50 CS FOR THE CONTROL OF Dilobopterus costalimai, INSECT VECTOR OF CVC IN CITRUS

O. Nakano¹, R. K. Atarassi¹ & A. C. P. Florim¹, ¹Dept. of Entomology, Fitopatology and Agricultural Zoology, Univ. of São Paulo - ESALQ/USP, Av. Pádua Dias 11, P. O. Box 9, Piracicaba, São Paulo, Brazil.

Citrus Variegated Chlorosis (CVC) has become one of the main phytossanitary problems of Brazilian citriculture today. In 1987, the disease was observed in the center of the main citrus growing region in Brazil and losses for the last 5 years (Fundecitrus) are estimated in, at least, 360 millions of dollars. Up to the moment, 11 species of leafhoppers that transmit this disease (Xylella fastidiosa - bacteria) were found. A possibility to avoid this disease consists in the elimination of the leafhoppers, of which D. costalimai is one of the main species. However, for a more efficient and economical control it is necessary to control this pest at the adequate moment, since it occurs during the whole year, mainly during sprouting, from which they suck the sap. Citrus plants sprout 4 to 5 times a year and the first sprouting occurs after winter and so, insecticide spraying during spring can interrupt the leafhoppers cycle and prevent F2 generation and successive infestations. Such handling is viable because the biological cycle of the leafhoppers is relatively long, of about 50 days. Due to its performance, Karate Zeon 50 CS (Lambdacyhalothrin) is one of the viable insecticides to control this species of leafhoppers. This is because its acaridstatic effect, that is, it does not cause an unbalance favoring phytophagous acarids, which are very common on citrus plantations. Moreover, it is a microencapsulated product, resulting in less toxicity during application and higher residual effect, providing improved contact efficacy in the long term. The tests were conducted at the doses of 10-20-30 and 40 ml of the commercial product for 100 L of dilution, using ECHO motor knapsack spray, fitted with 3 conic nozzles, model X-6, at the pressure of 75 lb/pol², and at the flow rate of 1000 L/ha. Each parcel consisted of 5 adult leafhoppers inside tulle bags, on the sprouts, 4/treatment. Deaths were evaluated through direct contact of the spray with the adults and through indirect contact at 1-3-8 and 12 days after spraying. The results showed that Karate Zeon 50 CS was highly efficient through direct contact 3 days after spraying, even at the lowest dose, 10 ml of the commercial product/100 L of spray. This is a bacterium transmitting pest and therefore, the residual effect is necessary for a lasting control. The dose of 40 ml of the product/100 L of dilution can be recommended to be sprayed onto the sprouting, a point of frequent access of adults, with the residual of up to 12 days. Key words: citrus, leafhoppers, control, Lambdacyhalothrin

[0295] BIOLOGICAL ACTIVITY OF ORANGE MOTII, *ECDYTOLOPHA* AURANTIANUM, WHEN SUBMITED TO THE PHYSIOLOGICAL INSECTICIDE - METHOFENOZIDE

O. Nakano¹, F. C. Rutkósky¹ & A. C. P. Florim¹, ¹Dept. of Entomology, Fitopatology and Agricultural Zoology, Univ. of São Paulo - ESALQ/USP, Av. Pádua Dias 11, P. O. Box 9, Piracicaba, São Paulo, Brazil.

The orange moth, from the Lepidoptera Order, Family Oleuthretidae, has a larva which is known to damage the citrus fruit. It's been found also, but not so often in lichy and guava. The population in citrus usually gets higher when the prices get lower, then the fruits are left in the orchard, exposed to the worm attack. When there is a large population the control becames harder, once the worm doesn't need much time to penetrate the fruit. Once inside the fruit, the worm is protected from the insecticide action. Because of it's sterilizing propriety on the moth, the physiological insecticides advent, allowed a rational pest control management. Males and females were isolated in cages treated with different dosages of Methofenozide (ecdise agonist hormone) during 48 hours, to assure the moth contamination. After that, males and females were placed together to reproduction. Another treatment consisted on direct insecticide pulverization over the adults. The treatment dosages were: 1)Methofenozide 240 SC - 18,75 ml/100l; 2)Methofenozide 240 SC - 37,5 ml/100l, both in total cage immersion; 3)Methofenozide 240 SC - 18,75 ml/100l, pulverized over the adults; 4)Check. During the every day eggs evaluation, 25 eggs were collected per parcel and placed in Petry box with filter paper to observe the moth eclosion. As soon as the moth was born, it was taken to an artificial diet to evaluate the treatment effect. The results demonstrated that 12 days after the emergence of adults the indirect contact of the insecticide over the adults killed 40% of the population when the lightest dosage was applied and 50% with the strongest dosage (check population lived 22 days). The adult pulverization (direct contact) did not show any difference from the check, in the indirect contact. No eggs production were found when the strongest dosage was applied and under the lightest dosage, eggs were displayed during the first 3 days, but 8 times minor than the normal population and no more eggs appeared after the third day. The direct contact treated moth produced eggs during the first 4 days, than stopped and presented a number of eggs 10 times minor than the check. Although the treatment reduced the egg production, the larva that made up to moth, also made up to pupae and emerged normally. The conclusion was that the physiological insecticide Methofenozide, when applied as recommended, acts quite efficiently over the adult of Ecdytolopha aurantianum, either by direct or indirect contact, with only 1.17% of viable eggs. Key words: Ecdytolopha aurantianum, methofenozide, citrus, sterilizing

[0297] EFFECT OF DIFFERENT DOSAGES OF NOVALURON (RIMON 100 EC) FOR SPODOPTERA FRUGIPERDA CONTROL IN CORN AT LONDRINA - PR -BRAZIL

<u>P. J. Neves</u>¹; M. U. Ventura¹ & M. Cassinelli², Depto. Agronomia, Univ. Est. de Londrina, C.P. 6001, Londrina, PR 86051-970, Brazil. E-mail pmojneve@uel.br;² Milenia Agro Ciências S/A R. Pedro Antônio de Souza 400 Londrina – Pr 86031-600 – Brazil.

The army worm Spodoptera frugiperda is the most important pest of corn in Brazil. This pest promote significantly yields reductions under severe infestation. This research was carried out to evaluate the efficiency of different insecticides for *S. frugiperda* control in corn. Cultivar Premium was used. Plots size were $(0.90 \times 6m) 5.4 m^2$. The experiment was carried out at the School Farm of Univ. Estadual de Londrina. The treatments used were : Novaluron (Rimon 100 EC) in the dosages of 7,5; 10; 15 and 20 g a.i /ha, Lufenuron (Match 50 EC) - 75 and 150 g a.i./ha, Clorpiryphos (Clorban EC) - 288 g a.i./ha, Clorfluazuron (Atabron 50 EC) - 500 g a.i / ha, and the control (only water). Lufenuron (Match 50 EC) and Clorpiryphos (Clorban EC) - were the standard treatments. Six plants per plot were assessed before and 3, 5, 7, 9, and 13 days after spraying. The worm number was divided in small worms (<1,5 cm) and big ones (>1,5 cm). For big worms significant differences were obtained from 5 to 13 days after spraying among all insecticide treatments and the control. All products kept the big worms under control. (Match 50 EC) - 150 days after spraying, levels of 80% control efficiency (Abbott) or bigher were observed for Novaluron (Rimon 100 EC) in all dosages and for Lufenuron (Match 50 EC) - 150 g, a.i./ha. Novaluron (Rimon 100 EC) in the dosages of 7,5; 10; 15 and 20 g. a.i. fha had efficiency levels equivalent with the standard products. Index terms : insect; growth regulaters, ecdyse inhibitors, army worm.

<u>O. Nakano¹</u>, C. F. Poletto¹ & G. G. F. B. de Oliveira¹, ¹Dept. of Entomology, Fitopatology and Agricultural Zoology, Univ. of São Paulo - ESALQ/USP, Av. Pádua Dias 11, P. O. Box 9, Piracicaba, São Paulo, Brazil.

In 1987 some citrus orchards in the State of São Paulo was striked by a bacterial disease classified as Xylella fastidiosa, the bacterium responsible for "CVC". One of the manners to control the disease is it's vectors elimination, known to be at least 11 different sharpshooters species. It usually happens to find a large adult population in a citrus orchard, but we do not find a similar nymph population, and at the same it's noticed that when we have a forest near by the orchards the populations is always larger than in orchards without contact with forests, what make us believed that the procreation take locations in other hosts. Due to this it's been developed a way to sterilize the adults. Some different insecticides were tested, on 3 different sharpshooters species: Acrogonia terminalis; Dilobopterus costalimai and Oncometopia facialis. The treatment dosages were: 1)Applaud 250 PM (Buprofezin) - 1,5 g; 2) Interpid 240 SC (MethoGenozide) - 0,27 ml; 3) Match 50 g/L (Lufenuron) - 1,20 ml; 4)Cordial 100 CE (Pyriproxifen) - 0,75 ml; 5)Neem 4000 (Azadiracthin) - 40,0 ml (tested only on D. costalimai). All of those dosages are correlated to 1 liter of water; 5) Check. The A. terminalis specie has shown a greater mortal rate when submited to Match followed by Applaud and Cordial. The D. costalimai happened to be more sensible to Neem than to the Intrepid. For the O. fascilais the best result was from Cordial, than Applaud, than Match. While that D. costalimai has not been affected by the insecticides, except for Neem and Cordial, either for adults or nymph. Cordial affected the A. terminalis adults, but to the nymph control, Applaud, Cordial and Match demonstrated better results. Finally, O. fascialis seemed to live even better when applied Cordial and Intrepid, only Match could affect the nymphs. Key words: physiological insecticides, sharpshooters, CVC, citrus.

[0299] BIONOMY OF THE BOLL WEVILL REARED ON ARTIFICIAL DIET

<u>S. D. N. Nobre</u>, E.R. Sujii, F. G.V. Schimidt, S. Dias; R. Lauman, O.B. Oliveira Neto, M.F. Grossi de Sá & R. Monnerat, Embrapa Recursos Genéticos e Biotecnologia, SAIN Parque Rural, Caixa Postal 02372. Brasília, DF, e-mail: rose@cenargen.embrapa.br

Studies about the bionomy of the boll wevill, Anthonomus grandis (Col.: Curculionidae) reared on artificial diet are fundamentals to obtain standardized individuals in adequate quantities for evaluation of microorganisms as potential biological control agents. The mass rearing is being developed on insectarium with temperature of 25°C, relative humidity of 60% and photophase of 12h. The insects are fed with the artificial diet that consists on a mixture of soybean crumb, seed of wheat, glucose, cotton seed crumb and supplement of minerals and vitamins. The life cycle of boll wevill was 5,47 days in average for the egg stage and 15 days for the stages of larvae and pupae. On the adult stage, the average period of pre oviposition was 5,6 days, oviposition 60,6 days and post oviposition 15,12 days for the females. The oviposition started four days after adults emergency, noticing that, in average, the population produced more than 90% of the eggs until 73 days after the emergency. The average number of eggs produced were 129,64 with variation range between 11 and 260 eggs. The average longevity of the adult stage was 80 days for the females and 61,96 days for the males and sexual ratio of 0,4313 (females/males +females). Based on the survival curve of the boll wevill, the intrinsic growth rate of the population was 5,24. It was observed an increase in adaptation of the insects to the artificial diet, considering the improve of their fitness through the generations

Index terms: Anthonomus grandis, life cycle, biological control

[0300] PROSPECTS FOR BIOLOGICAL CONTROL OF THE WHITEFLY BEMISIA TABACI WITH PHYTOSEIID PREDATORS

<u>M. Nomikou</u>, A. Janssen, R. Schraag & M. W. Sabelis, IBED, Univ. of Amsterdam Post box94084, 1090 GB Amsterdam, The Netherlands. E-mail: nomikou@bio.uva.nl.

Bemisia tabaci is a relatively new pest in greenhouses in the Netherlands (Fransen, 1994) and the currently used Biological Control Agents (BCA's) of whitefly are either insufficient or economically unfeasible (Szabo et al. 1993, Drost et al. 1998, Hoddle et al. 1999). Predatory mites of the family Phytoseiidae have been reported to feed and/or oviposit on whitefly prey (Teich 1966), yet have never being used as BCA's of whitefly. We investigated the possibility of using predatory mites against B. tabaci as they are associated with this prey, they are cheap and easy to rear and they have proven to be successful BCA's against various other pests *e.g.* spider mites, thrips. We collected predatory mites that co-occur with whiteflies in the Middle East area and 5 different species were identified, with one to six different strains of each species. Six selection criteria were formulated in order to evaluate phytoseiid mites as BCA's of whitefly: their capacity to suppress local whitefly populations; their efficiency at detecting local whitefly populations; their ability to control whitefly throughout a greenhouse; their ability to use alternative food; their compatibility with other natural enemies; and their ability to control a similar pest e.g. Trialeurodes vaporariorum, the greenhouse whitefly. Here, we present results from laboratory tests and small-scale greenhouse experiments with the collected predators and we discuss the perspectives of biological control of B. tabaci with predatory mites

[0301] SUBIRRIGATION APPLICATION OF IMIDACLOPRID FOR CONTROL OF BEMISIA ARGENTIFOLII

<u>R. D. Oetting</u>¹ & M. W. van Iersel¹, ¹Dept. of Entomology, ¹Dept. of Horticulture, Univ. of GA, GA Exper. Stn., 1109 Experiment St., Griffin, GA 30224, USA

Subirrigation systems can be used to apply systemic pesticides to greenhouse crops without pesticide runoff and with reduced worker exposure. However, there is little information on the plant uptake or efficacy of pesticides applied by subirrigation. The objective of this study was to determine whether silverleaf whiteflies, Bemisia argentifolii, on poinsettia, Euphorbia pulcherrima, can be controlled with imidacloprid applied by subirrigation. In experiment 1 different amounts of imidacloprid solution uptake by the growing medium were obtained by not watering the subirrigated plants for 0, 1, 2, or 4 days before the imidacloprid application. These treatments were compared with untreated control plants and plants that were treated with a standard drench application (100 ml) to the top of the growing medium. There was a reduction of imadacloprid in plant tissue from 3 days to 63 days after application with the standard drench treatment. The amount of imidacloprid increased during the same period with subirrigation. All imidacloprid treatments resulted in a significant decrease in both the survival of adult whiteflies and number of immature whiteflies on the plants. Subirrigation treatments resulted in better control of adult and immature whiteflies than the drench application. Withholding water for 2 or 4 days before the imidaeloprid application by subirrigation improved control of immature whiteflies. In a second experiment 100 ml of imadacloprid solution was applied either to the surface of the potting medium or by subirrigation. The plants were watered by the same method as application. Leaf tissue analysis and efficacy were determined for leaf tissue at different levels in the plant architecture. At the end of the experiment, imidacloprid was more concentrated in the Joan architecture. At the end of the experiment, imidacloprid was more concentrated in the lower plant tissue when applied to the medium surface and in the upper leaves when applied by subirrigation. Survival of adult and immature whiteflies was low with both application methods but lowest with subirrigation application. This indicates that the application of imidacloprid to poinsettia by subirrigation is a practical and efficient method to control silverleaf whiteflies. Index terms: Silverleaf whitefly, ebb-and-flow, systemic insecticide, insecticide application.

Session 02 - AGRICULTURAL ENTOMOLOGY

[0302] INSECTS ASSOCIATED WITH TOBACCO CULTURE WITHOUT CHEMICAL MANAGEMENT IN MISIONES ARGENTINA

D. V. Ohashi, C. L Fernandez Diaz, R. A. Vallejos, J. Verón, F. Mamani & M. Ledesma, Convenio CoTTaProM-FCEQyN. FCEQyN. Univ. Nacional de Misiones, Felix de Azara nº 1552. (3300) Posadas, Misiones, Arg. Tel: 0054-3752-422186. Fax: 0054-3752-425414. E-mail: ecologia@fceqyn.unam.edu.ar

Tobacco (Nicotiana tabacum) culture is widely spread around the province. There are 17.239 tobacco's farmers with 1,5ha each approximately, in many of the cases tobacco production is the most important money income for them; that is why it needs a lot of basic studies for efficient insect management. The objetive is to start studies knowing the entomofauna associated with tobacco culture and to know interactions between perjudicial and beneficial insects without any agrochemical management. We installed and compared two parcels with different management (without any agrochemicals and a conventional one) in three farmlands in southwest of Misiones (Feltan's farm, Cooperativa's farm and Melzew's farm). We made direct observation from september, 17th to december 16th of 1997. Here we will present the first one because there we were able to observe perjudicial and natural enemics interactions. Leaf damage: Caeporis stigmula, Cerotoma sp., Colaspis aemula, Diabrotica speciosa, Epitrix sp. y Lema biliniata? (Coleoptera: Chrysomelidae), Epicauta atomari (Coleoptera: Meloidae), Jalisus sobrinus (Hemiptera: Neididae), Dichelops furcatus, Edessa meditabunda y Nezara viridula (Hemiptera: Pentatomidae), Macrosiphum euphorbiae, Myzus persicae y Myzus nicotianae (Homoptera: Aphididae), Manduca sp. (Lepidoptera: Sphingidae), Spodoptera frugiperda (Lepidoptera: Noctuidae), Chromaeris speciosa y Ommexechia vitens (Orthoptera: Acrididae) y Thrips tabaci, (Thripidae: Thysanoptera). Inferior part of the stem damage: Agrotis ipsilon (Lepidoptera: Noctuidae), Conoderus sp. (Coleoptera: Elateridae), Faustinus cubae (Coleoptera: Curculionidae), Lagria villosa (Coleoptera: Lagriidae) y Neocurtilla hexaductylla (Orthoptera: Gryllotalpidae). Flower damage: Jalisus sobrinus (Hemiptera: Neididae), Myzus persicae y Myzus nicotamae (Homoptera: Aphididae). Natural enemies: Nimphs and adults of Cosmoclopius nigroanulatus (Hemiptera: Reduviidae) as Epitrix sp.'s predators. Complex of aphids (Myzus persicae, M. nicotianae and Macrosiphum euphorbiae) predated by larvae of Allograpta oblicua? (Diptera: Syrphidae), larvae and adults of Cicloneda sanguinea, Eriopis connexa, Hippodamia convergens (Coleoptera: Coccinelidae) and, nimphs and adults of Zelus sp. (Hemiptera: Reduvidae). Larvae of Manduca sp. parasited by Cotesia sp. (Hymenoptera: Braconidae). Some natural enemies were also found in the conventional management parcel, but with less density. Index terms: Nicotiana tabacum, biological control, pest, natural enemies.

[0304] PERFORMANCE AND FEEDING PREFERENCE OF NYMPHS AND ADULTS OF *PIEZODORUS GUILDINII* (HEMIPTERA: PENTATOMIDAE) ON SOYBEAN PODS AT DIFFERENT DEVELOPMENTAL STAGES

E.D.M. Oliveira¹ & A.R. Panizzi², ¹Universidade Estadual de Londrina, Departamento de Agronomia, Caixa Postal 6001, Londrina, PR, 86051-970, Brasil. E-mail: emerson@enpso.embrapa.br. ²Embrapa-Soja, Caixa Postal 231, Londrina, PR, 86001-970, Brasil. E-mail: panizzi@enpso.embrapa.br.

A study was conducted in the laboratory to test the suitability of soybean (Glycine max) pods at different phenological stages of development (R3-R8) on the performance of nymphs and adults of the small green stink bug, *Plezodorus guildinii* (Hemiptera: Pentatomidae). In the field, a survey was carried out to determine the population fluctuation of this stink bug with relation to the soybean plant phenology. In the laboratory, nymphs showed a better performance when fed soybean pods during the podfilling stage (R5-R6), compared to the remaining stages of pod development. Despite nymphs required similar time to complete development and attained similar body weight at adult emergence, mortality was smaller at stage R6 (47.5%) than on the remaining stages of pod development. On soybean pods without seeds (R3-R4) and on soybean pods mature (R8) nymph mortality was 100%. On soybean pods beginning maturation (R7) and on soybean seeds mature, mortality reached 81.7 and 76.7%, respectively. When pod pilosity was removed, nymph mortality on soybean pods at R6 increased to 60.0%, and decreased to 35% on soybean pods at R6 with pilosity. P. guildinii adults showed better performance on soybean pods at stages R5 and R6, compared to soybean pods at R3, R4, R7, R8, and mature seeds (R8MS). Females and males showed greater longevity when fed on soybean pods at R5; 50% of females oviposited when fed on soybean pods at R5, and no females oviposited when fed on soybean pods at R3 or R4; at R7, 20%; at R6 45% of the females oviposited; at R8, 10%, and on R8MS, 5% of the females laid eggs. Preoviposition period was shorter when females fed on soybean pods at R6 and longer when they fed on soybean pods at R7. Mean number of egg masses and total number of eggs was greater for females fed on soybean pods at R5; greater female body weight was observed on soybean pods at R6 at day 29 of adult life. P. guildinii showed greater feeding activity on soybean pods at R5, and visited more often soybean pods at R6, than soybean pods at R3, R7 or R8. Adults colonized soybean from the beginning of pod filling (R5), and nymphs from the period pods were completely filled (R6); both, nymphs and adults peaked at maturation (R8). These results indicate that P. guildinii nymphs and adults show a better performance when fed on filling soybean pods, and, when the pods are elongating or maturing, the performance is less satisfactory.

Index terms: Heteroptera, Glycine max, stink bug, biology

[0303] INSECTS RELATED TO BEAN AND CUCUMBER INTERCROPPING CULTURE IN MISIONES, ARGENTINA

D. V. Ohashi^{1,2} & E. Steger², ¹Fac. of Exact, Chemical and Life Sciences (FCEQyN – UNaM). Felix de Azara 1552, (3300) Posadas, Misiones, Argentina. Fax: 03752-425414. E-mail: ecologia@fceqyn.unam.edu.ar.² Agricultural Experiment Station Cerro Azul INTA, C.C. Nº 101, L.N. Alem, Mnes., Arg. Tel/fax: 0054-3754-22787. E-mail: vitrocultivo@cerro.inta.gov.ar

Horticulture grew up in the state of Misiones (Argentina) from 10,58ha during 1995 to near 22ha in 1997. Horticulture Project at EEA Cerro Azul INTA started with culture experience, where entomological observation were made for the necessary basic needs of farmers. So, a bean (Phaseolus vulgaris) and cucumber (Cucumis sativa) associated culture was installed inside a greenhouse, looking for cultures not interfering between them when used in the same greenhouse without sanitary troubles. The objective was to identify harmful and beneficial insects in relation to the intercropping system. Weekly samplings using direct and indirect observations (Moericke traps) were made in a mixed bean and cucumber culture, from March of 1997 to March of 1998. The harmful insects associated with bean culture were: Picturaphis brasiliensis (Homoptera: Aphididae); Calliothrips phaseoli (Thysanoptera: Thripidae); Diabrotica speciosa, Cerotoma sp., Maecolaspis sp., Epilachna cacica (Coleoptera: Chrysomelidae); Dichelops furcatus, Nezara viridula (Hemiptera: Pentatomidae); Lagria villosa (Coleoptera: Lagriidae) and Urbanus proteus (Lepidoptera: Hesperiidae). Associated with cucumber were: Aphis gossypii (Homoptera: Aphididae); Diaphania nitidalis (Lepidoptera: Pyralidae); Pseudoplusia includens (Lepidoptera: Noctuidea); Frankliniella schultzei (Thysanoptera: Thripidae), Anastrepha grandis (Diptera: Tephritidae), Idiysus sobrinus (Heniptera: Neididae); Diabrotica speciosa, Epitrix sp. and Cerotoma sp. (Coleoptera: Chrysomelidae). The natural enemies against P. brasiliensis at the bean culture were Pseudodorus clavatus, another unidentified hoverfly (Diptera: Syrphidae) and Symmus argentinicus (Coleoptera: Coccinelidae). Predators of Aphis gossypii in cucumber culture were P. clavatus, Ocyptamus antiphates, Syrphus phaeostigma (Diptera. Syrphidae) and S. argentinicus (Coleoptera: Coccinelidae). As parasitoid we found: Diaeretiella rapae (Hymenoptera: Aphidiidae). Both cultures can grow in the same greenhouse, because the only common harmful insects were D. speciosa and Cerotoma sp. They are poliphagous and they do not produce important damages to those cultures, apart from that, P. clavatus and S. argentinicus were common natural enemies for both. Index term: harmful insects, beneficial insects, mixed cultures.

[0305] CICADELLIDAE (INSECTA-HOMOPTERA) SPECIES RICHNESS AND ABUNDANCE ON MAIZE IN ARGENTINA

S. Paradell¹, E. G. Virla² & A. Toledo¹, ¹ Dept. Cient. De Entomología, Fac. de Cs. Naturales y Museo de La Plata, Paseo del Bosque s/nº (1900) La Plata, Argentina, E-mail: paradell@museo.fcnym.unlp.edu.ar, ² CONICET. "INSUE", M. Lillo 205 (4000) S.M. de Tucumán, Argentina, E-mail: evirla@infovia.com.ar

Among the plant virus vector taxa known, 80% belongs to the Suborder Homoptera and between them, 70% correspond to the family Cicadellidae. Leafhoppers affect diverse cultivation, and particularly the maize (Zea mays), whose production is severely diminished by diseases of diverse etyology. Among these, the most important diseases are the "Corn Stunt Spiroplasm" and several phytoplasms that are transmitted, in persistent form, by leafhoppers of the genera *Dalbulus*, *Baldulus*, *Exitianus*, *Stirellus* and *Graminella*. In Argentina, the only known Cicadellidae species with vector capacity is Dalbulus maidis, an important pest in tropical and subtropical areas of America; but surely there are several other species involved in the epidemiology of the corn spiroplams or phytoplasm-bored diseases. Due to the importance of the diseases and the lack of information about the leafhopper fauna that inhabits maize crops in Argentina, a survey was carried out in order to know the species communities composition. The leafhoppers collected with entomological nets in 33 localities of 11 provinces of Argentina, during 1993-94, 94-95, 95-96 and 98-99, were examined in terms of species richness and abundance. Overall, 17 species were detected. The most abundant species is Empoasea curveola with (23%) of relative abundance, followed by Exitianus obscurinervis (20%), Haldorus sexpunctatus (19%), Dalbulus maidis (16%), Syncharina punctatissima (9%), Agalliana ensigera (4%) and Graminella puncticeps (1%). The study determines differences between areas, and fenological stages of maize; the information is shown in tables and maps. The known geographical distribution of Dalbulus maidis is enlarged. Index terms: Leafhoppers, maize, pests species.

Symposium and Poster Session

[0306] CHEMICAL CONTROL OF THE BOLLWEEVIL, ANTHONOMUS GRANDIS, WITH PYRETHROIDS

A. Pasini, M. U. Ventura & P. M. O. J. Neves, Depto. Agronomia, Univ. Estadual de Londrina, C.P. 6001, Londrina-PR, CEP 86051-970, Brasil. E-mail: pasini@uel.br

This study was conducted in a school farm at the State University of Londrina, Paraná, to verify the efficiency of pyrethroids in the control of bollweevil, Anthonomus grandis. The cotton variety IAC-22 was planted on 10/4/1996. It was employed the randomized complete block design with four replications and five treatments. Experimental units of 9 m by 8 m long with 0,9 m between rows was used. The following products were tested: Karate 50 CS (lambdacyhalothrin,15 g a.i./ha), Karate 250 CS (15 g a.i./ha), Karate 50CE (15 g a.i./ha), Decis 50 SC (Deltametrina, 10 g a.i./ha), Decis 25 CE (10 g a.i./ha). The applications was accomplished on 11/29/1996, 12/6/1996, 12/13/1996, 12/19/1996 and 1/3/1997. Data were submitted to analysis of variance and the means were classified by Tukey's multiple range test at 5% probability level. All the treatments with pyrethroids were efficient to control the bollweevil. However the largest efficiency were showed by the products: Karate 250, Karate 50 and Decis 50, employe in the formulations CS and SC, respectively.

Index terms: pyrethroids, Anthonomus grandis, cotton, chemical control.

[0308] MACROFAUNA OF THE SOIL IN DIFFERENT TILLAGE SYSTEMS, IN OXYSOL OF PARANÁ, BRAZIL

A. Pasini, N. P. Benito & E. P. Melo, Dept. of Agronomy, State Univ. of Londrina, P.O.BOX 6001, Zip Code 86051-970, Londrina, Paraná, Brasil. E-mail: pasini@uel.br

A study was conducted to analyze the biomass and the spineless macrofauna populational density of soil in different agricultural tillage systems, in an area with oxysol (latossolo roxo) in Bela Vista do Parafso, PR. The treatments were: conventional, no tillage and an area with forest. Sampling has been done using the method recommended by the Tropical Soil Biology and Feitility Programme. Five monoliths of soil (25x25x30 cm) were taken at regular 10 m intervals; each soil monolith was separated in three layers: 0-10cm, 10-20cm and 20-30cm, in two seasons of the year (wet and dry). The taxonomic groups more frequent were Oligochaeta, Hymenoptera, Coleoptera, Isoptera, Diplopoda, Chilopoda, Diptera, Hemiptera, Arachnid and Molluse. In the forest, the biomass and populational density, were superior statistical to the other treatments. However, conventional and no tillage systems were similar to each other.

Index terms: soil macrofauna, land management, latossolo, taxonomic richness.

[0307] CHEMICAL CONTROL OF THE VELVETBEAN CATERPILLAR, ANTICARSIA GEMMATALIS WITH PYRETHROIDS

A. Pasini, M. U. Ventura & P. M. O. J. Neves, Depto. Agronomia, Univ. Estadual de Londrina, C.P. 6001, Londrina-PR, CEP 86051-970, Brasil. E-mail: pasini@uel.br

Field experiments were conducted in Parana State, at the State University of Londrina, in Brasil to evaluate the efficiency of pyrethroids in the control of the velvetbean caterpillar, Anticarsia gemmatalis (Lepidoptera: Noctuidae). The variety BR-4 was planted on 10/22/96. Experimental units of 6m by 15m long, with 0.4m between rows was used. The applications was accomplished on 11/18/1996, in the vegetative stage. The following treatments were used: Karate 50 SC (lambdacyhalothrin, 3,75 g a.i./ha), Karate 250SC (3,75g a.i./ha), Karate 50 CE (3,75 g a.i./ha), Bulldock 125 SC (Betacyfluthrin, 2,5g a.i./ha) and Corsair 500 CE (Permethrin, 15,0 g a.i./ha). Four samples were taken in the central rows of each plot, being used ground cloth method. Data were submitted to analysis of variance and the means were classified by Tukey's multiple range test at 5% probability level. All the treatments with pyrethroids were efficient in the control of velvetbean caterpillar.

Index terms: pyrethroids, chemical control, Anticarsia gemmatalis, soybeans.

[0309] PEST IDENTIFICATION AND MONITORING ON A IRRIGATED AGRICULTURAL SYSTEM AT BAIXO ALENTEJO (PORTUGAL)

M. I. Patanita¹ & M. M. Pereira¹, ¹Escola Superior Agrária de Beja, Rua Pedro Sores, Apartado 158, 7801-902 Beja Portugal. E-mail: ipatanita@esab.ipbeja.pt

Changing the present extensive agricultural systems existing in Alentejo, into new and more productive irrigated systems, implies a deep knowledge of the crop systems used, its sequence in time and the local agricultural techniques in order to provide a greater profit to local farmers. The success of a well adapted crop system, for well-known climatic conditions and landscape structure is prone to imply, the correct knowledge of crop pests forecasts, its natural enemies and also about the multiple interactions that may be detected in such crop systems, between the crop, the crop enemies, their antagonists and their habitat. Integrated in a project of the technical and the economic viability of an irrigated crop system with cereals and field vegetable crops, which was based on Integrated Production guidelines, we have developed a fieldwork in order to: identify the most important pests problems for the crops considered in that project (tomato, wheat, sugar beet, maize and one cruciferous crop) and its natural enemies; and to study their populations dynamics, including the crop-pests -beneficial organisms-habitat interactions. For these purposes, we have monitoring the crops pests and their natural enemies using a lot of insect trap types, according to the insects features, the visual observation to detect the first infections, and also some of the existing and validated forecasting models for pests activity. The methodology used in this field followed as much as possible, the guidelines, the methods and the models published and approved by the International Organisation for Biological and Integrated Control of Noxious Animals and Plants/ West Palaearctic Regional Section (IOBC/WPRS) for Integrated Production.

Index Terms: irrigated crops, crop enemies, Integrated Production, pest monitoring.

[0310] LITCHI INSECT PESTS RESEARCH AND CONTROL

T. X. Peng ' & J. L. Xu², 'Guangdong Academy of Sciences, 100 Xian lie Rd. C.,Guangzhou 510070, China, E-mail txpeng@gis.sti.gd.cn; ²Guangdong Institute of Entomology, 105 Xingang Rd. West, Guangzhou 510260, China, E-mail jlxu@gei.gis.sti.gd.cn

The litchi tree is from China originally, and China has the history that the litchi is planted more than 2000 years. At present, no matter planting area of litchi and output, China all is the first in the world. In China, the litchi insect pests have 83 species which belonging to 7 orders, 30 families according to the investigations. Among them the important species are Tessaratoma papillosa, Aristobia testudo, Amplophora chinessis, Conopomorpha sinensis, Eriophyes litchii, Lepidarbela dea, Oxyodes scroliculata, Orgyia postica etc. The dominant litchi pests are belonging to Coloeptera, Heminoptera, Lepidoptera and Acarina which cause loss rate reaching 20 - 30% . A large number of insecticides used in the past many years for control litchi pests and the big areas of litchi trees linking planted, that makes the change of insect component in litchi garden. Some secondary pest rise to the primary position. Population dynamics of litchi pests changed obviously following seasons. Dominant species degree index D reaches to 0.8 or more from March to September every year and the highest value of diversity index H'= 4.1 by May and June ... The measurement of diversity index indicates that leaf surface>flower and fruit>trunk>underground pests , and H 'value of leaf surface reaches 4.0 .Most of insect pests concentrates occurring in new tip period , florescence and fruit period , thus influences to output seriously. China is the earliest country to study and use biological control for litchi pests. At the initial of 60's successfully has used Anastatus japonicas to control Tessaratoma pupillosa, and has established 1 set of method to culture and release Anastatus. At 80's in China Anastatus has been cultured with the artificial eggs and has been produced by machine. Entomopathogenic nematodes Steinernema carpocapsae has been used to control Aristobia testudo, Lepidarbela deu ,Zeuzea coffeae in a large area successfully, control efficacy reached to 80 - 96%. Recent years, the integrated pest management has been emphasized in the control of litchi pests , such as protecting natural enemies, improving agriculture ecosystem, reasonable using insecticides etc.

[0312] TOMATO LEAF SIZE AND CONSPECIFIC INTERACTION EFFECTS ON TUTA ABSOLUTA (MEYRICK) (LEPIDOPTERA: GELECHIDAE)

P. Perevra, Centro de Estudios Parasitológicos y de Vectores, Univ. Nacional de La Plata-CONICET, 2 No.584 (1900) La Plata, Argentina.

The leaf miner Tuta absoluta is a major pest of tomato crops in La Plata, Argentina. Intraspecific competition is an important cause of mortality for many microlepidopteran leaf miners as well as other sources of vertical mortality. The objective of this work is to explore whether or not the tomato leaf size influences intraspecific competition among individuals of this species. In particular I examine how variation in leaf size influences the abundance of larvae and mines, and how the density affects survival, pupal weight and developmental time. Tomato leaves (var. Platense) of various sizes were collected in the field and width, length and area of each leaf were measured. Tomato leaf areas were estimated from length and width of the leaf using the formula of the triangle area (R²=0.948; P<0.001; n=94). Significant positive correlations between the number of mines and leaf size (P< 0.001) and between the number of larvae and leaf size (P<0.001) were found. Leaf size, however explained 25,2 % of the variation in mines density per leaf and only 3.6 % of the variation of larval number per leaf. I also performed an experiment whereby females were allowed to oviposit on tomato plants with different leaf sizes. Individuals were followed until pupation and regression analysis were done to determine whether there were relationships between densities of eggs and larvae (number/per leaf cm²) and the survival, larval developmental time and pupal weight of individuals reared on leaves of known size. Density of eggs showed a negative relationship with larval survival $(R^2= 0.19, P < 0.05)$. Survival of larvae was not correlated with larger leaves $(R^2=0.03, P < 0.05)$. P>0.5). Pupal weight regressed on density of eggs showed a negative but non significant trend ($R^2 = 0.05$, P > 0.05). Larval developmental time showed a positive but non significant relationship with density of larvae (R²=0.10, P>0,05). Other regressions showed no relationships (i.e. larval density with pupal weight). Results from this analysis indicate that with increasing density of eggs, density-dependent mortality may be imposed by competition, in early instars among co-occurring larvae. However, results of correlation analysis of mines and larvae on leaf area showed that individuals of T. absoluta are not sedentary enough to be vulnerable to effects of intraspecific competition and they appear to be able to avoid nearby individuals leaving the mine and feeding in another one. Tomato leaf size does not appear to affect the performance of T. absoluta and could not be considered as a predictor of tomato susceptibility.

Index terms: Lycopersicum esculentum, tomato leaf miner, intraspecific competition, survival

[0311] EVALUATION OF POSSIBLE PLANT ASSOCIATIONS WITH STRAWBERRY: EFFECT ON THE TWO-SPOTTED MITE IN THE LABORATORY

<u>P. Perevra¹</u> & N. Greco¹, ¹Centro de Estudios Parasitológicos y de Vectores, Univ. Nacional de La Plata-CONICET, 2 No.584 (1900) La Plata, Argentina. E-mail: Erro! Indicador não definido., ngreco@netverk.com.ar.

Tetranychus urticae is an important pest of the strawberry crop in greenhouses in La Plata, Argentina. Chemical control of this pest is ineffective and promotes environmental and health problems. Associate host-plants to a main crop may contribute to increase diversity and to decrease herbivore pressure. In order to find an alternative control measure to acaricide use, the object of this study was to assess the effect of strawberry, onion, parsley, leek and chrysanthemum as possible intercropped plants, on the offspring and short distance movements of the two-spotted mite. The following experiments were performed using discs of leaves (1.8 cm diam): assessment of fecundity and maximum number of individuals / female, oviposition preference (number of eggs laid in a choice test), permanence of individuals (fate of females after 24 h) on different host-plants; and movements from strawberry leaves to other host-plants leaves and viceversa. Mean fecundity and maximum number of individuals of all developmental stages / female were higher on strawberry and lower on onion and leek (P<0.05). The choice test also showed a preference for strawberry followed by parsley, not only for the oviposition but in the persistence of the females as well (P<0.05). No displacements were found from strawberry to any other host-plant, but mites did migrate from leek to strawberry (P<0.05). The experiments showed that T. urticue performed better on strawberry leaves than on any other associated host-plant. However, it showed some preference for parsley, indicating that populations of the pest night be maintained on this plant. Parsley therefore does not appear to be a good associate host-plant since it can support the reproduction and development of the two-spotled spider mite. Neither could it be considered a crop trap because it is not more attractive than the main crop. Onion, chrysanthemum, and leek seem not to be suitable for the development of T. urticae. Chrysanthemum and onion need to be more deeply evaluated as host-plants. Mites did migrate from leek to strawberry, suggesting that leek should be rejected as associate host-plant. Onion seems to be a good associate host-plant: mites had a poor performance on it, and it did not promote migrations to strawberry. This study tries to explain the effect of the four associate host-plants as a whole, if they are cultivated with strawberry. Assays of this kind are useful for an early evaluation of possible associate host-plants to a main crop, since not all plants seems to be suitable for intercropping for a more sustainable crop production.

Index terms: Tetranychus urticae, Fragaria chiloensis x Ananassa, herbivory, intercropping, diversity

[0313] POPULATION DYNAMIC OF SCARLET MITE, *BREVIPALPUS PHOENICIS* AND ITS PREDATOR IN TEA AREA WHICH TREATED AND NON TREATED BY PESTICIDES

A. D. Permana¹, H. Pratiknyo² & S. Sastrodihardjo¹, ¹Department of Biology, Institut Teknologi Bandung, Ganesa 10, Bandung 40132, Indonesia. e-mail : agus@bi.itb.ac.id ; ²Faculty of Biology, University of Jenderal Soedirman, Purwokerto, Indonesia.

Brevipalpus Phoenicis Geijskes is one of the tea important pests in Indonesia. The economic injury level of this pest is 24 mites/tea-leaf. In this study, the diversity of predatory mites were identified, and the effect of pesticides on the population of scarlet nuite and predatory mites was investigated. The relative density of *B. Phoenicis* was also analyse. Result of this study indicated that six predatory mites were: Amblyseius deleoni Muma & Denmark; Proprioseiopsis cuflagelatus Karg; Phytoseiulus crinitus Swirski & Sheehter; Phytoseiulus persimilis Athias-Henriot; Zetzelia javanica Ehara & Oomen; Agistemus terminalis Quayle. The abudance of scarlet mite and predatory mites were higher in the area treated by pesticides than those in the area non-treated. Relative density of scarlet mite was not significant to the tea-leaf damage ($r \le 0.57$). This study also showed that the relative density of predatory mites was lower than that of scarlet mite, however, the tendency of the population dynamic of predatory mites succeeded the population of the scarlet mite, and naturally, the predatory mite could controlled the *B. Phoenicis*.

Index term: Brevipalpus Phoenicis, Amblyseius deleoni, Proprioseiopsis euflagelatus, Phytoseiulus crinitus, Phytoseiulus persimilis, Zetzelia javanica, Agistemus terminalis.

Session 02 - AGRICULTURAL ENTOMOLOGY

[0314] IDENTIFICATION OF PROTEOLYTIC ACTIVITY IN *BEMISIA TABACI* B TYPE (HOMOPTERA: ALEYRODIDAE)

T. Pham, D. R. Frohlich & <u>R. C. Rosell</u>, Biology Department, University of St. Thomas, 3800 Montrose Blvd., Houston, TX 77006 USA. Email: rrosell@stthom.edu.

Digestive system physiology is an important component in the ability of whiteflies to persistently transmit Begomoviruses to host plants. Whiteflies ingest phloem which contains sugars, amino acids, and free proteins, and, in virus-infected plants, proteincoated virus particles. Acquisition and passage of the infective virion in the whitefly digestive system is a critical component of begomovirus transmission. The transmissible form of Begomovirus is, as yet, unidentified. However, it has been shown that the coat protein is necessary for successful transmission, thus, the virion is postulated to be the transmissible form. As virions move through the digestive system of the whitefly, they may never encounter digestive system proteases, or if proteases are present, may in someway be protected from digestion or resistant to the vector's proteases. Recent studies have reported that whiteflies ingest and metabolize plant proteins which suggests that proteolytic activity is present in the whitefly digestive system. We used casein substrate plate assays to identify enzymatic activity in whiteflies and found that proteolytic activity was detectable and quantifiable in whole body whitefly extracts. Preliminary studies demonstrated protease activity at pH 5.5, but not at pH 7.4, and no inhibition with several trypsin and chymotrypsin inhibitors: N-α-p-tosyl-L-lysine chloromethyl ketone (TLCK), soybean trypsin inhibitor (SBTI), bovine pancreas trypsin inhibitor (BPTI), lima bean trypsin inhibitor (LBTI), and chicken egg white trypsin inhibitor (CEWTI). Because proteolytic activity of whitefly extracts was detected at pH 5.5, we suspected that the observed enzymatic activity was cysteine proteinase-like. Cysteine proteinases are common in the midgut of Hemiptera and Heteroptera. Based on these data and comparable information from other Homoptera, a putative identification of cysteine protease was made. Herein we report spectrophotometric and inhibitor data with specific cysteine protease substrates and inhibitors.

Index terms: whitefly, proteases, cysteine proteases, virus-vector

[0316] SAMPLING DISTRIBUTION PATTERNS OF *RACHIPLUSIA NU* (LEPIDOPTERA: NOCTUIDAE) AND DESIGN OF SAMPLE PLANS

M. C. Plazas, J. D. Edelstein, E. V. Trumper & M. A. Linares, Sección Entomología, E.E.A. Manfredi, INTA, Ruta Nacional 9 Km 636, (5988) Manfredi, Córdoba, ARGENTINA, E-Mail: etrumper@arnet.com.ar

Rachiplusia nu (Lepidoptera: Noctuidae) is one of the most common defoliating larvae present in soybean crops in Córdoba Province, Argentina. Its incidence fluctuates over different growing seasons but it frequently motivates the application of insecticides to prevent economic losses. An economic threshold has been proposed but sampling protocols have not been developed yet to make precise assessment of pest abundance, neither for estimating density nor for decision making. The aim of this work was to describe the sampling distribution of R. nu larval stages and to develop and evaluate sampling plans. An intensive sampling program was carried out during three growing seasons in soybean fields in a central area of Córdoba Province, Argentina. The vertical cloth technique was used. On each sampling date, 30 to 40 sampling units were collected at random. More than one hundred samples were taken along the three growing seasons. Larvae were grouped according to size in three stages: small, medium and large. Taylor's power law (TPL), Iwao's patchiness regression model (IPR) and Bliss & Owen's technique (BO) were used to describe the distribution of sample data. The following parameters, were estimated: a and b (TPL); α and β (IPR) and $1/K_c$.(BO). The last four parameters are regarded as describers of sample distribution patterns. a, b, α and β were used to obtain minimum sample size curves and sequential sampling critical lines, with known predicted precision levels, according to Green's and Kuno's models. Iwao's β and Taylor's b ranged between 1.15 and 1.39 and 1.13 and 1.3, respectively, suggesting a slight aggregation pattern of sample data. The estimated $1/K_c$ for medium and large larvae were used to calculate Wald's Sequential Probability Ratio Test critical lines. Operating Characteristic and Average Sample Numbers functions were obtained to analyse the performance of sampling plans. Validation of sampling plans is preliminary assessed with independent data, using a resampling software.

Index terms: Soybean looper, distribution patterns, sequential sampling.

[0315] RELATIONSHIP BETWEEN THE ARTIFICIAL INFESTATION OF DIATRAEA SACCHARALIS EGGS AND THE DAMAGE IN SUGARCANE STALKS

<u>A. de S. Pinto¹</u>, J. R. P. Parra² & H. N. de Oliveira², ¹C. U. Moura Lacerda, Ribeirão Preto-SP, Brazil, E-mail aspinn@uol.com.br; ²Dep. Entomol., Fitop. e Zool. Agrícola, ESALQ-USP, 13418-900, Piracicaba-SP, Brasil.

The relationship between the artificial infestation of *Diatraea saccharalis* eggs (Fabr., 1794) and the damage in sugarcane stalks was studied in commercial sugarcane fields in Piracicaba and Araras, SP, Brazil from 1996 through 1998 in different varieties and phenological stages of the plant. Three experiments were set up at different times. A direct relationship occurred between the number of eggs of the sugarcane borer per unit area and the intensity of damage in stalks, with the latter being influenced by several factors such as egg predation and weather conditions. Predation was directly proportional to the number of eggs on artificial infestation of D. saccharalis under field conditions. The studies on artificial infestation of the sugarcane borer must use areas with infestation points with low egg density, which can be achieved by using older females in the cages attached to the plants in which they lay fewer egg masses.

Index terms: sugarcane borer, sugarcane pest, IPM

[0317] MASS REARING AND RESISTANCE SCREENING TECHNIQUES FOR HE BEAN STEM MAGGOT (*OPHIOMYIA* SPP.)

H. du Plessis₁ & U. du Plessis₂, ARC - Grain Crops Inst., Private Bag X1251, Potchefstroom, 2520, South Africa. E-mail: hanalene@igg2.agric.za.

The common bean (Phaseolus vulgaris) is an important source of protein in Africa, but is prone to severe attacks by bean stem maggot (BSM). Yield losses of up to 100 % have been reported. Three species of BSM occur in Africa, namely Ophiomyia phaseoli, O. spencerrella and O. centrosematis. The distribution and importance of the three species vary with location and season. Resource-poor farmers suffer most as they have limited access to additional inputs such as insecticides and fertilisers. There is, therefor an urgent need for high-yielding pest resistant varieties. However, breeding for resistance is slow as plant breeders have to rely on natural infestations of BSM only. Mass rearing of BSM could provide sufficient numbers of insects for infestation of breeding material and accurate screening for resistance. The aim of the study was to develop techniques for mass rearing of BSM as well as to develop screening techniques. Collection of BSM was done by cutting off bean stems infected with larvae and pupae beneath the leaves. These stem cuttings were kept in cages in a greenhouse and moistened daily. Emerging flies were collected, transferred to an outdoor cage and reared on cowpea (Vigna unguiculata). These cages of different sizes provided for different screening options that included preliminary screening of beans in pots to estimate feeding preference under field conditions. Seedlings in trays placed in the rearing cage were infested by flies from the mass rearing colony and subsequently planted into a screening cage, where they were screened for tolerance. Beans planted directly in screening cages could be inoculated by a specific number of flies collected from the stock colony in the rearing cage and screened for tolerance under field conditions. The advantages of these techniques are that they are cost-effective, not labour intensive, do not need skilled people as with artificial rearing under laboratory conditions and screening for resistance can be conducted under field conditions. Key words: Ophiomyia spp., Phaseolus vulgaris, resistance breeding

[0318] *NYSIUS NATALENSIS (HETEROPTERA: LYGAEIDAE*) – A NEW PEST OF SUNFLOWER (*HELIANTHUS ANNUUS* L.) IN SOUTTI AFRICA

H. du Plessis ARC - Grain Crops Inst., Private Bag X1251, Potchefstroom, 2520, South Africa. E-mail: hanalene@igg2.agric.za.

Nysius natalensis (Heteroptera: Lygaeidae) is a new pest of sunflower in South Africa. The genus Nysius is cosmopolitan and attacks a wide variety of cultivated plants and weeds, but different species are confined to specific regions. A few species is known to damage grain crops. Nysius huttoni damages wheat in New Zealand. Sunflower is damaged by N. vinitor as well as N. clevelandensis in Australia and N. inconspicuus in India and Pakistan. In South Africa, occurrence of N. natalensis populations is sporadic and unpredictable. The insects occur on weeds such as Portulaca oleracea and Amaranthus hybridus from where invasion of sunflower occurs during the budding stage and from anthesis onwards. Damage concurs with those inflicted by other Nysius species in Australia and Pakistan. During the budding stage, some plants wilt and die while others appear unharmed. Damage to seeds results in a reduction of yield, oil content and poor germination of damaged seeds. South African sunflower producers are remunerated according to oil content of their crop and damage by these insects therefore results in a direct loss. Sunflower seed producers experience biggest losses because their total harvests are unacceptable as seed. The most vulnerable period of sunflower to attack by N. natalensis is from anthesis onwards, which is also the period when pollination by bees is important. Problems are experienced with chemical control on sunflower seed multiplications due to the toxicity of most insecticides to bees. Key words: Nysius natalensis, Helianthus annuus, damage

[0319] THE ECOLOGICAL ROLE OF NATURAL HEDGES ON LEAFHOPPERS POPULATIONS IN VINEYARDS OF CENTRAL ITALY

L. Ponti & C. Ricci, Dept. of Arboriculture and Plant Protection, Faculty of Agriculture, Univ. of Perugia, Borgo XX Giugno, 06121 Perugia, ITALY, E-mail cricci@unipg.it.

Hedges and other landscape features have received significant attention in Europe regarding their effects on arthropod distribution and abundance in adjacent fields. In many cases natural vegetation around crop fields harbours alternate host or prey for natural enemies, thus providing seasonal resources to bridge gaps in the life cycles of entomophagous insects and crop pests. As regards the green grape leafhopper Empoasca vitis and its egg parasitoid wasp Anagrus atomus, wild vegetation is hypothesised to enhance the effectiveness of this parasitoid. In fact natural vegetation around vineyards provides an alternative leafhopper to A. atomus during the winter. E. vitis is considered a severe problem in the vineyards of northern Italy, but it is not a major pest in central Italy. This difference seems to be linked with a loss of floral diversity and landscape features in northern Italy. Our study is the first that compares population dynamics of leafhoppers and their natural enemies both within vineyards and in natural hedges. During two years monitoring of the adults was carried out weekly by mean of yellow sticky traps, while nymphs were sampled every week by direct count on leaves. Movement of the leafhopphers and their parasitoids between natural vegetation and cultivated fields were also studied, by the only mean of yellow sticky traps. We surveyed different types of natural edges, mainly Rubus sp. and Ulmus sp. Our data show that these hedges act as natural biofactories in agroecosystems. We also describe non-ampelophagous leafhoppers species supported by natural hedges. These leafhoppers bridge the gaps in biological cycles of ampelophagous ones, providing alternative hosts to egg parasitoids. Our study highlights the key role played by Zygina rhamni, which is correctly called the true Italian grape leafhopper, and Rubus sp. hedges, in reducing damage by E. vitis. In this way we confirm the hypothesis of a pre-agriculture grape-Rubus association. Our data suggest that existing diversity in the agroecosystem is more likely to have an influence for stability than newly created diversity, adding importance to the study of traditional agriculture in order to design agroecosystems that are both productive and resource conserving. Index terms: Empoasca vitis, Zygina rhamni, Anagrus atomus, hedges, landscape

[0320] STATUS OF PEST CONTROL IN CENTRAL EUROPE

R. Pospischil, Bayer AG, Animal Health, R & D, Clinical Development, 51368 Leverkusen, Germany

The living standard has changed dramatically since the middle of the 20th century in Central Europe with increasing prosperity and progress. Modern buildings with central heating, carpet floors and insulation are responsible for a constantly warm temperature conditions. Extensive food production areas and an intensive world trade are also responsable for the establishment of tropical pests in the temperate zones. Hygiene pests were introduced to Europe with man thousands of years ago. However, due to the cold temperatures in winter time most species could not easily establish. Modern life style with constantly convenient temperatures indoors even in winter gave many tropical and subtropical species a chance to survive after their introduction to Europe. Disease transmission grew to a severe problem especially in sensitive areas like the food processing industry and in hospitals. Allergic reactions to indoor pests (eg cockroaches, house dust mites) have become more and more important over the last thirty years. Due to their high reproduction rate and fast development some hygiene pest have become resistant to commonly used insecticides (eg Musca domestica). Modern pest control has to recognize this situation and to keep an eye on new invadors. In the past the pest control operator had to focus on pest control only - now his task is to manage pest problems according to the rules of integrated pest management. His main task should be to prevent pest problems with monitoring, sanitation and physical systems. When control is required, the PCO has to develop a strategy, which does not harm the environment, e.g. in sensitive areas like hospitals or food processing industry. Control strategies are discussed using the example of cockroaches, which have become an immense problem on the European continent. Modern pest control strategies against these species include products which were especially developed for sensitive areas. Such areas include restaurants, supermarkets, hospitals, nursing homes, schools, hotels, food processing industry, aircraft and others. The sprays which were used in the last decades are now being replaced more and more by cockroach gels, cockroach baits which are offered in special bait boxes, and larvicides. Cockroach gels allow a very targeted application close to the cockroach population. Very little active ingredient needs to be applied to achieve an amazing result. Modern gels have a residual efficacy which lasts up to one year or longer. Pest management will continue to be an important task with prevention being the most important aspect. PCO's should be aware of the fact that introduction and establishment of new species may occur at any time. Pest control should be carried out with an appropriate formulation which was developed for the pest species and situation. Mallis A (1997): Handbook of pestcontrol, 8th edition, Mallis Handbook & Technical Training Company, 1456pp; Pospischil R (1998): Einschleppung von Schädlingen nach Mitteleuropa. Pest Control

[0321] EGG DEVELOPMENT IN *DIATRAEA SACCHARALIS* (LEPIDOPTERA: PYRALIDAE) UNDER DIFFERENT TEMPERATURE REGIMES

M. J. Prola, M. Moré, F. Fava & <u>E. V. Trumper</u>, Sección Entomología, E.E.A. Manfredi, INTA, Ruta Nacional Nro. 9 Km 636, (5988) Manfredi, Provincia de Córdoba, ARGENTINA, E-mail: etrumper@arnet.com.ar

Diatraea saccharalis (Lepidoptera: Pyralidae) is one of the most damaging pests to corn crops in most of the maize growing areas in Argentina. Apart from the recent, availability of transgenic hybrids that cover a small proportion of the cultivated area, traditional management tactics include early harvest, rotations with non host crops and the most frequently recommended, chemical control based on a nominal egg incidence of about 20% as a decision rule. However, insecticides have been regarded as inefficient so far. Chemical control could be significantly improved provided a better understanding of the pest dynamics is gained. One aspect on which a quantitatively based tactic can be designed is the precise estimation of time remaining to egg hatch from a field sample. This work concentrate on the temperature dependent development of eggs. Through maturation, eggs show changes in pigmentation and "colour sub-stages" can be identified. It was assumed that these colour sub-stages take constant time from oviposition, at a given temperature regime. The objective of this work was to estimate the temperature-dependent development time of the complete egg stage and each colour sub-stage. Adult females were captured with light traps and maintained in paper bags to induce deposition of egg masses, which were then carefully collected and put in Pert dishes, in climatic chambers at different constant temperatures. Additional sets of eggs put in small green carton cards were clipped on corn leaves in the field (fluctuating temperature regime). All eggs were observed daily. Changes in colour and egg hatch were recorded. At each temperature, development times were fairly constant, although some variability was observed both within and between egg masses. Different empirical and biological models were fitted to describe the variation of the mean time from egg deposition to yellow, orange, and brown sub-stages and complete mean egg development time, as a function of temperature, with high correlation coefficient. The potential contribution of these results to optimisation of chemical control timing is discussed.

Index terms: corn borer, development rate, developmental models, maize.

[0322] DIFFERENT PESTICIDE APPLICATION METHODS IN CONTROL OF WHITEFLY AND LEAFMINER ON TOMATO PLANTS UNDER VINYL HOUSE

C. G. Raetano¹, F. J. Bengozi¹ & M. R. Kobayashi¹, ¹Dept. of Crop Production, State Univ. of São Paulo, P. O. Box 237, Botucatu, SP, 18603-970, Brazil, E-mail raetano@fca.unesp.br

The objective of this works was to contrast the effects of two insecticide application methods, conventional spraying (400 to 800 L/ha) and reduced-volume application (90 L/ha) in control of Bemisia sp. and Tuta absoluta on tomato plants under vinyl house. The experiment was conducted in two adjacent commercial vinyl house, with 0.05 ha each, located in Botucatu, SP, Brazil. Four different insecticides tank mixture treatments were applied with a hand held knapsack sprayer (Jacto SA) consisting of a simple lance three Db hollow nozzle type at the end on plants under one vinyl house and a thermal fog generator, Swingfog SN 50 type, another vinyl house. The treatments: imidacloprid + betacyflutrin (21.0 + 2.50 g), imidacloprid + teflubenzuron (21.0 + 3.75 g), acephate + betacyflutrin (75.0 + 2.50 g) and imidacloprid + methomyl (21.0 + 21.5 g) of a. i./100 L of water were applied at the seventeen days of October, 1997 and replicated at three days intervals with nine applications in the total. Samples, consisted of twenty five leaflets each, were randomly removed from the upper third of the canopy of the plants from each vinyl house for these insects evaluations. The number of whitefly nymph per leaflets were evaluated on underside surface in the upper third of the canopy in two application conditions. Similarly the number of actives miners inside leaf mines were monitored in this position of canopy in two vinyl house. The different application methods showed equivalent control levels of whitefly at 33 days after the first application, but the greatest control levels were obtained with conventional spraying (93.3 and 84.7%, respectively) at 7 and 14 days. The efficiency in control of leafminer with thermal fog generator was greater than in the conventional spraying during the most period of the experiment, but your maximum efficiency was 68.7%.

Index terms: Bemisia sp., chemical control, Tuta absoluta, spraying.

[0323] INFLUENCE OF DIFFERENT APPLICATION METHODS AND DOSAGES OF THIAMETHOXAM IN THRIPS CONTROL

C.G. Raetano¹, W.R. Kuwahara¹, R.R. Vinchi¹ & M.R. Kobayashi¹, ¹Dept. of Crop Production, State Univ. of São Paulo, P. O. Box 237, Botucatu, SP, 18603-970, Brazil, Email raetano@fca.unesp.br.

The thrips *Frankliniella schultzei* Trybom (Thysanoptera: Thripidae) is one of the most important vector species of tomato spotted wilt tospovirus (TSWV) in Brazil. Two different pesticide application methods were evaluated with thiamethoxam (Actara 250 WG) insecticide in thrips control on tomato field. A completely random experiment was set up to evaluate this purpose. One knapsack sprayer was used in the thiamethoxam application with a simple lance one JD 14-2 hollow nozzle type or modified lance at the end for spray or drench application, respectively. Dosages of 150 and 200 g of a. i. were used in just one drench application and 50 g of a. i. per hectare (ha) sprayed at weekly intervals, fourty eight days after seeding. The efficacy of this insecticide was compared with diafenthiuron (400 g of a. i./ha), profenofos + cypermethrin (320 + 32 g of a. i./ha, respectively) and methamidophos (60 g of a. i. per hectolitre of water) in spray application. The mean cumulative number of plants with tospoviruses did not permit the identification of significative differences between thiamethoxam application methods and dosages on *F. schultzei* twenty four days after application, showing advantage for just one drench application. The efficacy of thiamethoxam insecticide tor 93 to 95% for this vector thrips of TSWV, independent of the application method and doses. Diafenthiuron and profenofos + cypermethrin showed less efficacy (78 and 88%, respectively) but greater than those with methamidophos (71%). The products and doses in the test did not lead to verification of phytotoxicity symptoms in tomato plants.

Index terms: Frankliniella schultzei, chemical control, drench application.

[0324] BT CORN IN CONTROLING ECB IN CROATIA

<u>E.Raspudiœ</u>¹, M.Ivezić¹ & I. Lovrinčević², ¹Univ. of J. J. Strossmayera in Osijek, Faculti of Agriculture in Osijek, Trg sv, Trojstva 3, 31000 Osijek, Croatia, e-mail remilija@suncokret.pfos.hr ²Croatian Agricultural Extension Service, Valpovačka ulica 2, 31222 Bizovac, Croatia.

In Croatia corn is grown on approximately 350,000 ha and ECB is one of the permanent corn pests. Attack intensity was 58% in the period 1995-1999. Its control has practically not been carried out. In 1998 and 1999 Bt corn hybrids of selection firm Pioneer were subjected to the investigation carried out on several localities in Eastern part of Croalia. Hybrids Landia Bt, Evelina Bt, Clarica Bt were under study and compared to the same hybrids without built-in gene. In the maturity stage period corn dissection was carried out aining at determination of ECB attack intensity, number of tunnels and caterpillars per plant, stem damage length and obtained yield. In 1998 ECB attack intensity with Landia hybrid amounted to 98%, Landia Bt 21%, and Evelina 51% whereas Evelina Bt was not attacked by ECB. In 1999 hybrids Evelina and Clarica were investigated on two localities. Average ECB attack with Evelina was 87%, Evelina Bt 11%, Clarica 89% and Clarica Bt 7%. Hybrid Landia had 5 tunnels and 1 caterpillar per plant wheres stem damage length was 21 cm. Only 0.25 tunnels and 0.04 caterpillar per plant were determined with hybrid Landia Bt whereas stem damage was 0.45 cm. Average stem damage on hybrid Evelina was 3 cm with two tunnels and 0.42 caterpillar in 1999. As for hybrid Evelina Bt, the stern damage amounted to 0.29 in length, with 0.93 tunnels and 0.012 caterpillar. Hybrid Clarica with average ECB attack of 89%, per stem had 2 tunnels and 0.52 caterpillar whereas damage length was 6 cm. Clarica Bt had attack intensity of 7%, 0.73 tunnels and 0.008 caterpillar per plant whereas damage stem amounted to 0.23 cm. Corn kernel yield with Eveline Bt and Landie Bt was higher whereas with Clarica Bt it was lower by 36 kg/ha compared to standard hybrids. Bt corn hybrid use showed attack intensity decrease of ECB and other plant damage parameters. In our country there are no legal regulations of transgenic plants use since many organizations are against transgenic plants spreading. Index terms: Ostrinia nubilalis, GMO, intensity of attack

[0325] SAMPLING PARASITIC EGGS OF PHYTOPHAGOUS STINKBUGS IN SOYBEAN [*GLYCINE MAX* (L). MERRIL] CROPS IN THE SOUTHWEST REGION OF GOIAS

<u>J.F. Rattes¹</u>, Fesurv/Esucarv. Caixa Postal 104. Cep: 75901-970 Rio Verde-GO. E-mail: rattes@fesurv.br.

Eggs of phytophagous stinkbugs were sampled in soybean crops in the southwest area of Goiás. It was performed in Rio Verde, Jataí and Santo Antônio da Barra counties in February and March, during the planting season of years 1995/96, 1996/97 e 1997/98. Natural incidence of parasitoids, its host preferences, population fluctuation and the main species occurring in the area were evaluated. High rates of natural parasitism were verified. The scored results were 77,34% (1995/96); 77,48% (1996/97); 61,49% (1997/98) for the host species Euschistus heros and 63,83% (1995/96); 78,27% (1996/97); 61,86% (1997/98) for the host species Peizodorus ghildinii. Among the parasitoid species sampled, Telenomus podisi (Scelionidae) was the most common, achieving parasitism levels of 95% and 100% (1995/96); 85,5% and 97,0% (1996/97); and 95,8% and 95,5% (1997/98) for *E.* heros and *P. guildinii*, respectively. The determined frequencies of *Neorileyn* sp. (Eurytomidae) parasitism in host eggs were 100% for N. viridula, 14,5% for F. heros and 3% for P. guildinii in 1996/97. Frequencies of Trissolcus brochymenae and Trissolcus basalis (Scelionidae) were small, lower than 5%. The average indexes of natural parasitism observed in the region were 65,88% in 1995/96; 73,73% in 1996/97 and 61,80% in 1997/98. It demonstrates the high potential for biological control, showing that this natural control must be preserved in soybean crop areas. It might be achieved by the adoption of cultural and phytosanitary practices which affect as less as possible the population of these biological agents.

Index terms: Insecta, biological control, paraside

[0326] ENHANCED CHEMICAL CONTROL OF NEZARA VRIDULA USING UNCONVENTIONAL SPRAYING TECHNOLOGY

C.C.M.Resta, Departamento de Agronomia, Universidade Estadual de Londrina, Caixa postal 6001, Londrina, PR CEP 86051-990, Brasil, E-mail cesarmarre@hotmail.com

The stink bug Nezara viridula (Heteroptera: Pentatornidae) is one of the most relevant pests in soybeans. Its chemical control is sometimes unsuccessful due to its habit of being hidden inside soybeans foliage. Besides, it presents high mobility in the crop. The present study aimed to evaluate the efficacy of insecticides in the control of stink bug by two types of nozzles : conejet visiflo steel (TXVS 4 - hollow cone) and twinjet (TJ 11002 - even double fan). Two experiments were carried out in Sertanopolis PR, Brazil, in 1998 following strictly the guidelines and official recommendations from Brazilian Soybeans Research Committee according to the integrated pest management (IPM) procedures. Each field trial was sprayed with the same insecticides and doses but with different nozzles. After the sprayings, periodic evaluations were done by counting live stink bugs (nymphs larger than 0.5 cm long and adults) collected in 2 meters long between soybeans rows by using a cloth with two sticks attached by its edges (pliable cloth). The treatments were endosulfan 35% EC at 437.5 and 525 g of a.i. / ha, endosulfan 50% SC at 400 and 500 g of a.i. / ha, monocrotophos 40% EC at 150 g of a.i. / ha and control. The best results were obtained with TJ 11002 nozzles decreasing drastically the pest population. TJ 11002 nozzles improved the efficacy of all insecticides taking into consideration their mode of action. No fitotoxicity was observed. Index terms : soybeans, insecticides, conejet, twiniet, behavior.

[0328] BASIL-TOMATO INTERCROPPING EFFECT ON MACROSIPHUM EUPHORBIAE (HEMIPTERA: APHIDIDAE) ABUNDANCE

S. M. Rodríguez, ¹, P. I. Carrizo³, S. Clemente¹, A.M. Folcia¹, S.Panzardi¹ & M.Yaber Grass³, ¹Cátedra de Zoología Agrícola, ² Cátedra de Química Orgánica Fac. de Agronomía, Univ. de Buenos Aires. Av. San Martín 4453 (1417). Be. As. Argentina. 3 Cátedra de Zoología Agrícola, Fac. de Ciencias Agrarias y Forestales, Univ. de La Plata. Calle 60 y 119 (1900) La Plata, Bs. As., Argentina. E-mail: silro@mail.agr.uba.ar

Intercropping may reduce herviborous population on crop, in relation to single crop, by means of direct or indirect effects. If mixture has an aromatic species, essential oils might add its influence on main crop pests. The aim of this work was to determine the influence of basil on *Macrosiphum euphorbiae* (Hemiptera: Aphididae) abundance on tomato. It was analyzed in two levels: for aromatic presence itself, and because of essential oil. The trial was carried out in experimental plots - free from weeds and mites - at Agricultural Faculty. They were two treatments: T1: basil-tomato intercropping, and T2: tomato (n=5); plots were $9m^2$, and a completelly randomized design. Samples were taken weekly and sampling unit was a single plant. ANVA was performed (α =0,05 y 0,01), for total aphids/plant, by each sampling date. In order to determine essential oils, there were taken basil plants - one by plot and sampling date The extraction was carried out for disillition with vapor. Meaningful differences were obtained only in first sampling date (T1:10 aphids / plant; T2:6,4 aphids / plant). In earlier samplings, the amount of essential oils seemed to produce some effect on aphids abundance. It was not possible to establish any relationship for later sampling dates.

[0327] IMPACT OF *DIURAPHIS NOXIA* (HOMOPTERA: APHIDIDAE) ON WHEAT YIELD

M.E. Reviriego¹, L.R. Descamps¹& <u>A.A. Suarez²</u>, ¹Univ. Nac. Del Sur, San Andrés S/N, (8000) Bahía Blanca, Argentina, e-mail Errol Indicador não definido. ²E.E.A.INTA Anguil, Ruta Nac. N°5 Km 580, C.C. 11, (6326) Anguil, La Pampa, Argentina; e-mail Errol Indicador não definido..

Russian wheat aphid (RWA) is an important pest in the wheat growing aerea of Argentina. The objective of this experiment was to determine the impact of RWA on wheat yield under field conditions. A randomized complete block design with four replications was used. Plots were treated with Clorpirifos 48% (400cc/ha) at different wheat growing stages. The treatments were: control (no insecticide application), always treated (insect free) and treated from a)tillering, b)jointing, c)boot stage, d)heading, c) milk and f)dough. Aphid numbers, grain yield, spiklets per head, kernels per head, seed weight, seed germination and protein content were determined for each plot. The data obtained were analized using PROC ANOVA and means were compared using Means / LSD test (P=0.05) (SAS Institute, 1988). RWA infestations reduced wheat yield, seed protein content, seed weight and number of seeds per head. Index terms: Russian wheat aphid, damage, wheat.

[0329] SPATIAL DISTRIBUTION OF THE COFFEE BERRY BORER HYPOTHENEMUS HAMPEI ON COFFEE TREES, ANS ITS IMPLICATIONS FOR SAMPLING

R. Ruiz¹, A.E. Bustillo¹ & P.S. Baker², ¹Centro Nacional de Investigaciones de Café, A.A. 2427, Manizales, Colombia. E-mail: rreardeu@carpa.ciagri.usp.br ; ²CABI bioscience, Silwood Park, Ascot SL57TA, UK

An important aspect of controlling any insect is to understand their movements. The coffee berry borer (CBB) is one of the most serious pests of commercial coffee, threatening a production of about 15 billion dollars per year worldwide. A descriptive analysis on the distribution of its attack along 4 years (1995-98) in a coffee plot censused monthly, located in the central colombian zone, allowed to identify several phases into the advance of the infestation; so, at the plot level, infestation started very slowly, and the proportion of infested trees was below 5% for the first 7 months of observation. However, during next two months, infestation increased very quickly as much in percentage of perforated fruits, as in the proportion of infested trees, the latter increasing it to 70%, promoved probably for horers arriving from plots which were cut down for those days, located at least at 300 m from the experimental area. The highest level of infestation was reached at sept/97 (98.2% of infested trees), after of lowest rain and humidity periods generated by "El niño". Counts of bored fruits fitted the negative binomial distribution in 29 of 40 dates, with k values ranging between 0.0129 and 1.3511, but it was not possible to find a k common value for all dates; besides it was discontinuity in the fitting through consecutive dates. Fitting of counts to Taylor's power law was significative in all cases showing a spatial pattern generally aggregated (b values between 1.25 and 2.18). Variability study for both, total and bored fruits, at both, tree and branch level, was always significantly bigger (F<0.05) for the latter. It was a explicit trend of CBB to distribute it as following the distribution of coffee berries through the time, which occupy a progressively greater space as the tree produces more branches and nodes, constituting one of the fundamental problems of controlling this pest. Significantly higher density of CBB were found on the nodes nearest to main stem in each branch. A function describing the behavior of infestation in agreement with the age of berries was fitted following a geometric model. In conclusion, the spatial and temporal pattern of CBB attack is predicated upon the complex architecture and phenology of coffee plant, and the unpredictable rainfall pattern, which determine flowering and development of fruits. Index terms: Dispersion, IPM, Scolytidae, Taylor's power law.

[0330] PRESENCE OF HYPSIPYLA GRANDELLA IN THE STATE OF TAMAULIPAS, MÉXICO

<u>E. Ruíz-Cancino¹</u>, J.M. Coronado-Blanco¹ & L. Durán-Estrada², ¹UAM Agronomía y Ciencias, UAT. Cd. Victoria, Tam., 87149. México; ²SEDUE, Gobierno del Estado de Tamaulipas, Cd. Victoria, Tam., México.

One of the most important species of tropical wood is the red cedar Cedrella odorata (Meliaceae), this tree is present in the Gulf of México states and southern Mexican states. In Tamaulipas, this species has been used by several decades in the South zone of the state and now the State Goverment is promoting the cultivation. C. odorata has several pest species in México, the most important is Hypsipyla grandella, the red cedar borer. Moreover, the ant Atta cephalotes, the termites Coptotermes crassus and Heterotermes aureus convexinotatus, the bark beetles Xyleborus volvulus and X. ferrugineus, and the buprestid Chrysobothris yucatanensis are also present. Earlier, H. grandella was recorded from the following states: Veracruz, Tabasco, Campeche, Yucatán, Chiapas, Oaxaca and Quintana Roo. This pest attacks also Carapa guianensis, Guarea tonduzzi, Sweitenia humilis, S. macrophyla, and Trichilia spp. The last tree, was recorded from Gómez Farías, Tamaulipas, but without H. grandella attack. In August, 1999, small red cedar plants from the State Goverment nursery were detected with some borer damage. Then, the plants were taked to the Laboratory of Biological Control in the UAM Agronomía y Ciencias, UAT, where were put under observation in cages to wait the emergence of the adult pest. H. grandella typical damage was observed in the apical shoot: the larva bored the stem and take out the excrement, involving them with silk at the top of the tunnel, the shoot is folded and later dries. Two weeks later the moth emerged, being determined as H. grandella. So, this is the first record of the presence of H. grandella in Tamaulipas, and also the northernmost record about its distribution in the country. This material is deposited in the Insects Museum of UAM Agronomía y Ciencias, UAT, in Cd. Victoria, Tam., México.

Index terms: Lepidoptera, Pyralidae, red cedar borer

[0331] SCALE INSECTS OF CITRUS IN ITALY (HOMOPTERA COCCOIDEA)

<u>A. Russo</u>, S. Longo, G. Mazzeo & P. Suma, Dip. di Scienze e Tecnologie Fitosanitarie, Univ. di Catania, Via Valdisavoia 5, 95123 Italy, E-mail agarusso@mbox.unict.it

The number of scale insects living on Citrus in Italy is still increasing, in relation to a better taxonomic knowledge and continuous introductions of exotic species. Targioni Tozzetti (1881) listed 4 species, subsequently Silvestri (1933) reported 11, Lupo (1959) 13, Barbagallo (1980) 17 and Longo et al. (1994) 24 taxa respectively. They are: 1 Monophlebidae, 5 Pseudococcidae, 9 Coccidae and 9 Diaspididae, but only a few of them are really injurious in citrus orchards. The most dangerous scale insect in Italian citrus cultivation is the California red scale, Aonidiella aurantii (Maskell), restricted for a lot of years to lemon but now widespread on orange and mandarin. Pheromone traps for males flights monitoring together with climatic data have been recently used in I.P.M. programs, in order to produce forecasting models useful to define a good period for spraying insecticide; inundative releases of the parasitoid *Aphytis melinus* De Bach have been also done. As to the other armored scales, Lepidosaphes gloverii (Packard) is still a problem only in restricted coastal areas where the entomophagous Encarsia herndoni (Girault) is not present. Aspidiotus nerii Bouchè is a pest of lemon, bergamot and cedar. Less important are Parlatoria pergandei Comstock, P. zizyphi Lucas, Aonidiella citrina (Coquillet), Lepidosaphes beckii (Newmann) and Unaspis yanonensis (Kuwana). Chrysomphalus dictyospermi (Morgan) is now very rare on citrus. Among the mealybugs, Planococcus citri Risso infests all citrus cultivar, reaching high population level during late summer. Actually a successful biological control has been achieved with the introduction of exotic natural enemies as Leptomastix dactylopii (Howard), spraying at the same time chemicals in the ants nests. For this species, males flights have been also monitored in I.P.M. programs. Pseudococcus affinis (Maskell), Ps. calceolarie (Maskell), Ps. longispinus Targioni Tozzetti are occasionally present in low density and produce no damages. Phenacoccus madeirensis Green is a recently introduced species recorded also on ornamental citrus plants. The Coccidae Ceroplastes rusci (L.) and C. sinensis Del Guercio, reach sometimes high infestation level in citrus orchards, while C. japonicus Green is fortunately restricted to the Northern and Central part of Italy where citrus are not so diffused. The other soft scale Coccus hesperidum L., C. pseudomagnoliarum (Kuwana), Saissetia coffeae (Walker) and S. oleae (Oliver) are not primary pests. Parthenolecanium persicae (F.) and Pulvinaria floccifera (Westwood) are only occasionally recorded in citrus orchards. The Monophlebidae *Icerya purchasi* Maskell could be a problem only where I.G.R. have been used, reducing the ladybird *Rodolia cardinalis* (Mulsant) activity. Index terms: Monophlebidae, Pseudococcidae, Coccidae, Diaspididae, I.P.M.

[0332] ATTRACTION OF SHOOT BORER, CHILO INFUSCATELLUS, DAMAGED SUGARCANE TO THE BRACONID COTESIA FLAVIPES

K. P. Salin, N. Mukunthan, R. Nirmala & Y. S. Goud, Sugarcane Breeding Institute, Coimbatore - 641 007, India E-mail: sugaris@md3.vsnl.net.in

The attractancy of sugarcane plants damaged by the shoot borer, Chilo infuscatellus and its frass to Cotesia flavipes, an oligo parasitoid of sugarcane internode borer, Chilo sacchariphagus indicus and sorghum borer Chilo partellus, was examined in the laboratory. The experiments were conducted in 20cm dia petriplates and a 'Y' tube olfactometer with freshly emerged mated females of C. flavipes reared on C. infuscatellus over ten generations. In one set of experiment in 'Y' tube fresh shoot borer frass and cotton wool (control) formed the treatments and in the second set of experiments shoot borer damaged plants and undamaged plants formed the treatments. A total of 935 females were subjected to observation. Behavioural observations in the petriplates were conducted with fresh frass and cotton ball impregnated with extracted plant volatiles, one at a time. Results indicated that significantly (p=0.025) more number of parasitoids were attracted towards both frass (62.2%) and damaged plants (57.6%) implying involvement of chemicals derived from the salivary secretions and faecal matter in the frass and active production of synomone by the herbivore damaged plants. The parasitoid exhibited distinct behavioural response of increased turning movements and antennal drumming when it came very close to the frass. Behavioural response to the plant volatiles extracted using adsorbents was similar except that the tendency to tunnel through the plant volatile, in cotton wool, was absent. The parasitoid seems to use the highly volatile synomone produced by the plant as a long distance cue to locate the damaged plant in a mosaic of damaged and undamaged plants and on landing the damaged plants, the frass derived low volatile chemicals serve as short distance cue to home in on the host larva actively feeding inside the plant. C. flavipes parasitises the larva feeding inside the tunnel. The chemicals in the frass induce the parasitoid to tunnel through the frass and parasitise the host larva. High parasitisation rate is often associated with the corresponding high host density. In high host density situations the chances of encounter with host is high, thus increasing the parasitoid efficiency. In situations where host density is not adequate to retain and increase the foraging, augmentation of the chemical cues by external application or by engineering the plants to produce synamones in response to the synamone produced by the damaged plants might increase the parasitisation rate.

Index terms: Cotesia flavipes, Chilo infuscatellus, C. sacchariphagus indicus, C. partellus.

[0333] BUMBLEBEE FORAGING ACTIVITY AT GREENHOUSE TOMATO CROP WITH DIFFERENT POLLINATOR DENSITY

E. Salvado¹, S. Albano¹, F. Amaro² & A. Mexia³, ¹Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal; ²Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, DEESA, Quinta do Marquês, 2780 Oeiras fernandamaro@isa.utl.pt; ³Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras amexia@isa.utl.pt

General aspects of hive activity and behavioural foraging of bumblebecs (Bombus terrestris) had been compared in two greenhouses with different densities of pollinators (1 hive/900m² and 1 hive/1600m²). The number of foragers in activity on the crop did not differ significantly (α =0.05) in the two greenhouses, as well as the number of visits received by each flower. In the greenhouse with higher density, all the resources were explored along the day in the intense way. However, in the greenhouse with lesser pollinators density the foraging activity showed a higher frequency of visits to the upper clusters during the hours of the day when the availability of pollen was higher (beginning of the day). In the afternoon period it was registered an exchange forwards the inferior clusters flowers. Each colony adjusted his activity in accordance with available resources in each one of the greenhouses: the total number of hive entrances and the number of hive entrances with pollen baskets were significantly higher in the greenhouse with smaller density. Concerning the individual behaviour of foragers, no significant differences were detected either in duration and number of visits per minute or interflower time. In the greenhouse with higher pollinators density, the colony development and longevity was affected by the smaller amount of available pollen to the colony. Index terms: Bombus terrestris, pollinator efficiency

[0334] PATTERN OF BUMBLEBEE VISITS TO GREENHOUSE MUSKMELON FLOWERS

E. Salvado¹, S. Albano¹ & J. Cadima², ¹Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal; ²Instituto Superior de Agronomia, Departamento de Matemática, Tapada da Ajuda, 13449-017, Lisboa, Portugal.

The characterisation of visits made by bumblebees (Bombus terrestris) must be based on quantitative aspects as well as some qualitative aspects. In that order, the time spent per muskmelon flower was recorded and the scraping movements of the mouthparts during each visit was also registered, whenever visible. Other information about the forager were recorded, like presence/absence of pollen baskets on posterior legs, kind of visit (directed towards the nectar or not) and type of visited flower (staminate or hermaphroditic).The high number of visits directed towards the nectar (99.10%) and high number of individuals visiting flowers without presenting pollen baskets (71,40%) indicated that the main resource collected in muskmelon flowers was the nectar. The mouthparts scraping behaviour, detected in 11.32% of the visits, was more frequent in the morning (21.80%) that in the afternoon (18.10%). This fact can indicate that the morning visits involves the processing of higher quantities of pollen. This behaviour can be advantageous to the plants, especially during the period of higher stigma receptivity (morning), because it facilitates the pollen dropping on them. The average of time per flower was 3.89 ± 0.10 s. In spite of the higher volume of nectar presented by hermaphroditic flower presents, it was observed that time per flower is significantly smaller (α = 0.05) in this case than in staminate flowers. Under the studied conditions, during the sampling process, each bumblebee should record information about nectar level in the surrounding flowers and, since depletion was never accentuated, the bumblebees adopted to make more frequent visits other than to invest on longer visits to the few hermaphroditic flowers. Visit durations decreased along the day as a result of depletion that occurs in the flowers, during the day. In the afternoon, each bumblebee increased its pollination rate decreasing time per visit and increasing the number of visited flowers per minute. The highest time per visit occurred in the first days of this study decreasing in the following days as far as the pollinators did learn the better way of muskmelon for exploitation of muskmelon flowers. Index terms: Bombus terrestris, Cucumis melo, pollinator behaviour.

[0336] FACTORS AFFECTING QUALITY OF ALFALFA-LEAFCUTTING BEE COCOONS IN SOUTHERN BUENOS AIRES PROVINCE, ARGENTINA

E. San Román¹, <u>N. J. Cazzaniga</u>¹ & E. C. Santamaría², ¹Depto. de Biología, Bioquímica y Farmacia, Universidad Nacional del Sur, San Juan 670, RA-8000 Bahía Blanca, Argentina, E-mail: sanroman@criba.edu.ar, ficazzan@criba.edu.ar; ²Vicente López 160, RA-8000 Bahía Blanca, Argentina.

More than 10 000 tons of alfalfa seeds are sown per year in Argentina, but despite the availability of wide areas suitable for alfalfa production, the country is still far away from self-sufficiency. Annual crops of 500 kg/ha were common 50 years ago at Hilario Ascasubi, in the South of the province of Buenos Aires; yields have reduced to about 60 kg/ha afterward as a consequence of the decimation of wild pollinators. The introduction of the alfalfa-leafcutting bee, Megachile rotundata, in the 70's promised the reversal of this decreasing trend. Since then, local farmers attempted to produce bees with variable results, but they have not been able to increase, or even maintain their populations for several years, so that they have to import new pre-pupae from USA or Canada almost every year; this increases production costs and causes reduced and/or late emergence of the bees, because the transportation from North to South hemisphere determines a shortening of the necessary period of low temperature storage. We present here the results of analyses conducted during the last three years, to determine the quality of cocoons obtained locally from uni- and bivoltine lines of Megachile rotundata, as compared to the imported ones. Cocoons were opened and inspected under binocular microscope and their contents were assigned to one of ten categories: healthy pre-imaginal bee; parasitized; discolor; attacked by nest destroyers; chalkbrood disease (caused by Ascosphaera aggregata); moulds; empty cell; second generation adult; pollen ball; other causes. In the first year, a high incidence of chalkbrood (18 %), and of second generation adults (14 %) was detected in bivoltine leafcutter bees reared locally; these values had decreased significantly two years later as a result of improved management procedures, though viability is still well below that of imported pre-pupae. Multivariate analysis showed that the factors responsible for the poor quality of local cocoons do not define a clear pattern, and that the sanitary condition of the univoltine bees remained closer to the high quality imported cocoons.

Index terms: Megachile rotundata, Hymenoptera, pollinators, management

[0335] EVALUATION OF DOSES OF IMIDACLOPRID AND THIAMETHOXAN AS SEED TREATMENT ON APHID CONTROL IN WHEAT

J.R. Salvadori, Embrapa-National Wheat Research Center, Cx. P. 451, 99001-970 Passo Fundo, RS, Brazil. E.mail jrsalva@cnpt.embrapa.br

Although wheat aphids (Hemiptera, Aphididae) are well controlled by biological agents in Brazil, especially by microhymenopterous parasitoids, they can still cause direct damage in some wheat cropping areas and indirect damage, mainly as vectors of Barley Yellow Dwarf Virus. Two experiments with two seed dressing treatments, imidaeloprid and thiamethoxan insecticides, were carried out in 1999 to evaluate aphid control, yield, and other agronomic characteristics of wheat. Both experiments consisted of seven treatments, i.e., three doses of each insecticide (24.5, 35.0, and 52.5 g a.i./100 kg of seeds) and a control without insecticide, replicated four times. The first experiment was conducted in greenhouse conditions. The experimental unit consisted of one jar with ten plants, in a completely randomized design. The jars were infested with five-winged adult aphids (Schizaphis graminum) per plant at 7, 14, 21, 28, 35, and 42 days after plant emergence. At each period of seven days the number of aphids was counted and the jar reinfested. At each fourteen-day period the jars were replaced by new ones with the same treatments. The second experiment was carried out in the field in a complete randomized block design. The wheat plots measured 6.0 m x 6.4 m. Aphid infestation was natural and consisted of Metopolophium dirhodum, Sitobion avenae, and Rhopalosiphum padi. The results were submitted to analysis of variance and the means compared by Tukey test. Although the greenhouse results showed differences between doses, both insecticides were efficient in controlling S. graminum up to 49 days after plant emergence. The field experiment showed no statistical difference between treatments probably due to the low number of aphids observed in the experiment.

Index terms: Metopolophium dirhodum, Schizaphis graminum, Sitobion avenae, Rhopalosiphum padi, insecticides. [0337] STUDY OF SIMULIIDAE (DIPTERA: NEMATOCERA) AND ITS BREEDING AREAS IN A STREAM OF THE MUNICIPAL DISTRICT OF "SANTO ANTÔNIO DO TAUÁ", STATE OF PARÁ, EASTERN AMAZONIA, BRAZIL

E. M. Santos¹ & I. S. Gorayeb², Dept. of Zoology, Museu Paraense Emílio Goeldi, Av. Perimetral 1901, Belém, Pará, Brazil. E-mail: ¹ emerson@museu-goeldi.br; ² gorayeb@museu-goeldi.br.

The black flies are of great importance under the bioecological, medical, and veterinarian point-of-views. The objectives of this study are to register the species of simulids and its breeding sites, besides the associated aquatic fauna and flora in the Tauá stream, municipal district of Santo Antonio do Tauá, Pará, Brazil; to characterize the abiotic factors of the water; to study the activity and abundance of anthropophilics species; and to correlate with microclimate parameters. These data will be obtained in two times of the year, characteristics of the rainy and dry seasons. For the rainy period, we made a collection in the stream and registered the occurrence of the following species: Simulium quadrifidum, S. perflavum and S. aequifurcatum (= incrustatum), and we made the checklist for the aquatic entomofauna, with registrations of: Chironomidae (Diptera), Hydropsychidae (Trichoptera), Perlidae (Plecoptera), Coenagrionidae and Libellulidae (Odonata), Naucoridae and Gerridae (Hemiptera), Corydalidae (Megaloptera), Baetidae (Ephemeroptera). The small vegetation strips adjacent to the course of the stream samples great wealth and prevalence of Leguminosae and Melastomataceae, besides the individuals occurrence within vertical stratum of high dossel (25 to 30m) and a total of 116 species. It was also observed among the bed flora the predominance of aquatic macrophytes as Urospatha sagittifolia (Araceae), Cabomba aquatica (Cabonaceae), Ninphaea gardineriana (Ninphaeaceae), vegetation that functions as substratum and influences the habitat for the existence of many immature forms, mainly that of black flies. We noted the periodicity of S. aequifurcatum (= incrustatum) in attack activity to the man, in elapsing of one day, with anthropophilic peaks correlated to a temperature around 26°C, relative humidity of the air in 99% and high brightness, with two main peaks, one in the morning and another in the afternoon, without the interference of rains. Index terms: Simulium, bioecology, entomofauna, abjotic factors

Session 02 - AGRICULTURAL ENTOMOLOGY

[0338] BASELINE SUSCEPTIBILITY OF SPODOPTERA FRUGIPERDA (LEPIDOPTERA: NOCTUIDAE) POPULATIONS TO LUFENURON IN BRAZIL

F. B. Schmidt, R. B. Silva & C. Omoto, Depte. de Entomologia, Fitopatologia e Zoologia Agrícola, Escola Superior de Agricultura "Luiz de Queiroz", Av. Páduas Dias, 11, 13418-900 Piracicaba, SP, Brasil, E-mail: fbschmid@carpa.ciagri.usp.br.

Lufenuron is a newly benzoylphenyl urea chitin synthesis inhibitor insecticide. The use of this compound to control Spodoptera frugiperda, a major corn pest in Brazil, has increased significantly in the last years. This increase can be attributed to its high activity against S. frugiperda and to the reduction of efficacy due to resistance to some traditional insecticides (such as organophosphates, carbamates and pyrethroids) recommended for controlling this pest. In this study, a baseline susceptibility data of S. frugiperda populations to lufenuron were obtained for implementing a proactive resistance management program. An artifical diet treatment surface bioassay was used to characterize the response to lufenuron in a susceptible strain. Third instar larvae were exposed to the treated diet up to 4 days. Diagnostic concentrations of 3.2 and 10.0 up of lufenuron/mL of distilled water were chosen for monitoring resistance. Field populations of S. frugiperda were collected from major corn-growing regions located in the States of Rio Grande do Sul, Paraná, São Paulo, Goiás and Minas Gerais. Preliminary results showed some significant differences in susceptibility to lufenuron among S. flugiperda populations. Laboratory selection studies are in progress in attempt to isolate lufenuronresistant individuals for characterizing the intensity of the resistance. These findings indicate the urgent need for an implementation of resistance management strategies to preserve the lifetime of lufenuron for controlling S. frugiperda in Brazil. Index terms: fall armyworm, insecticide resistance, insect growth regulator

[0340] SURVEY OF ARTHROPODS IN TWO SEEDING SYSTEMS OF SORGHUM (SORGHUM BICOLOR (L.) MOENCH)

R.C.A.S. Seffrin¹ & <u>E.C. Costa</u>¹, iDepto. de Defesa Fitossanitária. Centro de Ciências Rurais -- Universidade Federal de Santa Maria, Campus Universitário, prédio 42, 1º andar, 3225 -- CEP 97105-900 -- Santa Maria -- RS -- Brasil -- e-mail: eccosta@ccr.ufsm.br.

This work had as objetive the quali-quantitative survey of arthropods in conventional and no till system of sorghum (*Sorghum bicelor* (L.) Moench). This research was conducted during 1996/97 season in "Campus" at University of Santa Maria, Rio Grande do Sut, Brazil. The population of arthoropods was collected by soil trap, soil extractor, sweeping trap, packing of panicles, atractive coloured trays and visual evaluation of insects in plants. The total number of arthropods was 14.512. They were classified into five classes, 12 orders, 35 families and 43 species. The Insecta was the most significant class in both conventional seed planting and no till system. Both systems showed no influence on total number of arthropods. However, the population of arthropods was most expressive in the no till system.

Key words: collect methods; no till system; tillage systems

[0339] CHANGING POLICIES AND PRIORITIES: THE EVOLUTION OF LOCUST MANAGEMENT PRACTICES FOR AFRICA

A. C. Schroeder

Locust and other emergency pest management policies have changed over the past 100 years. This is particularly true in Africa, where the lion's share of the world's emergency pest and locust management resources are spent, and where the risk from over-dependence on pesticides is high. Locust plagues can be prevented but rarely controlled. New policies aim to reduce the amounts spent on emergency management measures by preventing outbreaks from occurring. African Ministries of Agriculture staff and farmers are better trained to identify and report upsurges. New environmentally friendly biological control agents are nearing the end of the research pipeline, and may soon be used to control primary outbreaks, and replace older generation pesticides. Donor countries are requiring more and better verification of the severity of damage due to outbreaks as well as the potential for impacts on farmer and national food security. Economic analyses are being required to justify the investment in large and expensive pesticide and material-dependant campaigns. Donor coordination through the United Nations' Food and Agriculture

Organization has improved with the development of new rapid response mechanisms in the descrt locust primary breeding areas. Donors, such as USAID are in the process of cleaning up stocks of obsolete pesticides left over from past campaigns. Africau Ministries of Agriculture are in the process of drafting regulations and training staff on the safe import, handling and use of pesticides, with the aim of using the most environmentally benign pesticide for each situation. And,

improvements in infrastructure, local policy, and communications assist in the rapid assessment of outbreaks and their damage, to determine the best means of control needed, if any.

Index: management of migrant pests, plagues, farmer training

[0341] THIAMETHOXAM USED AS SEED TREATMENT (CRUISER[®]/ADAGE[®]), OR AS SOIL APPLICATION (ACTARA/PLATINUM[®])

R. Senn, D. Hofer, F. Brandl, L. Zang & A. Morcos, Novartis Crop Protection AG, CH-4058 Basel Switzerland, E-mail: robert.senn @cp.novartis.com, dieter.hofer@cp.novartis.com

Thiamethoxam is a novel broad-spectrum insecticide currently marketed by Novartis Crop Protection. The molecule belongs to a new chemical class - the neonicotinoids. Neonicotinoids have a new mode of action interfering with the nicotinic acetylcholine receptor of the nervous system of insects. Thiamethoxam is highly active on a broad spectrum of insects. Compared to the most important competitor in the same chemical class, thiamethoxam can be used at lower dose rate to achieve the same or even higher level control effects with longer lasting activity. The main features that clearly differentiate thiamethoxam from its competitors are the ideal water solubility of 4100 mg/l and the negative log P value of -0.13. Thiamethoxam is neither adsorbed to the organic matter nor affected by normal soil pH values of 5.5 to 8.1 nor by organic matter content of 2-20%. Thiamethoxam is used as seed treatment under the trade names CRUISER® /AGADE® or as soil and foliar application under the trade names ACTARA[®]/PLATINUM[®]. The unique technical advantages of CRUJSER[®]/AGADE[®] may be separated into 3 general areas: robust performance under different climatic conditions; strong initial crop vigor which results in increased yield effects; and carryover of treated seed. Each of these unique technical advantages provides added value to crop genetics, farmers and environment. CRUISER®/AGADE[®] shows excellent performance of seed safety on seeds carried over from one season into the next. Canola seed for example can be stored for at least 18 months without loosing viability and germination power. ACTARA®/PLATINUM® used as soil application methods such as into drip irrigation system injection, in furrow spray, drench after transplanting, side dress or seedling dip, are suitable methods to control broad spectrum of insect pests over an extended period. The best placement of thiamethoxam is in the root zone, which means 2-4 cm below the sowing line at planting. In order to reach the root zone, thiamethoxam should be incorporated. Product placement and irrigation have to be combined in a way that the water will lead the compound to the root zone. Main advantages of ACTARA®/PLATINUM® used in any soil application method are the long time protection, the protection of the whole plant including the new growth and its convenient application.

Index terms: Thiamethoxam, Cruiser, Actara

[0342] COMPARISON OF CITRUS SPECIES AS HOSTS FOR CITRUS LEAF MINER *PHYLLOCNISTIS CITRELLA* (LEPIDOPTERA: GRACHLARIDAE)

A. A. Serai, Plant Protection Department, Shahid Chamran University, Ahvaz, I. I. Iran.Email: aseraj@ahvazuni.neda.net.ir

The relationship between ovipositional preference of *Phyllocnistis citrella* (Lepidoptera: Gracillaridae) and host plant suitability on seven citrus species: *Citrus aurantifolia* (Rutales: Rutaceae), (Mexican lime), *C. sinensis* (Valencia orange), *C. sinensis* (L.) Osbeck Siavaraze Variety, *C.reticulata* Blanco King Variety) *C. reticulata* Blanco Willowleaf Variety (Kinnow mandarin), Citrus volkamerina (Volkamer lemon), Citrus *aurantium* (Sour orange), *Citrus paradisis* Macf. Red Blush Variety (Grape fruit) were determined by measuring numbering larvae per 10 leaves and percentage of mined leaves after adult female moths were given a simultaneous choice and non choice of all citrus species for oviposition. All studies were performed under ambient conditions. *P. citrella* istinct hierarchical ordering in the ovipositional preference with mexican lime, sour, valencia and siavaraze oranges and kinnow mandarin being preferred overall others. Index terms: Grapefruit, lime, citrus leaf miner, sour orange. [0344] STALKBORER DAMAGE AND ESTIMATION OF LOSSES CAUSED BY SESAMIA SPP. (LEPIDOPTERA: NOCTUIDAE) IN KHUZESTAN SUGARCANE INDUSTRY

A. A. Seraj, Ali Asghar Seraj, Plant Protection Department, Shahid Chamran University, Ahvaz, I. I. Itan. E-mail: ascraj@ahvazuni.neda.net.ir

Sesania spp. (Lepidoptera : Noctuidae) are serious pests of sugar cane in the Khuzestan and damage about 20% of stalks annually. Field studies on S. cretica Led. damage and potential crop losses on two important cultivars in the region, NCo 310 and CP 57-614 were carried out at southern Khuzestan state between 1998-1999. CP 57-614 showed greater mean percentage of bored nodes and internodes (20.7%) than in NCo 310 (11-2%). Apart from the direct losses in cane weight (cane yield) due to boring from the larvae, cane juice quality is also adversely affected, resulting in lower recovery of sucrose in the factory. Sugar per ton also was greater in NCo 310 (132 kg) than in CP 57-614 (110 kg). Estimated sugar losses were 0.11 tones ha⁻¹ for every 1% bored and rotting stalks. Other indirect losses are also discussed.

Index terms: Sesamia cretica, sugarcane, pol., brix.

[0343] EFECTS OF SOME INSECTICIDS AND PETROLEUM SPRAY OILS ON THE CONTROL OF CITRUS LEAF MINER IN KHUZESTAN STATE AND REVIEW OF ITS IPM

<u>A. A. Seraj</u>, Ali Asghar Seraj, Plant Protection Department, Shahid Chamran University, Ahvaz, I. I. Iran. E-mail: aseraj@ahvazuni.neda.net.ir

Citrus leaf miner (CLM) Phyllocnistis citrella control in citrus integrated pest management was evaluated during three years (1995 - 98) in Khuzestan district on different citrus cultivars as follows: Citrus sinensis (Rutales: Rutaceae), C.reticulata Blanco King Variety, C. reticulata Blanco Willow leaf Variety C. aurantifolia and C. paradisi Macfadyen Red Blush Variety. Five species of eulophid wasps were reared from the larvae and pupae of CLM. Low levels of parasitism were recorded in sprayed treatments compare to control. Permethrin, Danitol and Carbaryl provided good control for CLM within two weeks after spray, but Diazinon was no more effective. Chemical control of CLM adults would be difficult because of their prolonged and overlapping emergence and may require multiple sprays. Oils significantly suppressed leaf miner infestations. Mean number of larvae per 10 leaves in 0.5%, 2% (v/v) oils treatments and control in different citrus cultivars were respectively as follows (1st week after spray): Lime: 0.15, 0.17 & 3.2, Grapefruit: 0.1, 0, & 1, Valencia orange: 0.5, 0.3, & 2.1 and Kinnow mandarin: 0, 0, & 2.1. Combining the oil with pesticides did not reduce its efficacy against the pest. The ability to mix them will allow spray application costs to be reduced Index terms: natural enemies, lime, Phyllocnistis citrella

[0345] USE OF PETROLEUM SPRAY OILS FOR CONTROL OF CITRUS LEAF MINER AND SAP-SUCKING PESTS OF CITRUS IN SOUTHERN IRAN

<u>A. A. Scraj</u>, Plant Protection Department, Shahid Chamran University, Ahvaz, I. I. Iran. E-mail: aseraj@ahvazuni.neda.net.ir

Oils are an essential component of integrated pest management programs for citrus based on the use of natural enemies. The efficacies of 0.5% and 2% (v/v) petroleum spray oils (volk oil) for the control of citrus leaf miner (*Phyllocnistis citrella* Stainton were determined in spring 1997. Both oils significantly suppressed leaf miner infestations to similar levels. Mean number of larvae per 10 leaves in 0.5%, 2% oils, copper oxychloride 35% wp + oil and control treatments in different citrus cultivars were respectively as follows (1st week after spray): Sour Lime: 0.15, 0.17, 0 & 3.2, Grapefruit: 0.1, 0, 0 & 1, Valencia Orange: 0.5, 0.3, 0.14 & 2.1 and Kinnow Mandarin: 0, 0, 0 & 2.1. Combining the oil with copper fungicide did not reduce its efficacy against the leaf miner. The ability to mix them will allow spray application costs to be reduced. Oils are used to control pests such as scale insects, aphids, and mites when natural enemies are ineffective. Oils offer 4 major advantages over broad-spectrum pesticides: They may be handled without protective clothing; they have low toxicity to vertebrate animals; they have little detrimental effect on beneficial insects and pests cannot develop resistance. Petroleum oils act as an ovipositional deterrent to the pests.

Index terms: Petroleum spray oils, copper fungicides

[0346] BIOLOGY AND REPRODUCTIVE ASPECTS OF *PIEZODORUS GUILDINII* (HEMIPTERA: PENTATOMIDAE) UNDER LABORATORY CONDITIONS

G. Serra¹ & <u>N. C. La Porta</u>¹, ¹ Dep. of Vegetal Protection, Faculty of Agricultural Cs., Univ. of Córdoba, C. C. 509, 5000 Cba, Argentina, E-mail Erro! Indicador não definido.

Piezodorus guildinii is an important pest on many vegetable species including soybean and alfalfa crops. A cohort study was conducted under controlled laboratory conditions: $24,9 \pm 0.5 \,^{\circ}$ C; $53,6 \pm 7.9 \,^{\circ}$ R RH and 16 h L. Insects were fed with fresh fruits of *Phaseolus vulgaris*. Aspects of the life cycle, reproduction and mortality of this hemipterous were evaluated. The following parameters were estimated: the net reproductive rate (Ro), the generation time (T), the intrinsic rate of natural increase (r), reproductive value (V_x) and the finite rate of increase (λ). The following results were obtained: first - instar nymphs hatched from eggs in 4.91 \pm 0.22 days and the percentage of emergence was $87 \pm 17 \,^{\circ}$; nymphs completed their development in 27 days, showing a mortality of 60.1 $^{\circ}$, the greatest occurring in the fifth nymphal instar. Mean number of eggs per female was 43,4; mean fecundity was 4.4 egg masses per female with an average of 9.5 eggs per mass. Adult longevity averaged $58,2 \pm 41,3$ and $67,2 \pm 48,8$ days, for males and females, respectively. No significant differences (p=0.05) were observed between sexes. Other results were Ro= 7,48 females/ female; T=95,9 days; r= 0,0209 / day; λ = 1,02 females/ female. The reproductive value (V_x) showed two definite peaks: 22,1 and 24 at 77 and 133 days, respectively, from egg hatch.

Index terms: Piezodorus guildinii, biology, survival, reproduction

[0348] CHEMICAL CONTROL OF "WHITE FLY", *BEMISIA ARGENTIFOLII* (HEMIPTERA: ALEYRODIDAE) WITH CALYPSO 480 SC (THIACLOPRID), CONFIDOR 700 GRDA (IMIDACLOPRID0) E CONFIDOR 200SC (IMIDACLOPRID) IN EGG PLANT CROP, *SOLANUM MELONGENA*

A.C. Silva¹, R.S. de Mendonça² & L.O. Salgado¹, ¹ Agroteste-Pesquisa e Consultoria, P.O.Box 201, Lavras, MG, Brazil, Zip Code 37.200-000, E-mail: agrotest@ufla.br, ² Inst. de Ciências Agrárias, Univ. de Alfenas/UNIFENAS, P.O. Box 23, Alfenas, MG, Brazil, Zip Code 37.130-000, E-mail: fileni@artefinal.com.br

A serious damage occur in Brazil due to "white fly" in many crops, including cgg plant crop. This way, the efficiency of the farm chemicals Caypso 480 SC, Confidor 700 GRDA and Confidor 200 SC to control white fly *B. argentifolii* on egg plant was evaluated at Uberlândia City, Minas Gerais State, Brazil. The trial was set up during February up to April, 1998. The experiment design was the randomized blocks with 9 treatments and 4 replications. Each plot had 32.4 m^2 with 36 plants. Three application in spray method were realized to the treatments 1, 2, 3 and 8 and just one application in sidedress method was realized to the treatments 4, 5, 6 and 7. The efficiency of the treatments was evaluated according to the number of alive nymphs per samples of 12 leaves per plant. It was used the Abbott formula as a measure of efficiency and means were separated by Tukey test (p<0,05). As a whole of five evaluations where done during the observation period. Index terms: Hemiptera, Aleyrodidae, insecticides, white fly

[0347] CHEMICAL CONTROL OF "WHITE FLY", BEMISIA ARGENTIFOLII (HEMIPTERA: ALEYRODIDAE) WITH CALYPSO 480 SC (THIACLOPRID), CONFIDOR 700 GRDA (IMIDACLOPRID) E CONFIDOR 200SC (IMIDACLOPRID) IN PAPRIKA CROP, CAPSICUM ANNUUM

A.C. Silva¹, R.S. de Mendonça² & L.O. Box 23, Alfenas, MG, Brazil, Zip Code 37.130-000, E-mail: fileni@artefinal.com.br

White fly became an important pest for several crops in Brazil so the focus of this study was to evaluated the efficiency of the commercial product (c.p.) Calypso and Confidor to control *B. argentifolii* in paprika crop. The trial was set up at the Uberländia City, Minas Gerais State, Brazil, during December, 1998 up to February, 1999. The experiment design was the randomized blocks with 9 treatments and 4 replications. Each plot had 16.80 m² with 24 plants. The efficiency of the treatment was evaluated according to the numbers of alive nymphs per samples of 15 leaves per plot. It was used the Abbott formula as a measure of efficiency and means were separated by Tukey test (p<0,05). As a whole of three evaluation were done during the observation period and the results are presents in the Table 1.

Index terms: Hemiptera, Aleyrodidae, insecticides, Capsicum annuum.

[0349] EVALUATION OF THE THIAMETHOXAN IN THE CONTROL OF "RICE WATER WEEVIL" ORYZOPHAGUS ORYZAE (COLEOPTERA-CURCULIONIDAE)

<u>R.F.P.</u> da Silva¹ & J.V.Oliveira², ¹Dept. de Fitossanidade, Univ. Federal do Rio Grande do Sul, Cx.P. 776, Porto Alegre,RS, CEP 90001-970,Brasil, E-mail: rogeriop@vortex.ufrgs.br; ²Instituto Riograndense do Arroz/EEA, Cx.P. 29CEP 94930-030, Cachoeirinha,RS, Brasil

Considering the Brazilian agriculture as whole, the culture of rice gets prominence not only by its social, economic and commercial importance, by also by its area of cultivation, both in flooded and dry farming systems. The breeding cultivars for flooded system showed potential for grain yield up to seven tons/ha in the last fifteen years. However, the damaging effects may negatively impact rice production. Insect pests have contributed significantly to decrease the grain yield by qualitative and quantitative damage to this culture. The "rice water weevil" Oryzophagus oryzae is an important pest of rice. It's control, due to the aquatic behavior, usually requires high amount of toxic insecticides, The objective this work is to encounter news alternatives with low toxicity to superior animals and efficient to pest. The research was carried out on the crop season of 1999/2000, at the experiment station of Instituto Riograndense do Arroz, Cachoeirinha, RS. The rice cultivar IRGA-417, very susceptible to O. oryzae, was sown in nov.16.1999. Each plot consisted of 11 rows with 2-m lenght and 0.2 m spacing, covered by an iron structure with 2.0x2.0x0.3 m. The design was randomized blocks with four replicates. The area was irrigated 23 days after sowing and level of water kept at 15 cm to facilitate the chemical's dilution. The thiamethoxan insecticide was applied in three formulation. Actara 250 WG was sprayed before irrigation and applied by "benzedura" method three days after irrigation, using about 200 and 40 L of mix/ha, respectively. The formulation granulate (Actara GRI) and standard (carbofuran), were mixed to 100 g of fine sand and spread through the plots with saltcellar, 27 days after irrigation. The treatment with thiamethoxan was applied to seeds too by planting time. Evaluation was done at four and 13 days after applying granulated products, corresponding to 31 and 37 days after irrigation. In this procedure, a method adapted from Tugwell and Stephen(1981) was used, consisting of the extraction of four cylindrical soil and roots samples per plot, using PVC tubes 8.5 cm high and 10 cm diameter. To release the larvae, samples were shaken and washed with water through a nylon screen sieve. The results showed that all formulations and application methods of thiamethoxan were highly efficient in the control of the rice water weevil, with a control index higher than 80% in all the evaluation. Index terms:Insecta, Erirbininae, rice, chemical control

[0350] WHITEFLIES (HOMOPTERA: ALEYRODIDAE) ON SPECIES OF MEDICINAL HERBAL PLANTS

A. M. Simmons¹, G. S. McCutcheon², R. J. Dufault², R. L. Hassell² & J. W. Rushing², ¹USDA-ARS, U.S. Vegetable Lab., 2875 Savannah Hwy, Charleston, SC 29414, USA, Email asimmons@awod.com; ²Coastal Research and Ed. Center, Clemson University, 2675 Savannah Hwy., Charleston, SC 29414, USA.

Whiteflies are destructive worldwide pests on many plant species of economic importance. A study was conducted on the production potential of selected medicinal herbal plant species as new crops suitable for cultivation in South Carolina, USA. Whiteflies (Bemisia argentifolii Bellows and Perring) were found in an experimental production field infesting 5 perennial species of medicinal herbal plants (feverfew, Tanacetum parthenium (L.) Schultz-Bip.; St. John's wort, Hypericum perforatum L.; purple coneflower, Echinacea pallida (Nutt.) Nutt. and E. purpurea (L.) Moench; and common valerian, Valeriana officinalis L.). Whiteflies have not been previously reported in the literature on these plant species. The density of whiteflies was greater on some of the species than on others. Relative abundance based on capture of adult whiteflies on yellow sticky cards agreed with the relative density of immatures among the plant species. Adult capture on sticky cards was high in plots of E. purpurea compared with plots of the other 4 species, and adult counts were elevated in the highest (440 kg N/ha) of 3 fertility rates in E. purpurea. Likewise, laboratory tests agreed with the observation of a higher population of B. argentifolii on E. purpurea compared with the other 4 plant species. The whitefly completed development on all 5 plant species, and whitefly associated parasitoids emerged from field leaf samples of each plant species. These perennial plants can help support over wintering populations of B. argentifolii in mild climates. Commercial use of these plants dictates restrictions on the use of traditional insecticides. Hence, biological control would be especially attractive for use in a pest management system on these herbal medicinal crops

Index terms: Bemisia argentifolii, parasitoid, fertility, host plant, population.

[0351] MOLECULAR CHARACTERISATION AND QUANTITATION OF THE AMPLIFIED CARBOXYLESTERASE GENE ASSOCIATED WITH ORGANOPHOSPHORUS INSECTICIDE RESISTANCE IN THE BROWN PLANTHOPPER, *NILAPARVATA LUGENS*

G.J. Small¹, J.G. Vontas¹, S.H.II.P. Karunaratne², J.C. Morgan¹ & <u>J. Hemingway¹</u>, ¹School of Biosciences, Univ. of Wales Cardiff, P.O. Box 915, Cardiff CF10 3TL, UK, email: Hemingway@cardiff.ac.uk. ²Dept. of Zoology, University of Peradeniya, Sri Lanka.

Widespread resistance to organophosphorus insecticides (OPs) in Nilaparvata lugens, a major pest of rice in Asia, is associated with elevation of carboxylesterase activity. The underlying mechanism of resistance to these insecticides is elevation of carboxylesterases. A cDNA encoding a carboxylesterase, NI-EST1, has been isolated from an OP-resistant Sri Lankan strain of N. lugens. The full-length cDNA codes for a 547-amino acid protein with high homology to other serine hydrolases. NI-EST1 has an N-terminal hydrophobic signal peptide sequence of 24 amino acids which suggests that the mature protein is secreted from cells expressing it. The nucleotide sequence of the homologue of NI-EST1 in an OP-susceptible, low esterase Sri Lankan strain of N. lugens is identical to NI-EST1. Southern analysis of genomic DNA from the Sri Lankan OP-resistant and susceptible strains shows that NI-EST1 is amplified in the resistant strain. Therefore, OP resistance in N. lugens is through amplification of a gene identical to that found in susceptible insects. Quantitative real-time PCR was used to demonstrate that NI-EST1 is amplified 3-7-fold in the genome of resistant compared to susceptible planthoppers. Expression levels were similar to amplification levels, with 1-15-fold more NI-EST1 mRNA in individual insects and 5-11-fold more NI-EST1 mRNA in mass whole body homogenates of resistant females compared to susceptibles. These values corresponded to an 8-10-fold increase in esterase activity in the head and thorax of individual resistant insects. Although amplification, expression and activity levels of NI-EST1 in resistant N. lugens were similar, there was no linear correlation between esterase activity and NI-EST1 mRNA levels in individuals of the resistant strain. The lack of a direct correlation between esterase activity and esterase gene amplification levels in individual females and in pooled homogenates of females may be due to variation in the localisation and stability of the amplified esterase in the planthoppers with physiological state or with age. The stability of NI-ESTI may be influenced by differential glycosylation of this protein, which results in a diffuse band on native polyacrylamide gels in contrast to the sharp bands seen with the amplified esterases of both aphids and mosquitoes.

Key words: Gene amplification, quantitative PCR, head separation

[0352] POPULATIONAL STUDIES OF LEPTOGLOSSUS. ZONATUS (HETEROPTERA: COREIDAE) ON CORN (ZEA MAYS) IN BRAZIL

<u>C. E. P. Souza^{1, 2, 3}</u>, **B. F. Amaral-Filho^{1, 3} & A. Mafra-Neto^{1, 2}**, 1- Fac. Filos. Ciênc. Letras de Ribeirão Preto, Univ. de São Paulo, Av. Bandeirantes, 3900, Ribeirão Preto, São Paulo, Brazil,14040-901; 2- 100A Chapman Hall Univ. of California-Riverside, Riverside, United States, 92521; 3- Univ. Est. de Campinas- Depto. de Zoologia, caixa postal: 6109, Campinas, São Paulo, Brazil.

The fluctuation of a population of the leaf-footed bug *Leptoglossus zonatus* was monitored in corn fields for two seasons (1997/98). The fields were located in the farm Santa Elisa/Instituto Agronômico de Campinas, Campinas (22°55' of South latitude, 47°04' of West longitude and 650 m of altitude), São Paulo, Brazil. The first occurrence of adults was during the vegetative development of corn, $41,0\pm5,57$ days after planting (minimum 21 and maximum 55 days, n=5 fields). The density of nymphs and adults increased continuously with the development of corn ears until the harvest, when the corn was completely dry. We will discuss the effects of the maturation of the crop and natural environmental conditions on fluctuations of the population density of the leaf-footed *L*. *zonatus* as well as the potential use of natural enemies and pheromones in alternative management strategies.

Index terms: Leptoglossus zonatus, leaf-footed bug, coreid bug, fluctuation, corn

[0353] POPULACIONAL APPRAISAL OF OWLET MOTHS (LEPIDOPTERA, NOCTUIDAE) AND THEIR NATURAL ENEMIES IN MORNING AND NIGHT COLLECTIONS IN THE RYEGRASS CULTURE, WITH NET SWEEPING

A. Specht^{1,2} & E. Corseuil², ¹ Curso de Agronomia, UNISUL, Av. José Acácio Moreira, 787, CEP 88704-900, Tubarão, SC, Brasil, E-mail spechta@puers.br; ² PPG Biociências, PUCRS, Av. Ipiranga, 6681, C. Postal 1429, CEP 90619-900, Porto Alegre, RS Brasil, Email corseuil@puers.br.

The populational control levels of Noctuidae in cereal cultures are limited on the defoliate percentage, without regarding the caterpillar population. These traditional indexes are obtained subjectively, what brings about an array of environmental and economical potential risks. These are expanse use of agricultural defense products, decrease of efficiency due to poor knowledge of target species, elimination of natural enemies and unnecessary environmental contamination. This work aims to supply subsidies to the development of a methodology of populational evaluation of noctuid caterpillars and agents of its natural control that can be applicable to several cereal crops. The work was conducted in two ryegrass areas (Lolium multiflorum), in Salvador do Sul, RS. The collections, in number of 17, were weekly, beginning on July 22, 1994, using sweeping net in the morning (10:00) and night (22:00). The caterpillars were counted, being considered small when up to 1.5cm, mean between 1.5 and 2.5cm and big when larger than 2.5cm. A total of 2,044 caterpillars were analyzed. The number collected in the daytime was smaller than a tenth of that collected in the night. The variance analysis evidenced interaction between shift, size and dates. Out of 523 caterpillars bred in laboratory 11 species emerged, being the community composed by the plague key Pseudaletia sequax representing 78% of the individuals and the accessory species, Dargida meridionalis 11%, Anicla ignicans 6%, Spodoptera frugiperda 2% and the others 3%. The proportion of P. sequax, in relationship the other species, was larger at night, especially in the reproductive and maturation phases of the ryegrass. In relationship to the organisms related to the natural control of Noctuidae, 387 spiders, 577 microhimenopterans and 983 insects distributed in 8 orders and 19 families were collected. It was obtained significant differences among averages of week collection for Carabidae, Tachinidae, Forficulidae, Vespidae, microhimenopterans and Araneae. These results indicate the convenience of using sweeping net for an populational more accurate evaluation of both Noctuidae and its agents of natural control in cereals crops.

[0354]PHOSPHAMIDON 40SL AGAINST SUCKING PESTS OF RICE, COTTON AND BRINJAL

S.Suresh & T.Srinivasan, Department of Agricultural Entomology, TamilNadu Agricultural University, Coimbatore- 641 003

Due to the toxic effect to natural enemies and other related problems like high mammalian toxicity use of Phosphamidon 85SL is banned from April, 2000 though this one of the chemicals being used by the farmers widely for the control of sucking pests and stem borer of rice. A new formulation with 40SL was evaluated for the first time in India against sucking pests of rice, cotton and brinjal. Phytotoxicity and toxicity to natural enemies in the field condition were also tested.

Two field trials in rice, two in brinjal and one in cotton laid out indicated that Phosphamidon 40SL sprayed @ 250 g ai /ha for brinjal and ,350 g ai/ha for rice and cotton was found to be effective in reducing the population brown planthopper, green leafhopper and white backed plant hopper for a week in rice and white files, leafhopper, thrips and aphids for ten days in brinjal and cotton respectively. Yield was also comparable with Phosphamidon 85SL.Triple the dose tested for phytotoxicity indicated that there was no phtotoxicity. It was comparatively safer to natural enemies though for initial three days there was a slight reduction in population. Among the three doses, tried 250g ai/ha for brinjal and 350 gai/ha for rice and cotton were found effective.

[0356] GENETIC VARIATION AND GENE FLOW AMONG POPULATIONS OF THE COTTON BOLLWORM *HELICOVERPA ARMIGERA* (LEPIDOPTERA: NOCTUIDAE) IN CHINA

S. J. Tan, X. F. Chen, S. P. Li, R. Y. Liu, Y. Wang & D. M. Li, The State Key Lab of Integrated Management of Insect Pests & Rodents, Institute of Zoology, Chinese Academy of Science, Box 70, Beijing 100080, P. R. China, E-mail Lidm@panda.ioz.ac.cn

The cotton bollworm Helicoverpa armigera is one of the most serious agricultural insect pest in China. It has adapted to many different host crops and occurs in Asia, Europe, Africa and Australia and caused huge damage to cotton production in recent years. Although much research has been conducted on the ecology and population biology of this pest, the dispersal and migration patterns of the cotton bollworm are not well understood. The forecast of Cotton bollworm's population density is difficult, and one of the reason is the absence of information about the migration among geographic populations. As direct field study on the migration of insects is usually very costly and difficult, analysis of the population genetic structure becomes an important information source for studying gene flow among populations, Genetic variation among different local populations of the cotton bollworm in China, and possible migration or gene flow pattern of the insect were studied, using genetic marker data. High rate of gene flow occured among local populations in China, which supported the migration hypothesis of Helicoverpa armigera. The genetic distance was not found to be correlated significantly with geographic distance of the populations, and the Fst/(1-Fst) did not shown a linear correlation with the logarithm of geographic distance, which suggested that the migration and gene flow of *Helicoverpa amigera* in China conform to the island model. The Fst estimated from gene frequency data and the F' from the band sharing data are quite close, which means that these two indexes could both be used to measure the division of genetic variation within and among populations.

[0355] THE FIELD EXPERIENCES OF MOSQUITO'S (*DIPTERA, CULICIDAE*) CONTROL IN SOME AREA IN PIEDMONT (ITALY)

<u>A. Talbalaghi ¹</u>, ¹Freelance Consultant for Urban Pest Control, P. Gubellini St., 4, 40141 Bologna (BO) I, E-mail dom2034@iperbole.bologna.it

In Italy the problem of mosquitoes, historically linked to malaria, has in recent years returned to forefront. This due to increases in the mosquitoes themselves as well as the populations' greater sensitivity due to improved and therefore expected high standards of living. In 1995 the region of Piedmont introduced a law to favor initiatives to combat biologically culicidi. In light of the law, some municipality agreed to the joint program. In this area, of roughly 210.000 hectares, that a feasibility was completed, to investigate the breeding sites and to quantify the problem. The territory is mainly agricultural with many large inhabited centers. In order to increase productivity, in the warm season the fields are flooded. The water is left for several days in the fields, nonetheless the puddles formed last for a sufficient period for the complete life cycle of 2 lethal mosquitoes which lay their eggs in the earth and hatch after the prolonged flooding: Aedes caspius (Pallas) and Aedes vexans (Meigen). This due to Ae. caspius which their eggs hatch after flooding of chambers not enough time to release the mosquito fish Gambusia sp. After the first flooding, the larvae of Aedes caspius are gathered on the edge of chambers, so that's sufficient to spray BTI on one meter of chamber's perimeter. Just after the 2nd flooding of chamber (mainly 3 flooding), the treatments are done up to September on 5 meters of perimeters of chambers. The over-infestation of chambers by Culex modestus (Ficalbi), Culex pipiens (L.) and Anopheles maculipennis s.l. Meigen, during the latest flooding is usual. In this case generally during of July and August , because of advanced growth of crop and others particular conditions, the toughest way is the release of mosquito fish into chambers up to 1-2 kilometers distance from inhabited centers. After 5 years from the beginning of this plan, no longer active larval breeding sites are reported. Nonetheless, the high presence of Acdes caspius adult during July 1999, are raised everywhere because an overall raising of the average of temperature in this month, (even 3-4 C°) raising temperature, enough to contribute so high level of infestation. Due to inborn attitude of Aedes caspius, to very long distance flight, come from those neighborhood where, up to now, there is generally not any mosquito's control plan on larval breeding sites and the Aedes caspius one are not treated, thus, are still dramatically active. The information, that inhabitants of cities have received to how combat the mosquito's micro-breeding site in their own private area, during 5 years of this on going plan, have supported further good results. Besides, technical approaches to mosquito's control, the knowledge of any single inhabitants, is been always highlighted. Index terms Aedes caspius, Rice-field, Urban p

[0357] SPATIAL AND TEMPORAL DISTRIBUTIONS OF PREDATORY INVERTEBRATES WITHIN, AND DISPERSING FROM, OVERWINTERING REFUGES IN UK CEREAL FIELDS

S.R.Thomas¹, D.Goulson¹ & J.M.Holland², ¹Biodiversity and Ecology Division, School of Biological Sciences, University of Southampton, Bassett Crescent East, Southampton, Hampshire SO16 7PX, ²The Game Conservancy Trust, Burgate Manor, Fordingbridge, Hampshire SP6 1EF, UK, Email: st3@soton.ac.uk.

The importance of polyphagous predators in providing biological pest control has been increasingly appreciated over the last few decades. There are currently many incentives to boost their populations and counteract problems such as pesticide-induced mortality and habitat loss caused by agricultural intensification. These invertebrates, with other species, are now also considered important in providing prey for farmland birds, which are in serious decline in the UK. Some beneficial invertebrates are able to live and reproduce within fields all year round, but others have been found to migrate from uncultivated field boundaries into the crop in spring, and return after harvest. Beetle banks, raised grassy strips positioned mid-field in arable crops, provide suitable overwintering refuge for such field-edge sheltering carabid and staphylinid beetles and spiders (Sotherton, 1995). They were designed to lessen the distance that these spring-dispersing species must travel in order to reach all areas of a field, allowing maximum pest control in this context. Invertebrate spatial distributions have not been fully researched because of the need for intensive sampling regimes, and statistical methodologies used have often been inadequate. Much work examining predators in cereals has merely sampled transects or small areas and extrapolated densities and distributions to cover the whole field, but many species have actually been found to be heterogeneously distributed, according to diet and microhabitat preferences. Recently developed techniques can measure the amount of spatial pattern in spatially-referenced count data (Perry, 1998) and can be further modified to detect non-random clusters of invertebrate counts (Perry et al. 1999). This research evaluated densities of polyphagous predators within established beetle banks, before, during and after the period of expected dispersal into UK cereal fields. It also examined the within-field distribution of these invertebrates at regular intervals over the period of January to July, 1998, comparing those species which are known to be permanently field resident with those known to have invaded during spring from the beetle banks. Destructive turf sampling and barriered pitfall trapping over extensive field-scale grids were used to collected invertebrates, which were identified and analysed used SADIE (spatial analysis by distance indices). Results are discussed in relation to the efficacy of the sampling and analysis methodologies, potential pest control benefits, and future developments and applications for the farmer.

Index terms: polyphagous predator, SADIE, beetle bank, biological pest control, spring colonisation.

[0358] EFFICIENCY OF INSECTICIDES TO CONTROL ADULTS OF STERNECHUS SUBSIGNATUS IN SOYBEAN

<u>G. L. Tonet</u>, Embrapa – National Wheat Research Center, BR 285, km 174, 99001-970 Passo Fundo, RS, Brazil. E-mail: gabriela @ cnpt.embrapa.br.

Sternechus subsignatus Boheman, 1836 (Coleoptera, Curculionidae), has been cited for many years as a pest on soybean in southern Brazil. The damage of adults on young plants may cause death of them, resulting in low stand and low crop yield. The larvae damage results in weak plants due to the insect feeding on the stems, which could break by the action of wind and may die. The pest remains in the infested area and soybean cropping may become unprofitable in the following season if control strategies are not taken. As just metamidophos insecticide has been officialy registered in Brazil to control this pest, an experiment was done at Embrapa - National Wheat Research Center, in the locality of Coxilha, RS, in 1998/99 crop season. The aim of the experiment was to evaluate the efficacy of deltamethrin (Decis 25 CE and Decis 50 SC, both 5.0 and 7.5 g a.i./ha), metamidophos (Tamarom BR, 480.0 g a.i./ha), and permethrin (Tifon SC, 37.5 g a.i./ha) sprayed on soybean plants to control the pest. The results showed that deltamethrin (Decis 50 SC) at 7.5 g a.i./ha at three and five days after insecticide application had 82 % and 81 % of pest control, respectively, but there was no statistical difference between insecticides and doses tested. The reduction in the number of insects has resulted in 14 % and 17 % less damage on plants with deltamethrin, while the control plots had 41 % and 62 % of plants damaged at three and five days after application, respectively. No insecticide reached 80 % of efficacy after five days from date of insecticide application. Index terms: Chemical control, deltamethrin, metamidophos, permetrin, soybean pest

[0360] FIRST EVIDENCE OF *COPTOTERMES HAVILANDI* IN CAMPOS DOS GOYTACAZES (RJ), BRAZIL

A.A. Trindade¹; A.L.O.S. Nunes¹; V.S.G. Silva¹; F.C. Freitas¹ & <u>E.B. Menezes</u>¹, ¹CIMP "CRG"/ UFRRJ, BR 465 – km 7, Seropédica, RJ 23890-000, Brazil, E-mail ebmen@zaz.com.br.

The Asian subterranean termite Coptotermes havilandi (Isoptera: Rhinotermitidae) was introduced in Brazil between 1915 and 1923. It's the most serious pest in urban areas in Brazil, mainly in its metropolises, such as São Paulo and Rio de Janeiro. The objectives of this study were to detect them and observe their behavior foraging in buildings, and to evaluate the efficiency of curative/preventive treatments for eradication of this termite. In a city called Campos dos Goytacazes, belonged to Rio de Janeiro State, we found the first focus of this termite's genus. There were two buildings, one far from each other, and we confirmed the altack in both. The first one to be inspected had 12 floors and two apartments by floor. All of the apartments had damages done by the C. havilandi, and it was confirmed in beds, doors, etc. We observed that the termites moved upward to the top floors through the electrical installations from the soil. In the other building the only difference is that it had one floor less than the first one, then 11 floors. In the majority of the buildings, C. havilandi constructed secondary nests mainly in apartments of the top floor. In urban areas, subterranean termites are usually controlled by insecticides. We used these products as curative and preventive treatments. The chlorpiriphos was applied by spraying and forced injection. New inspections were done and we verified that the result was positive. It means that the got the control of the termites.

Index terms: Coptotermes havilandi, urban areas, curative/preventive treatment, infested buildings

[0359] INSECTICIDE EFFICACY TO CONTROL STERNECHUS SUBSIGNATUS ON SOYBEAN SEED TREATMENT

<u>G. L. Tonet</u>, Embrapa – National Wheat Research Center, BR 285, km 174, 99001-970 Passo Fundo, RS, Brazil. E-mail: gabriela @ cnpt.embrapa.br.

Sternechus subsignatus Boheman, 1836 (Col., Curculionidae) was found in 1973, as a secondary pest problem in the State of Rio Grande do Sul (southern Brazil). Nowadays it is a major pest on soybean in the region. Damages are caused by adult insects on seedlings and young soybean plants and by larvae that penetrate branches causing "galls" that reduce sup circulation. Damaged plants may die or branches may breake down, reducing yield potential. Cultivating host plants sprayed with insecticides on the border of cropped areas and crop rotation with no-host species are alternatives to diminish pest population. Very few insecticides are efficient to control the pest at seedling and young plant stages, as adult insects emerge from soil during long periods. For this reason insecticide spraying should be repeated several times. Therefore, seed treatment with insecticides can be an efficient pest control strategy. A field experiment was done at Embrapa-National Wheat Research Center, in Passo Fundo, RS, Brazil, in 1998/1999 soybean season. The aim was to test three infesting periods after planting and three doses of thiamethoxam (Cruiser 700 WS), compared of doses of imidaclopride (Gaucho 600 PS), thiodicarb (Semevin 350 RA), carbofuran (Furadan 350 SC), and carbosulfan (Marshal 400 SC). The results showed that thiamethoxam 210 g a.i./100 kg of soybean seed and carbofuran 1050 g a.i./100 kg of soybean seed were efficient in controlling adults of Sternechus subsignatus, resulting in low population of larvae and high crop yields. Carbosulfan 1200 g a.i./100 kg of soybean seed was efficient in controlling adults when infested 14 days after emerging of plants. Imidaclopride and thiodicarb were not efficient to control the pest in all periods tested, resulting in high survivability of adult insects and larvae and low soybean yield.

Index terms: Seed treatment, soybean pest, thiamethoxam, carbofuran, chemical control

[0361] ARMADILLIDIUM VULGARE (CRUSTACEA: ISOPODA). NEW PEST TO SOYBEANS IN ARGENTINA?

E. V. Trumper¹, M. Linares¹, F. Fava¹ & M. Battán², ¹Sección Entomología, EEA Manfredi, INTA, Ruta Nac. 9 Km 636, 5988 Manfredi, ARGENTINA, E-Mail: etrumper@arnet.com.ar; ²Cat. Diversidad Animal I, Fac. Cs. Exactas, Físicas y Naturales, U.N.C., Av. Vélez Sársfield 299, 5000 Córdoba, ARGENTINA.

The influence of low or zero-tillage on soil related fauna has been documented, including changes of diversity, and density of particular species. In Argentina, cutworms, grasshoppers, ants and slugs are among the organisms that show a clear increase of density as a result of more abundant refuges, higher levels of moisture and more stable microenvironments. An unexpected new consequence was identified in zero-tillage soybeans, particularly in irrigated fields. At the beginning of the last two growing seasons, newly established crops begun to show patches of increasingly weak plants, or decreasing plant density. No factors such as mechanical failure during sowing, herbicidal phytotoxicity, plant diseases or nutrients deficiencies could be associated with these symptoms, nor could the injuries observed in plants be attributed to any insect species present in those fields. Due to the unusually high abundance of isopods in those soybean crops, and in spite of their known detritivorous feeding habits, the working hypothesis that these crustaceans were the proximate cause of the damage observed was claimed. Essays and sampling were initiated to test this preliminary hypothesis. Soybean seeds were sown in pots with presence of different numbers of isopods per pot and a control with no isopods, and kept in a glasshouse for two weeks. The presence of isopods in the pots was associated with injuries on different parts ofd the seedlings, while no damages were observed in seedlings with no isopods present. The characteristics of injuries were very similar to those observed in the field. Different types of injuries will be illustrated. Similar essays were carried out in the field, with equivalent results. A sampling technique is proposed consisting of a 50 X 50 cm. frame which is dropped on the ground and isopods inside are collected for 5 minutes. Isopods density and seedling injuries were sampled along a transect in a soybean field. Percentage of seedlings damaged were highly correlated to isopods density (R2=0.62; P<0.01). The influence of seed quality on these results will be discussed. Index terms: soybean, zero-tillage, arthropods.

[0362] ALLOCATION OF ARTHROPODS IN WINTER WHEAT CROP AND AROUND IT

W.B. Tshernyshev, A.V. Timokhov, O.V. Timokhova, R. R. Seifulina, I.I.Soboleva-Dokuchaeva, V.M. Afonina & A.V. Sujazov, Dept. of Entomology, Faculty of Biology, Moscow State University, 119899, Moscow, Russia, E-mail tshern@3.entomol.bio.msu.ru

The investigations were carried out in Moscow region for 3 years and in Krasnodar region (the Northern Caucasus) for 1 year. The areas of the fields were 12-14 ha and 64 ha respectively. We used entomological sweeping and pitfall traps from March- April till harvest. Regular samples were taken in the field centre, on its edges, on grassy field margins and in adjoining biotopes. The distances of sites from field margin were: edge -7-10 m; halfway to the centre- 200 m (Krasnodar); centre - 170 m (Moscow) and 400 m (Krasnodar). Both the maximal number of all arthropod species and their maximal abundance were found on field margins and minimal - in the centre. However, the allocation of separate species was different. The number of species of carabid- beetles and spiders was the same in the centre and in the "halfway" but some other insects could distinguish these sites. The carabids more evenly colonise the field than spiders, the most drastic decrease of abundance towards the centre was observed in spiders, inhabiting plants. Very abundant in Moscow region carabids, Poecilus cupreus and Harpalus rufipes colonised the field from its margins and concentrated then in its central part. H. rufipes replaced P.cupreus in margins in spring and in the field in summer. In Krasnodar, groundbeetles Brachinus spp. emerged at first on margins and in forest belts. Later they occupied the edge of the field and then the whole surface of the field. Anchomenus (Agonum) dorsalis appeared there in forest belts in early spring and later on the margins, it was absent in the field. Spiders Tetragnatha extensa and Xysticus ulmi moved to the field from its margins. Later the former distributed evenly all over the field and its margins whereas the latter preferred field edges and margins. Hypsosinga pygmaea was found in the field mainly in its centre from spring and avoided its margins and forest belts. Ground dwelling spiders, Lycosidae, preferred the central part. There were many carnivorous red mites Trombidiiformes in spring in Krasnodar, especially in the centre. Chrysomelids *Phyllotreta* and flies *Oscinella* colonised the field at once and preferred its central parts. Chrysomelid beetles, Lema melanopus, concentrated on field margins in spring and later colonised the field edges. Aphids, Macrosiphum avenae as well as bugs, Eurygaster integriceps and Lygus rugulipennis. began to colonise the field from its edges. However, their offspring was abundant in the centre. Allocation of the majority of aphidophagous insects and aphids is the same.

Index terms: agroecosystem, pests, natural enemies, migrations, arthropods.

[0363] SPINOSAD - A NEW BIOMOLECULE FOR MANAGEMENT OF BOLL WORM IN COTTON ECOSYSTEM

<u>S. Uthamasamy</u> & S. Raguraman, Department of Agricultural Entomology, Agricultural college and Research Institute, Tamil Nadu Agricultural University, Madurai 625 104. India, E-mail: uthamasamy99 @hotmail.com.

Spinosad is a mixture of spinosyn A and spinosyn D which are naturally derived group of insect control molecules from a new species of actinomycetes, Saccharopolyspora spinosa (characterized as a bacterium) developed by Dow Elanco, USA. Spinosad demonstrated excellent control of many pests of crops. It acts as both contact and stomach poison. We tested the formulated product of spinosad 48 SC at 25, 50, 75 and 100 g a.i./ha along with three other insecticides viz., chlorpyriphos 20 EC, quinalphos 25 EC and endosulfan 35 EC against the boll worm, Helicoverpa (=Heliothis) armigera (Hubner) in cotton ecosystem in three consecutive seasons. The studies were conducted during 1999-2000 with SVPR 2 and MCU 10 cotton varieties. The results revealed that spinosad 48 SC at 75 and 100 g a.i./ha effectively contained the damage caused by larvae of H. armigera. Laboratory evaluation of spinosad revealed that 25 and 50 g a.i./ha were safe to egg parasitoid, Trichogramma chilonis Ishii. Spinosad did not show any phytotoxic symptom on cotton leaves at all the concentrations tested. Harvest time residue studies indicated below detectable levels of spinosad even at 150 g a.i./ha in/on cotton lint, seed, oil and soil samples 10 days after foliar application. It is concluded that spinosad is a compatible component in IPM in cotton for the management of Helicoverpa armigera.

Index terms: Spinosad, bioefficacy, Helicoverpa annigera, phytotoxicity, residues, cotton ecosystem.

[0364] WHITEFLY IMPACT ON IRRIGATED AGRICULTURE IN SEMI-ARID REGION OF BRAZIL: THE FARMER'S PERSPECTIVE

<u>S. D. Vasconcelos</u> & M.A.S. Bezerra, Mestrado em Biologia Animal, Depto, de Zoologia, Universidade Federal de Pernambuco, Av. Prof. Moraes Rego, s/n, Recife - PE, 52040-150, BRAZIL E-mail: simao@npd.ufpe.br

The whitefly known as Bemisia tabaci (B. tabaci strain B or B. argentifolii) (Hemiptera: Aleyrodidae) was first detected in the Northeast of Brazil in the end of 1995 and has, since then, established itself as the most important pest in irrigated agriculture. Its damage includes mainly transmission of geminiviruses in tomato and serious losses in the productivity of melon. While research has been speedy in finding new chemical insecticides and new technologies for pest control, an important component in integrated pest management seems to have been forgotten, namely the transfer to and use of technology by the small area farmers, responsible for most of food production in Northeast Brazil. This study was conducted in 1999 and had the objective to assess the impact of whitefly on the economics of irrigated agriculture under the farmers' point of view. To achieve that, interviews were conducted with farmers in the Petrolina-Juazeiro region, Northeast of Brazil. According to the answers, the average losses on yield for tomato and melon are around 40%; chemical control is still the most used method - despite of serious misuse of insecticides, and most farmers are replacing melon with other crops. Less susceptible varieties are beginning to be used by the farmers, as part of a technological package designed by local tomato industries. The losses in 1999 appeared to be less intense than in 1998, and, interestingly farmers seem to believe that the impact of the pest will diminish in the next years. When asked about what they needed to fight the pest, most of suggestions were related to training and technical orientation, especially about alternative methods of control. It seems, from this study, that a substantial production loss could be avoided if a serious, constant extension programme were being carried in that region.

[0365] SCARABAEIDAE S. STR. (COLEOPTERA: SCARABAEOIDEA) FROM VICOSA, MINAS GERAIS STATE, BRAZIL

F. Z. Vaz-de-Mello¹, C. Lopes-Andrade¹, S. A. Falqueto¹, J. N. C. Louzada², J. II. Schoereder¹ & E. R. Lima³, ¹Lab. Ecologia de Comunidades, Dept. Biologia Geral, Univ. Fed. Viçosa, Niçosa MG 36571-000, Brazil. E-mail scarab@insecta.u(v.br. ²Dept. Biologia, Univ. Fed. Lavras, Lavras MG 37200-000, Brazil. ³Dept. Biologia Animal, Univ. Fed. Viçosa, Viçosa MG 36571-000, Brazil. The last part of this work has been supported by FAPEMIG.

Viçosa region has a primitive habitat of Tropical Semideciduous rainforest, that has been largely cut for wood, and after for coffee plantations and pastureland. This resulted in a mosaic of habitats, with a pastureland matrix, patched with mainly secondary and disturbed forests, coffee plantations and a few other cultures. Durying eight years (1992-1999), all region has been sampled for scarabs, mainly in forest fragments, and sometimes also in pastureland. In the first five years, the aim of this sampling was to verify effects of fragmentation on Scarabaeidae communities, and, in the last years, to verify habitat and food segregation, and to evaluate all regional richness of species. The collecting techniques used were: pitfall traps baited with a variety of resources (human, cow, horse, monkey, dog or pig dung, various kinds of vertebrate carcass, roting fruits, dead or live millipeds, dead insects, snail dung, humus, etc.), canopy traps (baited with human dung, carcass and rotten fruits), flight intercept traps, incandescent, mercury and ultra-violet light traps, manual collecting, on the soil, leaves, termite and ant nests. As a primary result of such work, a total of about 100 species have been collected, included in the genera (approximate number of species in parenthesis) Agamopus (1), Anomiopus (6), Ateuchus (5), Canthidium (12), Canthon (8), Canthonella (2), Chalcocopris (1), Coprophanaeus (3), (1), Ontherus (4), Onthophagus (4), Pedaridium (1), Phanaeus (1), Scatonomus (1), Sinapisoma (2), Sulcophanaeus (1), Sylvicanthon (1), Trichillum (7) and Uroxys (4). Four species, in the genera Pedaridium and Trichillum, are currently being described as new, and 30 species could not be identified, includying genera poorly studied and some potentialy new species. Index terms: dung beetles, fragmented habitat, Tropical Semideciduous rainforest, inventory of species.

[0366] ASSESSING AREAS OF CLIMATIC STRESS FOR CERATITIS CAPITATA (DIPTERA: TEPHRITIDAE) IN ARGENTINA

M. T. Vera¹², R. Rodriguez³, D. F. Segura¹ & J. L. Cladera¹, ¹Inst. de Genética, INTA Castelar, CC 25, Castelar (1712), Bs. As., Argentina. ²Depto. Biología, Univ. Bs. As., Pab II, Ciudad Universitaria (1428), Bs. As., Argentina. ³Inst. de Clima y Agua, INTA Castelar, CC 25, Castelar (1712), Bs. As., Argentina. E-mail: tvera@enia.inta.gov.ar

Dynamic simulation models combining meteorological databases with the biological constrains for development imposed by abiotic factors are used to determine the potential risk of establishment of exotic pests. In areas where the pest is already present they may give an idea of which are the potential abiotic stress factors and their probable effect on population dynamics. The assessment of areas under climatic stress for the Mediterranean fruit fly Ceratitis capitate, in Argenting was attempted here with the simulation program CLIMEX, combining the potential population growth for a given range of temperature and soil moisture and the negative effect on growth (stress) during adverse conditions. In addition to using CLIMEX, areas under stress were determined by considering the duration along the year of the period with extreme temperatures and humidities (duration of extreme conditions, DEC). Summer and winter precipitation levels were also included in this second analysis as potential deleterious factors. CLIMEX and DEC were run using a meteorological database of 24vr-average recordings from 152 meteorological stations located along the country. Both approaches showed areas where C. capitata should not be present due to excess of cold during winter, and suggested that Argentina could be divided into unfavorable, marginal and favorable areas, but CLIMEX predictions seemed to over estimate winter mortality. With respect to variables other than cold (soil moisture, heat stress), CLIMEX output showed no detrimental effect, whereas DEC revealed possible reductions in abundance due to summer rainfall in two areas and winter precipitation in one of these areas. It also revealed areas with deficit in humidity and areas with excess of heat. When daily meteorological information was used to analyze both seasonal and interannual variation in some particular locations, the detrimental effect of relative humidity, precipitation and heat was shown to be important also by CLIMEX. Additionally indexes values presented a great variability among years. In conclusion, the two approaches used here show habitat heterogeneity and suggest that winter or summer temperatures, precipitation and deficit of humidity can be stressing factors in different areas of Argentina. This information may be used to improve pest control efforts, especially considering the climatic variability among years within areas.

Index terms: Medfly, CLIMEX, climatic stress assessment, population dynamics.

[0367] POPULATIONAL FLUCTUATION OF ARTROPODS EDAPHICS ON TILLAGE AND NO TILLAGE SYSTEMS IN THE AREA OF DOURADOS - MS

M.H. Vieira¹ & II. R. Santos², ¹DEB/UFMS, Cx. P. 322, CEP-79825-070 Dourados-MS E-mail: mhvieira@zaz.com.br. ²DCA, cx.P. 533 Dourados-MS, UFMS E-mail: hrsantos@ceud.ufms.br.

This research has been developed outdoors and also at the Laboratory of Entomology of the NCA/UFMS in Dourados, MS. The main objective was to study the populational fluctuation of Edaphic Artropods on tillage and no tillage Systems. The area measured 1.5 hectare, of which 0.750 hectare was utilised for no tillage systems and the 0.750 hectare remainder for tillage cultivating system. The esperiment was been led in entirely random deliceation, according to and factorial project 12x2, with three repetitions. The field gatherings were held from July 1996 to June 1997, using the Funnel of Berlese (modified). Afterward, these samples were submitted to na extracting process, during seven days time, for the collection of artropods. After identified, based on the results obtained and in the conditions the experiment was led, it's possible to conclude that the greater number of gups of edaphic Artropods, studied, was Acari, followed by Insecta, Collembola and Miriapoda. The population fluctuation had similar behavior in all crops, in tillage, with drastic effects as result from this cultivating method. In the no tillage system, the greatest decrese may be related to abiotic factors. Despite the high density of Acari, this group, Collembola and Miriapoda, showed up susceptible to the ambient alterations. Index terms: Artropods edhafics, Tillage no tillage

[0368] FRUIT FLY (DIPTERA: TEPHRITIDAE) QUARANTINE PROCEDURES FOR EXPORT OF AVOCADOS FROM ARGENTINA TO CHILE

M.E.Villagrán¹, N.Isola², <u>E.Willink¹</u>, M.L.Fonalleras², N.Vaccaro³, C.Grignola⁴ & R.N. Rodriguez Prado⁴, ¹ Estación Experimental Agroindustrial Obispo Colombres, C.C.n°9, Las Talitas, (4101) Tucumán, Argentina. E-mail: saneeaoc@tucbbs.com.ar, ² Dirección Cuarentena Vegetal, SENASA, Paseo Colón 367, 7º Piso, (1063) Buenos Aires, Argentina, ³ INTA, Concordia, C.C. n° 34, Estación Yuquerí, Concordia, (3200) Entre Ríos, Argentina, ⁴ Delegación Tucumán, SENASA, Haití 117, San Miguel de Tucumán, (4000) Tucumán, Argentina.

To export avocados, Persea americana cy. Hass from Tucumán, Argentina to Chile, 2 quarantine measures were established between the Phytosanitary Services of both countries in 1998: a) fumigation with methyl bromide or funigation with methyl bromide followed by cold treatment, as quarantine treatments for Ceratitis capitata, and b) a systems approach for Anastrepha fraterculus, that comprises risk mitigation measures such as varietal resistance, monitoring adult and larval populations in the field, and postharvest sampling. To monitor adult populations, 76 McPhail traps and 76 Jackson traps were distributed in a 36 ha avocado field (32 traps in the 10 exportation plots, and the other 44 in the neighbouring areas). A maximum value of 0,14 was established for the FTD (flies/trap/day). The traps were checked every week from April to July during 1998 and from April to August during 1999. In 1998 A.fraterculus only exceeded its FTD limit in 1 exportation plot during 2 weeks in June and in 6 plots, during the 2 last weeks of July; whereas in 1999 it remained below the FTD limit in all plots studied. During 1998 only 3 adult C.capitata were trapped, and 8 in 1999, always during April. To monitor larval populations, every 20 days all the fallen fruit from 12 pre-established sites was collected, along with 10 avocados cut from the trees. The fruit was placed in individual containers, kept in rearing chamber at 25°C and checked for pupae every 2 days. During 1998, seven hundred and twenty avocados cut from the trees were examined for pupae, and 1020 during 1999. One hundred and fifty avocados that fell from the trees were examined in 1998 and 316 in 1999. No fruit fly larvae or pupae were found in any of these fruits. The postharvest examination of 2% of the fruits in the packing line resulted in 6156 fruits checked in 1998 and 7528 in 1999. No live or dead fruit flies larvae were found. Considering that the adult populations of A.fraterculus and C.capitata were very low during the exportation period, and that no live or dead larvae were found in the fruits checked, it is believed that there is no risk of introduction of fruit flies with avocados exported from Argentina into Chile, even without a quarantine treatment. Anastrepha fraterculus, Ceratitis capitata, quarantine

[0369] EFFICIENCY AND RESIDUAL OF DIFFERENT ACEPHATE FORMULATIONS IN CONTROL OF GREEN-PEACH APHIDS ON PEPPER'S CROP

R.R. Vinchi¹, W.R. Kuwahara¹ & <u>C.G. Ractano¹</u>, ¹Dept. of Crop Production, State of Univ. of São Paulo, P. Box 237, Botucatu, SP, 18603-970, Brazil, E-mail ractano@fca.unesp.br.

The occurrence of aphid Mizus persicae (Sulz.), on pepper's crop is very important in Brazil by direct damage as well as vector aphid of viroses. With objective to check the efficiency of acephate insecticide at two different formulations: WP (Orthene 750 BR) and WG (Evolution) in control of green-peach aphid on this crop, a experiment was conducted in experimental farm located in São Manoel, SP. The experimental design was randomized bloks with 8 treatments and 4 replications in period between February to June, 1999. The treatments used were: acephate WP (Orthene 750 BR) at doses of 56.25 and 75.00 g. a. i./ hL; acephate WG (Evolution) at doses of 48.50 and 58.20 g. a. i./ hL, and a without insecticide treatment. One hand held sprayer equipped with simple lance one JD 14-2 hollow nozzle type at the end was used in this experiment. Before of insecticide applications was made a previous evaluation of aphids in both leaf's surface. During evaluation of insect population, before and after application, was established a grade scale for different number of green-peach aphid: zero: absence of aphids, one: 1 to 5 aphids, two: 6 to 10 aphids, three: 11 to 20 aphids and four: up 20 aphids. The evaluations were made at weekly intervals from 8 to 85 days after the initial application. At the end of spraying, fifty days after initial of them, the evaluations were realized with the purpose of to verify the residual effect of products. The acephate formulations wettable powder and water dispersible granule at doses in test showed excellent results (100% of efficiency) in control of green-peach aphids on pepper's crop, independent of the formulation utilized along the all evaluation period. Highly residual effect of acephate was proved until 85 days after initial spraying.

Index terms: Mizus persicae, chemical control, insecticide formulation,
[0370] EFFICIENCY OF FENPROPATHRIN AND CHLORFLUAZURON IN CONTROL OF *NEOLEUCINODES ELEGANTALIS* (LEPIDOPTERA: PYRALIDAE) ON TOMATO'S CROP

W. R. Kuwahara¹, R. R. Vinchi¹ & <u>C. G. Raetano¹</u>, ¹Dept. of Crop Production, State of Univ. of São Paulo, P. Box 237, Botucatu, SP, 18603-970, Brazil, E-mail raetano@fca.unesp.br

The tomato fruit borer have been considered one of the important pests on tomato fruits in State of São Paulo, Brazil. Now don't have been proved good levels of this insect control with commercial insecticides. The objective of this works was to check the insecticide efficiency of fenpropathrin and chlorfluazuron when apply isolated and in mixture, in control of tomato fruit borer, on tomato's crop. The experiment was conducted in São Manoel experimental farm, SP between January to May, 1999. The experimental design was randomized bloks with 8 treatments and 4 replications. In the mixture of application was added the adjuvant Extravon 0.01%. The treatments used were: chlorfluazuron (Atabron 50 CE) at doses of 3.75 and 5.00 g. a. i./ hL, cartap-cloridrato (Thiobel 500) at dose 100.00 g. a. i./ hL, fenpropathrin (Meothrin 300) at doses of 7.50 and 15.00 g. a. i./ hL, lufenuron (Match CE) at dose of 4.00 g. a. i./ hL; chlorfluazuron + fenpropathrin at doses of 3.75 + 7.50 g. a. i./ hL, respectively. The applications, in number of eight and at the weekly intervals were accomplished with hand held knapsack sprayer equipped with one JD 14-2 nozzle type (35 to 75 psi). The evaluations in the 1st, 2nd, 3rd and 4th stalk, were made with 32, 39, 48 and 55 days after initial spraying. The evaluations were consisted in to collect and cut of 20 fruits/plot and to account the number of attacked fruits. The most efficiencies 32.14% (1st stalk) and 81.82% (4th stalk) were obtained with the nuxture of chlorfluzzuron + fenoropathrin at doses of 3.75 + 7.50 g. a. i/ hL. When application wasn't in mixture the products chlorfluzzuron at dose of 3.75 + 7.50 g. a. i/ hL. When application dose of 7.50 g. a. i./ hL, showed intermediary results in control of tomato fruit borer, with efficiency of 57.57 and 60.61%, respectively at the end evaluation (55 days). The products chlorfluazuron at dose of 5.00 g. a. i./ hL and fenpropathrin at dose of 15.00 g. a. i./ hL showed good efficiency of control, with 66.67 and 75.76% has been comparable with the efficiency (72.73%) of cartap-cloridrato at dose of 100.00 g. a. i./ hL for the evaluation in 4th stalk. The lufenuron insecticide showed your maximum efficiency (48.48%) in control of tomato fruit borer at the end of experimental period.

Index terms: tomato fruit borer, chemical control, insecticid

[0371] MIGRATION-RELATED CHARACTERS OF THE BROWN PLANT-HOPPER, NILAPARVATA LUGENS, COLLECTED IN EAST AND SOUTHEAST ASIA

T. Wada¹, K. Ito² & A. Takahashi³, ¹Kyushu Natl. Agr. Expt. Stn., Suya 2421, Nishigoshi, Kumamoto 861-1192, Japan, E-mail twada@knaes.affrc.go.jp; ²Hokkaido Natl. Agr. Expt. Stn., Hitsujigaoka, Toyohira-ku, Sapporo 062-8555, Japan; ³Hokuriku Natl. Agr. Expt. Stn., Inada 1-2-1, Joetsu, Nigata 943-0193, Japan

The brown planthopper (BPH), *Nilaparvata lugens* (Homoptera: Delphacidae) is a serious pest of rice in tropical and temperate Asia. It does not hibernate in Japan and Central China. It invades Japan every year in early summer from Mainland China through Monsoons. We compare physiological characters of BPH populations collected in Japan, China and Indochina Peninsula. Laboratory experiments showed that 1) macropterous female adults of subtropical North Vietnam and temperate Japanese BPH populations matured slower than females of tropical populations, 2) newly-emerged macropterous adults of subtropical and temperate populations (virulence to BPH resistant rice 48 hr. feeding on rice, 3) the biotype compositions (virulence to BPH resistant rice distributed in subtropical and temperate East Asia. These BPHs with long pre-ovipositional period and starvation resistance are adapted for long-distance migration. There is a seasonal migration area of BPH in East Asia and BPHs there are isolated from tropical populations, which are adapted for fast multiplication.

[0372] SPATIAL RELATIONSHIPS BETWEEN A PREDATOR AND PEST INFESTATION IN WINTER RAPE AND RELEVANCE TO INTEGRATED PEST MANAGEMENT STRATEGIES

D. J. Warner', L. J. Allen-Williams¹, I. H. Williams² & J. N. Perry², ¹ Dept of Environmental Sciences, Univ of Hertfordshire, Hatfield, HERTS AL10 9AB, UK. Email warnerd@bbsrc.ac.uk; ² IACR - Rothamsted, Harpenden, HERTS AL5 2JQ, UK.

There is considerable interest in spatio-temporal distribution patterns of pest and beneficial insects in agro-ecosystems, both of which are important for the development of Integrated Pest Management (IPM) strategies. A knowledge of these patterns may allow temporal and spatial targeting of insecticides, which can enhance insecticide efficiency while conserving beneficial insects that may have an important role as natural agents of pest control. The brassica pod midge (Dasineura brassicae (Winnertz)) is an important and widespread pest of winter and spring oilseed rape in the UK, where it has two generations on winter rape and one on spring rape. D. brassicae oviposits into the developing rape pod in which its larvae develop. Infested pods split, prematurely releasing seeds, and the *D. brassicae* larvae drop to the soil before burrowing beneath to pupate. At this stage in its lifecycle D. brassicae is potentially vulnerable to predation by epigeal predators foraging on the soil surface. Carabid beetles are recognised as important generalist predators in agro-ecosystems, particularly in cereal crops, but little is known of their importance in oilseed rape. This is the first study in the UK to focus on the role of carabid beetles in the oilseed rape crop. The spatio-temporal distributions of both the larvae of D. brassicae upon dropping to the soil from the crop canopy and of adult carabid beetles active on the soil surface were investigated in two consecutive years. Insect samples were collected from spatially referenced sampling points across each crop. Counts of insects were mapped, analysed and the degree of spatial association between predator and prey determined using a novel statistical technique, Spatial Analysis by Distance IndicEs (SADIE). Carabid species abundant and active during peak drop of first generation D. brassicae larvae included Agonum dorsale (Pont), Amara similata (Gyllenhal), Harpalus rufipes (DeGeer) and Nebria brevicollis (Fabricius). Spatially, the larvae of D. brussicue had a marked edge distribution within the crop. SADIE analysis revealed significant spatial association between larvae of D. brassicae and adult H. rufipes (P<0.05) in 1998, but none with adults of A. dorsale, A. similata or N. brevicollis. However, strong spatial association existed between larvae of D. brassicae and adult A. dorsale (P < 0.01) in 1999. N. brevicollis adults aggregated in areas of high D. brassicae larval drop in 1999, but spatial association was not significant. The distributions are discussed in terms of their relevance to IPM strategies and spatial targeting of insecticides.

Index terms: D. brassicae; Carabidae; natural enemy; spatial association; insecticide targeting

[0373] EFFECTIVENESS OF METHYL BROMIDE ALTERNATIVES AGAINST POTENTIAL PESTS THAT MIGHT BE IMPORTED TO THE UNITED STATES ON CHILEAN LOGS

B.R. White, R.I. Gara¹, D. Lanfranco, H. Peredo, P. Montes², G.K. Smith & D. Bridgwater³, ¹College of Forest Resources, University of Washington, Box 352100, Seattle, WA 98195-2100; ²Facultad de Ciencias Forestales, Universidad Austral de Chile, Valdivia, Chile; ³USDA Forest Service, Forest Pest Management, 1 Oak Plaza, 331 1st Ave., Portland OR 97208.

We studied the effectiveness of alternative pesticide treatments to methyl bromide furnigation in controlling high-risk Chilean forest pests that could be imported to the United States on logs. Various treatments have been proposed as alternatives to current regulations requiring methyl bromide furnigation. Little data, however, was available concerning the effectiveness of proposed treatments on Chilean insects or pathogens of risk to United States forest tree species. Scientists from Chile and the United States collaborated in evaluating the efficacy of biocides in Chile in order to identify promising alternatives to methyl bromide for treatment of whole logs destined for the United States. Initial studies were conducted using radiata pine bolts (28 cm X 0.75 m) from which the best treatments were identified. Further field studies were conducted to test these pytosanitary products on export-sized logs that were handled under industrial conditions. Results showed that a combination surface treatment of "Timber-TreatTM" and "NP-1TM" effectively protected debarked logs against hitchhiking bark beetles and blue-stain fungi for three months. The addition of either methyl bromide or a "VikaneTM" fungigation treatment following the surface treatment had no observable effect over the surface treatment alone.

[0374] CORN ROOTWORM AREAWIDE MANAGEMENT IN KANSAS

<u>G. E. Wilde¹, R. J. Whitworth¹ & R. A. Shufran¹, ¹Dept. of Entomology, Kansas State Univ., Waters Hall, Manhattan, KS 66506-4004, USA, E-mail gwilde@oz.oznet.ksu.edu, USA.</u>

The effect of areawide management of western corn rootworm was assessed in north central Kansas from 1997-2000. Populations of corn rootworm beetles in a managed area were controlled with a semiochemical insecticide when they exceed treatment thresholds. Overall, populations in the managed area were significantly reduced compared to an unmanaged area where conventional soil insecticides were used. Index terms: *Diabrotica virgifera virgifera*, insecticides, corn

[0375] STRESS BY SUBLETHAL DOSES OF PYRETHROIDS ON THE DEVELOPMENT, SURVIVAL AND WEIGHT OF SUPPUTIUS CINCTICEPS (HETEROPTERA: PENTATOMIDAE)

<u>T.V. Zanuncio¹</u>, **R.N. Guedes¹ & J.C. Zanuncio¹**, ¹Dept. de Biologia Animal, Univ. Federal de Viçosa, 36571-0000, Viçosa, MG, E-mail zanuncio@email.ufv.br.

Pentatomidae bugs such as Supputius cincticeps, commonly found in many ecosystems, is a generalist species which feed mainly on larvae of Lepidoptera and Coleoptera. Since insecticides are used in such areas, the susceptibility of predators to them has been studied aiming to use selective products and to reduce negative effects on these natural enemies. The purpose of this research was to evaluate the effect of different subletal doses of permethrin and deltamethrin, in topical application, on 3^{th} instar nymph of *S. cincticeps.* Effects of these insecticides were assessed on nymph development, survival, and weight gain of this predator since stressful chemicals can stimulate organisms to increase their hability to respond and to adapt to new environment. Nymphs of S. cincticeps were individualised, conditioned in 40 ml plastic glasses, fed with pupae of *Tenebrio molitor* (Col.: Tenebrionidae) and maintained in at $25.0 \pm 0.5^{\circ}$ C and $75.0 \pm 5.0\%$ of RH. The technical grade insecticides permethrin and deltamethrin were diluted in acetone to obtain the concentrations used $(10^{-3}; 10^{-4}; 10^5; 10^{-6}, 10^{-7} \text{ and } 0 \text{ mg a.i./ml})$ and topically applied on the back of each nymph of S. cincticeps. Each one of them received 1 µl of the insecticide solution while those of the control treatment 1 µl of acetone. Deltamethrin in the doses of 10⁻⁵ and 10⁻⁶ favored the survival of S. cincticeps nymphs (F=66.58; P< 0.0001) but the length of all development stages were similar in all concentrations. None effect of insecticide was found on weight of nymphs which originated females (F=643.92; P<0.0001) or males (F=317.17; P< 0.0001). Weight increase was solely due to age increase of this insect. The permethrin in the doses of 10⁻⁶ and 10⁻⁷ increased survival of the nymphs of *S. cincticeps* (F=41.83; P<0.0001). Duration of 3^{th} (F=7.23; P<0.005) and 4^{th} (F=4.01; P<0.005) instars was longer at the doses of 10^3 and 10^4 and of 10^3 and 10^5 of this insecticide, respectively, for nymphs which originated females. Permethrin at the doses of 10⁻³ and 10⁻⁴ reduced weight gain of nymphs that originated females (F=394.68; P<0.0001) and of those that orginated males (F=387.57; P<0.0001). There was no insecticide effect on weight gain of 5th instar insects. The results obtained indicate only mild effects of sublethal doses of pyrethroids on S. cincticeps with higher doses (10⁻³ to 10^{-3}) negatively affecting the insect development and lower doses (10^{-3} and 10^{-6} mg deltamethrin/ml and 10^{-6} and 10^{-7} mg permethrin/ml) actually favoring the insect survival. Further studies should be carried out to assess the reproductive impact of pyrethroids dose on S. cincticeps.

Index terms: Predator, pyrethroids, sublethal, Supputis cincticeps.

[0376] NEW APPROACHES TO CREATING GLOBAL SPECIES DATABASES IN ENTOMOLOGY

M.J. Scoble, ¹Dept. of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, E-mail: m.scoble@nhm.ac.uk.

Global species databases are, broadly speaking, computerised taxonomic catalogues. Databases have, however, the capacity to be more extensive than catalogues, and they are much more effectively searched. They can also be networked. It is increasingly evident that the kind of information inherent in traditional taxonomic catalogues is of value beyond the systematics community. In particular, it forms the basis for such products as life-lists, biodiversity surveys and inventories, which are needed to meet certain requirements under the Convention on Biological Diversity. The main difference between creating global species databases for insects and most other groups of organisms is that of the size of the task. In this paper I give an example of the steps in creating one such database (on geometrid moths) and the hardcopy catalogue that was derived from it. Although a great deal of effort was required to complete the database in a timely fashion, such large compilations are quite possible given appropriate facilities and the right people. Key features in the production of the work, both material and in terms of human effort, will be discussed. Some other insect databases will be cited. These examples have been created from just a subset of extensive archival sources in natural history museums. Attempts are now being made by the University of Essex and The Natural History Museum, London, to build a Versatile Interactive Archive Document System (VIADOCS). The project proposes a novel interactive method of archive conversion by extending a current commercial optical character recognition system for completing forms. A demonstration interactive conversion system utilizing a particular Lepidoptera index-card archive (on Pyraloidea) will be developed, and evaluated against current manual conversion methods, and in interactive use 'on demand' over the Internet. The aim of producing this system is to provide a means of making accessible extensive quantities of data trapped in typed and hand-written archives. All these efforts should be seen in the broader context of computerising biological data typically associated with biological collections.

Index terms: taxonomic information, catalogues, archival data

[0377] THE INVENTORY OF THE WORLDS INSECT BIODIVERSITY: DOING THE POSSIBLE

E. S. Nielsen, CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia (ebbe.nielsen@ento.csiro.au).

Biodiversity is the total variety of all life on Earth. Biodiversity provides all our foods, most of our medicine, most ecosystem services and much of the quality and joy of life. Biodiversity is therefore arguably the most precious resource on Earth. At the same time, at most 1.8M of the 5-10M multi-celled organisms are named, and we have little effective access to the information associated with the estimated 3B specimens in the world's biological collections. Indeed, it can be argued that scientific knowledge and its use is not advancing as rapidly as the irreversible decline of biodiversity. We need to analyse why the inventory of biodiversity does not attract the same level of support as genomics, health and astronomy. Based on the assumption of 10M species, E.O. Wilson in 1985 estimated that a complete survey of Life or Earth would require 25,000 professional lifetimes. Since then we have witnessed rapid development in our ability to share information and training as well as new technologies that assist in nearly all aspects of systematics, taxonomy, field work and curation. In particular biological and biodiversity informatics has revolutionised our ability to capture, maintain and use information from research and collections. We have seen the development of concepts such as the All Taxa Biodiversity Inventory (ATBI), All Biota Taxonomic Inventory (ABTI) and Systematics Agenda 2000. New initiatives are also being established: recently the OECD Science Ministers have endorsed the establishment of the Global Biodiversity Information Facility (GBIF) as recommended by the OECD Megascience Forum, and the Conference of the Parties is likely during this year to endorse the recommendation to establish the Global Taxonomy Intitiative (GTI) under the Convention on Biological Diversity (CBD). If institutions with the mission to inventory Life on Earth maintain their focus, collaborate and coordinate resources and responsibilities, if we can share a vision for a concerted effort and if the resources are made available to collect, curate and research the world's flora and fauna, then Wilson's vision can be more readily fulfilled and be more beneficial to all than ever before.

Index terms: biodiversity inventory, taxonomy, systematics, Life on Earth

[0378] REPRESENTATION, PREDICTABILITY AND ROBUSTNESS IN ECOLOGY: IMPLICATIONS FOR BIOINDICATION

M. A. McGeoch, Dept. of Zoology and Entomology, Univ. of Pretoria, Pretoria 0002, South Africa. E-mail: mamcgeoch@zoology.up.ac.za

Ecological indicators, that are sensitive to environmental stressors and that demonstrate the effect thereof on other taxa, are by definition indicative of both environmental and biotic state. The requirements that an ecological indicator should satisfy are threefold. It should (i) readily reflect environmental state, (ii) represent the response of other taxa to environmental state, and (iii) the previous two relationships should be temporally and spatially robust within the context of the bioindication objective. Ecological indicators thus require predictability at multiple levels. The response of the bioindicator to the stressor should be clear and consistent. In addition, the relationship between the response of the bioindicator and the response of at least a subset of other taxa in the environment must be significant and strong. The essence of bioindication is these correlative complexes that exist as a result of direct and indirect causal relationships between environmental parameters and the state of, and change in, biota. The presence of significant correlations is however insufficient to be of practical value to bioindication, statistically strong relationships are necessary to provide the level of predictability that is required. In addition, the robustness of these relationships (predictability of the predictability) has to be established. Bioindication is not divorced from the rest of ecology in the degree to which it is able to identify relationships, and make predictions from these. Indeed, there is no shortage of generalities and strong relationships in ecology, but rather an absence of tests of the robustness of these. The shortage of robust, predictable relationships in the field may be attributed to what are among at least two possible explanations: (i) ecology is generally not a field of science from which immediate results are demanded, and predictability may thus not be a priority, or (ii) relationships between and within biotic and abiotic variables are fuzzy and non-linear. Identifying the reasons for the lack of predictability in ecology will inform both direction and priority setting in the field of bioindication.

Index terms: generality in ecology, ecological bioindicators, environmental change,

[0379] HABITAT CONSTRAINTS AND PATTERNS OF DIVERSITY

I. Ribera¹, G. N. Foster² & A. P. Vogler¹, ¹Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, and Department of Biology, Imperial College at Silwood Park, Ascot SL5 7B, UK, E-mail ignr@nhm.ac.uk; ²Environmental Division, The Scottish Agricultural College, Auchineruive, Ayr KA6 5HW, Scotland, UK.

Certain large-scale patterns in species richness (e.g. latitudinal gradients, species-area relationships) are well known and robust ecological regularities. Most of the many explanations that have been proposed depend on geographical variables correlated, ultimately, with area and latitude. However, these explanations typically fail to identify underlying causal mechanisms and, equally, to demonstrate a connection between the scale at which diversity is varying with the scale at which the supposed processes affecting the diversity operate. In Europe, two contrasting types of freshwater habitat can be identified, with markedly different persistence values. Rivers and streams persist over relatively long periods, and are semi-permanent features of the landscape. In contrast, small to medium-sized stagnant water bodies are short-lived, and discontinuous in time and space. Most water beetles inhabit only one of these two habitat types, with a minority able to live in both (in western Europe the overall proportions are: 43% of species in running water, 38% in stagnant, and 19% in both). Running water species have smaller range sizes than stagnant water specialists, and this is explicable on habitat persistence as a constraint on the evolution and ecology of these insects. A model for water beetles in 15 areas in western Europe, based solely on total area, minimum latitude and a measure of mainland "connectivity", predicts with great accuracy the total number of species per area. However, when this beetle pool is divided into running water and stagnant water specialists, the results are very different. For running water species within each area, minimum latitude (seen as a surrogate for proximity to glacial refugia) is the variable with the highest correlation. For stagnant water species, the main explanatory variable is connectivity. These differences remain essentially the same when the data are divided amongst the four main phylogenetic groups represented (Hydradephaga, Hydrophiloidea, Hydraenidae, Dryopoidea). Thus, when species are separated according to a biologically significant variable (e.g. habitat persistence), their differing requirements and responses can be inferred to be the very processes that generate the observed overall patterns of diversity. An improved ability to understand these underlying causal mechanisms will enable us to make much better predictions about the extent and distribution of diversity, especially in poorly known or under-worked areas.

Index terms: diversity gradients, habitat persistence, water beetles, Hydradephaga, Hydrophiloidea, Hydraenidae, Dryopoidea, species richness, diversity models, prediction.

[0381] MODELLING DISTRIBUTIONS AND MAKING COMPARISONS: CAN WE PREDICT RELATIVE GAPS IN OUR KNOWLEDGE OF INSECT BIODIVERSITY MORE ACCURATELY?

R.I. Vane-Wright¹, M. Araújo¹ & P. Williams¹, ¹Biogeography and Conservation Laboratory, The Natural History Museum, Cromwell Road, London SW7 5BD, UK.

The ideal indicator for conservation area selection would predict precisely the extent and distribution of all other, unsampled elements of biodiversity. If we had such a perfect indicator, it could be used "in reverse", to locate areas that would hold the most unknown or unsampled diversity of poorly known groups, and thus help direct efforts for diversity exploration. At present such a pipe-dream seems quite unrealistic, due to the supposed low correlation of diversity among various taxonomic or indicator groups, the paucity of empirical data on distribution that is available for cross-group evaluation, and a lack of well-developed techniques for making such comparisons appropriate and informative. However, because of the second and third failings, any conclusions about the general lack of bioindicator properties between groups, or among sets of groups, are almost certainly premature. Various methods have been described for extrapolating and interpolating limited empirical data on the distribution of individual species, and these methods will be reviewed briefly. However, before resorting to modelled multi-species data, we should endeavour to assess indicator relationships using well sampled groups (e.g. certain bird and butterfly families) to develop techniques for the comparison of patterns of species richness and, more importantly, patterns of complementarity (taxon turnover), across different groups. If such techniques can be developed successfully, they would not only help in the search for better bioindicators for conservation priorities, but could also identify regional gaps or low-points where high, unsampled, complementary biodiversity can be anticipated, and thus direct our efforts for the exploration and discovery of insect diversity more effectively in the future.

Index terms: biodiversity indicators, modelling distributions, species richness, complementarity, exploration, discovery, prediction.

[0382] SOIL BIODIVERSITY: THE NEED FOR A GLOBAL INITIATIVE

<u>P. Eggleton¹</u>, ¹Soil Biodiversity Programme, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, E-mail: pe@nhm.ac.uk.

Soil biodiversity and associated soil ecological processes are a neglected area of biological research. Although healthy soils are clearly vital for a range of processes including global biogeochemical cycles, plant growth, and habitat stability, the biological basis for these processes is poorly understood. A very good example of this is studies of the soil macrofauna. A few studies from a range of scattered localities have begun to suggest the critical influence of the soil fauna on plant growth. However, there is an almost complete lack of synthesis of information from such studies which might provide the subject with a rational framework. In this talk I will discuss, in the context of the soil macrofauna, how such weaknesses might be overcome and propose a series of possible steps, considered at a global level, that might contribute to their amelioration. These include: Standardisation of sampling methods. These methods should be developed in flexible ways that take into account diversity anomalies in patterns of co-existing soil fauna across all biogeographical regions. Proper measurements of soil properties and processes involving extensive soil multidisciplinary collaboration with botanists, mineralogists, physicists, microbiologists, and other soil scientists. Multi-taxon studies, both correlative and manipulative, examining the covariation of taxa across wide biogeographical and environmental gradients. These studies will be particularly helpful to clarify the combined compensatory effects of soil macrofauna on vital soil processes. Of particular interest will be the degree to which soil macrofaunal mass-effects diverge or converge within similar habitats across biogeographical regions. I believe that a global multi-taxon view of soil biodiversity is necessary to allow us to discover if there are general ecological laws controlling the influence of diversity on soil processes. Without such studies conducted by many groups across the World, soil biodiversity studies will remain disparate and of limited synthetic value.

Index terms: soils, soil biodiversity, soil processes, soil fertility, macrofauna, sampling methods, multi-taxon studies

[0386] A NEW PROGRAM FOR SYSTEMATICS: THE CONVENTION ON BIOLOGICAL DIVERSITY'S GLOBAL TAXONOMY INITIATIVE (GTI)

ABSTRACT NOT RECEIVED

I. D. Cresswell, United Nations Convention on Biological Diversity Secretariat, 393 St. Jacques Street, Suite 300, Montreal, Quebec H2Y 1N9, CANADA, E-mail ian.cresswell@biodiv.org.

The lack of taxonomic knowledge of biological diversity has been recognized worldwide as a significant problem in decision-making for conservation and sustainable use of our natural resources. In response the Convention on Biological Diversity (CBD) has created the Global Taxonomy Initiative (GTI) to facilitate the filling of known gaps in systematics, the training of new taxonomists and curators, and finding new ways of using our knowledge base to increase our ability to conserve, use and share the benefits of our biological diversity. The need for fundamental taxonomic knowledge of biological diversity to underpin the key objectives of the CBD is wide ranging. The CBD deals with diversity at all levels of the biological hierarchy; from genes, species, populations, communities, ecosystems to landscapes. The GTI must assist international funding agencies, national and sub-national governments, and non-government bodies address the need for adequate taxonomy as part of the worldwide demand for up-to-date biodiversity information. To do this requires the advancement and renewal of taxonomy associated with the protection and maintenance of our natural heritage. For the GTI to be effective in a timely way a major increase in partnerships need to be quickly formed between the world's natural history institutions in the developed and developing worlds. Increasing the world's taxonomic activity will need to be focused to ensure the results are not only scientifically correct but also provide practical, implementable information that is available to managers and decision makers. The developing training programmes, the strengthening of infrastructure for biological collections in countries of origin, the building the capacity for taxonomic research, and increasing the worldwide availability of taxonomic information are high priorities. The overall need has been identified and a new commitment to action has been agreed. Yet this paper asks more questions than it answers: what should be our work priorities, how should we get agreement on who does what, how can each individual make a difference to the overall goals of conservation and sustainable use? This paper will present the decisions from the 5th meeting of the Conference of the Parties (the political body of the Convention) held in Nairobi, May 2000, and will attempt to illustrate the way forward, including how the ICE can help implement the GTI.

[0385] BEFRI, GLOBIS AND THE MSEF INITIATIVES—INTERNATIONAL ENTOMOLOGICAL APPROACHES TO CBD, GTI AND GBIF

T. Bourgoin¹ & H. Hoch², ¹Museum national d'Histoire naturelle, Lab. Entomologie, ESA 8043 CNRS, 45 rue Buffon, F-75005, Paris, France, E-mail bourgoin@cimrs1.mnhn.fr; ²Museum für Naturkunde, Humboldt-Universität, Institut für Systematische Zoologie, Invalidenstr. 43, D-10115 Berlin, Germany, E-mail hannelore.hoch@rz.hu-berlin.de.

International agreements such as CITES (International Trade in Endangered Species), Convention on Biological Diversity (CBD), obligate nations to take action relating to a biological diversity, notably regarding its conservation and use, and the equitable sharing of benefits. However, for hyperdiverse organisms such as insects, the present levels of taxonomic knowledge and available expertise are inadequate even to start this process, let alone provide the basic scientific support necessary to meet such obligations and agreements. Since 1994, the Major Systematic Entomological Facilities (MSEF) group has worked towards the formulation of collaborative work programs to address some of these problems. In 1998, during its annual meeting in Copenhagen (Denmark), the Hemiptera Fulgoromorpha were selected as one of the target groups to help fulfil the objectives of the Global Taxonomy Initiative (GTI) and, potentially, GBIF. The project "Biodiversity and Evolution of Fulgoromorpha, a global Research Initiative" (BEFRI) is now underway (together with other MSEF projects, such as GloBIS, the "Global Butterfly Information System", all of which have comparable aims but vary in their focus and priorities). The aims of BEIRI are to promote Fulgoromorpha systematics through an international collaborative network, as a specific model to meet international needs and objectives. General objectives of BEFRI are: to give to the scientific community a tool to develop perspectives in discovering, describing and understanding biodiversity in terms of evolutionary scenarios, i.e. to promote systematics in the broadest sense; to shorten the time between discovery and delivery, i.e. to disseminate information efficiently, for scientific, public and administrative demand (this includes development and management of collections within a computerised framework); to promote Fulgoromorpha as a pertinent model to explore and understand biodiversity, by e.g. facilitating networking among experts, and organising student training in planthopper studies; and to attract funding to expand knowledge of the group. The three phase action plan that has been drawn up (Describing biodiversity, Organising Fulgoromorpha knowledge, Disseminating information), with the explicit intention of meeting the criteria and scientific perspectives required by the CBD, will be outlined. BEFRI invites all people working with Fulgoromorpha to express their interest and to participate in this project.

[0387] CANOPY ARTHROPODS OF THE WESTERN AMAZON BASIN

<u>T. L. Erwin</u>, Megadiversity Group, Department of Entomology, Smithsonian Institution, Washington DC 20560

Canopy insect populations are remarkably stable relative to each other across seasons and years with the exception of Diptera which dramatically increase in abundance in the rainy season. Fungus Gnats (Mycetophilidae) account for the super-abundance of Diptera in the rainy season. Combined data from soil, litter, understory, and canopy indicate that there are about 6.4 x 10¹² arthropods per hectare in Amazonia. Equatorial terra firme forests in west Amazonia contain at least 60,000 species per hectare. Initial β -diversity data suggest some species, particularly larger ones are widespread, while smaller and/or more specialized canopy species show complete species replacement at intervals of about 200 km latitude. Only two longitudinal samples are available with nearly 100% complementarity, therefore a pattern cannot be discerned across Amazonia yet. Considering that the average length of a canopy beetle is 3mm and species replacement of small forms is high, it can be expected that overall richness across Amazonia would be marked. Further, it can be predicted that when vast tracts of forests are lost or converted, extinction rates of smaller forms of life will be high.

[0388] DIVERSITY AND BIOGEOGRAPHY OF UPPER AMAZON BUTTERFLIES (LEPIDOPTERA)

<u>G. Lamas</u>¹, ¹Museo Nacional de Historia Natural, Universidad Nacional Mayor de San Marcos, Apartado 14-0434, Lima-14, Peru.

The richest communities of butterflies in the world are found in Western Amazonia (west of the north-south axis formed by the Negro and Madeira rivers), where >1300 species may coexist in sites $<5 \text{ km}^2$ in area. Roughly one-third of the species in these communities are Hesperildae, one-third Lycaenidae + Riodinidae, and one-third Papilionidae + Pieridae + Nymphalidae. Distribution patterns of rainforest-dependent butterflies conform closely to endemism centers postulated by proponents of the "Pleistocene Refuge Hypothesis" of species diversification, but such endemism centers correspond mostly to areas of occurrence of distinctive populations of mimetic butterflies (usually regarded as parapatric subspecies); distribution patterns of full species appear instead to have been shaped by landscape evolution during late Caenozoic palaeogeographical changes.

[0390] DIVERSITY AND LIFE HISTORY TRAITS OF TIGER BEETLES (COLEOPTERA: CICINDELIDAE) FROM CENTRAL AMAZONIA (BRAZIL)

M. Zerm¹, J. Adis⁴, W. Paarmann² & C.R.V. da Fonseca³, ¹MPIL, Postfach 165, 24302 Plön, Germany; ²FH Hildesheim/Göttingen, Büsgenweg 1A, 37077 Göttingen, Germany; ³INPA, CPEN, Caixa 20stal 478, 69011-970 Manaus/AM, Brazil.

With 26 tiger beetle species presently known to occur in the environs of Manaus, Central Amazonia, this region presents one of the most diverse tiger beetle fauna worldwide. Species distribution is characterized by restriction of most species to only one type of biotope: Eleven species inhabit floodplain areas, 16 species terra firma upland sites, and only two occur in both. Species from floodplains and/or terra firme uplands either occur in forests or in open areas. Seven floodplain species are solely found in whitewater areas (várzea), two only in blackwater areas (igapó), and another two in both floodplain types. Interspecific and intraspecific differences in microhabitat and activity patterns contribute additionally to the diversity and segregation of species. Studies on phenology and larval development in common species from uplands and floodplains revealed a variety of life cycles. Most species studied up to now are univoltine with a clear seasonality regarding larval and adult stages. Species with a long lifespan in larvae, of which some show a dormancy period, have short-living adults. This is characteristic for several species in uplands and for a few species from floodplains with larvae surviving the aquatic phase in tunnels in the soil. Most floodplain species have a short larval lifespan. The adult beetles have a long lifespan and survive through the high-water period of several months duration, with females often showing a gonad dormancy, and reproduce solely during the nonaquatic phase.

Index terms: life cycle, survival strategy, floodplain, terra firme, dormancy

[0389] SPATIAL PATTERNS OF SPECIES RICHNESS: TIGER BEETLES OF NORTHWESTERN SOUTH AMERICA (COLEOPTERA: CICINDELIDAE)

D. L. Pearson & S. S. Carroll, Dept. of Biology, Arizona State Univ., Tempe, AZ 85287-1501 USA

Species richness patterns of tiger beetles (Coleoptera: Cicindelidae) were analyzed using a grid of 407 squares (137.5 Km or 1.2 degrees per side) across northwestern South America (Guyana, Venezuela, Colombia, Ecuador, Perú, Bolivia and western Brazil). Reliable data on species numbers were available for only 149 of the squares. Using a trend surface model (a model used to represent the mean of a spatial process by a polynomial function of spatial coordinates) as well as altitudinal range, precipitation and biogeographical influence for each square, we were able to predict the number of tiger beetle species likely to occur in intermediate squares for which no or unreliable data were available. The resultant spatial patterns of species richness were compared to similar analyses for temperate areas of North America and differences should be useful in developing understanding general diversity patterns and in the environmental management of species richness.

[0391] GROUND BEETLE COMMUNITIES (COLEOPTERA, CARABIDAE) AT FRUIT FALLS IN A TERRA FIRME RAINFOREST NEAR MANAUS (AMAZONIA) - A FIRST REVIEW

W. Paarmann¹, J. Adis², N.E. Stork³ & C.R.V. da Fonseca⁴, ¹FH Hildesheim/Holminden, Büsgenweg 1A, 37077 Göttingen, Germany, ²MPIL, Postfach 165, 24302 Plön, Germany, ³Rainforest CRC, James Cook University, POBox 6811, Cairus QLD 4870, Australia, ⁴INPA, Caixa Postal 478, 690-970 Manaus/AM, Brazil.

During a field study about the ground beetle communities at fruit falls in the 'Reserva Florestal A. Ducke' near Manaus (1991-1996), we collected data on community structure, population dynamics, and migration patterns of these beetles at different fruit falls, observing also fruit fall duration, and the abundance of seed fall. We also tried to determine the development of larval populations. In laboratory studies we recorded the number of seeds consumed by single adults of the seed feeding species, according to sex and stage of gonad development. Breeding experiments informed us about host tree specificity of the ground beetle species, the amount of food (seeds) necessary to complete larval development, and the quality of seeds of the different host species. Seed feeding specimens dominated the ground beetle communities (n=8,926, 92% at fig fruit falls). They represent eight species of the genus Notiobia. Two species were fig seed specialists: N. pseudolimbipennis and N. flavicinctus. Of N. disparilis, we collected four immature females on fig fruit falls only. The other five species appeared at fig fruit falls, but did not reproduce there. N. nebriodes was found to be specialized on fruit falls of Vismia (Clusiacaceae) and Coussapoa (Cecropiaceae), while the other four species reproduced at fruit falls of Melastomataceae trees: N. maxima at Bellucia and Loreya, N. umbrata and N. aulica at Miconia, and N. glabrata at all three. From the results of the field studies it is clear that figs are a key stone tree group for the whole guild of spermatophagous carabid species, either for reproduction (two species) or as 'stepping stones' during migration between other host trees. From the results of our laboratory studies we expected -1) a complete understanding of the food supply for adults and larvae at the observed fruit falls, -2) the relation between fruit falls and adults of the spermatophagous guild as well as the development of its larval population. First results show that there is no food shortage for the beetles of the founder population. However, their rising larval population depend on seeds left by the adults. Predatory or cannibalistic behavior among larvae is low as long as there are enough seeds available. At the end of a fig fruit fall or thereafter seed shortage might result in predatory (cannibalistic) behavior: larger larvae killing smaller ones. The new beetles hatch in a seed exhausted area and start their migration flight while starving. terms: Notiobia, Ficus, seed feeding, population dynamics.

[0392] DUNG BEETLES OF CENTRAL AMAZONIAN FLOODPLAINS

<u>J. Adis¹</u>, W. Paarmann² & B. Ratcliffe³, ¹MPIL, Postfach 165, 24302 Plön, Germany, ²FH Hildesheim/ Göttingen, Büsgenweg 1A, 37077 Göttingen, Germany, ³Univ. of Nebraska, W-436 Nebraska Hall, Lincoln, Nebraska 68588, U.S.A.

Central Amazonian floodplains in the vicinity of Manaus are annually inundated for 5-7 months and up to several meters in height. Their fauna is adapted to this monomodal flood pulse. Dung beetles (Coleoptera: Scarabeidae) have been monitored for up to 18 months on the soil, tree trunks, and macrophytes. Of the total 1,900 specimens, about 40 morphospecies were recorded in a blackwater inundation forest near the Rio Negro and about 30 morphospecies in a whitewater floodplain (inundation forest and macrophytes of non-woody areas) at the Rio Solimões-Amazonas. Only one morphospecies occurred in both biotopes. The phenology is presented for common species and compared between biotopes. Three of the survival strategies found are that adult beetles pass the flood period in the trunk/canopy of inundation forests (black- and whitewater), in adjacent upland forests (blackwater) or in a gonad dormancy on aquatic macrophytes (whitewater).

[0394] PATTERNS OF TERMITE DIVERSITY ACROSS RECENTLY ISOLATED LAND-BRIDGE ISLANDS IN FRENCH GUIANA

G. Davies¹, L. M. Hernàndez¹ & P. Eggleton¹, ¹Dept. of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, E-mail ried@nhm.ac.uk.

Forest fragmentation is a key process affecting Amazonian biodiversity. The trajectories of community change and biodiversity loss within fragments are influenced by the nature of the matrix habitat. Termites are likely to be an important component in the changes in trophic structuring of collapsing tropical forest ecosystems, as they are the major arthropod decomposers. A previous study of termite assemblages in forest fragments surrounded by cleared land in Brazil, showed a decline in species richness in fragments compared with continuous forest, six years after fragment isolation (De Souza & Brown 1994). This decline affected soil feeding species more strongly than wood and litter feeders. We investigated patterns of termite assemblage diversity and feeding group composition across land-bridge islands and mainland forest at a dam site in French Guiana. Sampling was carried out 3.5 years after the original flooding, coinciding with the period when the rate of tree die-off accompanying biomass collapse is thought to be maximal (Laurance et al. 1997). Environmental data were collected to evaluate the extent of micro-habitat changes and tree die-off on forest islands. Results were similar to those of the Brazilian study in revealing the same proportional shift towards wood and litter feeding species in fragments. However, there was no overall decline in species richness on small islands, and abundance and diversity of wood and litter feeding species appeared to increase. The three smallest island sites showed the greatest dissimilarities in species compositions in comparisons amongst all sites. The results are discussed in the light of evidence for changes in micro-habitat and availability of dead wood on islands, and in terms of the community dynamics of land-bridge islands compared with other forest fragmentation systems.

Index terms: feeding group, forest fragmentation. De Souza, O. F. F., and Brown, V. K. 1994. Effects of habitat fragmentation on Amazonian termite communities. J. Trop. Ecol. 10: 197-206.

Laurance, W. F., Laurance, S. G., Ferreira, L. V., Rankin-de Merona, J. M., Gascon, C. Lovejoy, T. E., 1997. Biomass collapse in Amazonian forest fragments. Science (Wash: D. C.) 278: 1117-1118.

[0393] MODELLING THE ROLE OF TERMITES IN THE CARBON CYCLE OF NEOTROPICAL FORESTS

C. Hanne¹ & C. Martius¹, ¹ Center for Development Research (ZEF Bonn), Walter-Flex-Strasse 3, D-53113 Bonn, Germany, E-mail: c.martius@uni-bonn.de

Termites (Insecta; Isoptera) are important decomposers of plant material in tropical ecosystems. They play one of the key roles in the turnover of dead phytomass, since they exclusively feed on organic material. Their biomass is much larger than previous estimates suggest, since they are based on soil fauna asessments. Therefore, termites in arboreal and epigeal nests and those in standing dead tree trunks have not been considered. Current ecosystem models that deal with carbon pools are often based on abiotic factors (i.e. relative evapotranspiration) solely, and do not include faunal data. The integration of faunal data in carbon models, however, is imperative, as macrofauna determines the initial decomposition rates, and hence, the turnover time of carbon in terrestrial ecosystems. We provide respiration measurements for termite species from over 20 termite genera from a central Amazonian primary forest, which will allow to specify the role of termites in the carbon cycles of these ecosystems. With these data, the extrapolation and application of data to larger scale amazon ecosystem models is possible. In this contribution, genus-, caste-, and size-specific respiration rates will be discussed, and together with data on diversity, distribution, and biomass, a model on the quantitative contribution of termites to the carbon cycle in these systems will be presented.

Index terms: Isoptera, respiration, rainforests, ecosystem-model.

[0395] FACTORS AFFECTING TERMITE DISTRIBUTION AND DIVERSITY IN NATURAL AND MANAGED CENTRAL AMAZONIAN FOREST ECOSYSTEMS

C. Martins¹, ¹ Center for Development Research (ZEF Bonn), Walter-Flex-Strasse 3, D-53175 Bonn, Germany, E-mail: c.martius@uni-bonn.de

Termites are the most dominant group of decomposers organisms in soil arthropod assemblages in tropical rainforests. Litter and soil termites were collected in a primary forest site, a secondary forest site and two sites of a polyculture plantation system in central Amazonia. Termite genus diversity, abundance and biomass all were highest in the primary forest. The values in the secondary forest were half those of the primary forest, and they were lowest in the plantation systems, indicating that the latter sites may suffer from functional constraints concerning the process of organic residue decomposition. The average termite biomass of the sites was positively correlated to dead wood volume on the forest floor, but the termite biomass of the individual samples was not related to the wood in the litter layer of the sample. The possible correlation to other factors is discussed. In a second study, nest-building termite density was recorded in undisturbed primary forest site, and compared to the density in forest sites subject to selective logging. Only one genus, Nasutitermes, showed a (positive) correlation to increased logging impact, indicating that it is a group of species that follow forest disturbance. The implications of these findings for monitoring programs and for ecosystem management are discussed. Index terms: Isoptera, distribution, diversity, agroforestry, land use systems

[0396] HYMENOPTERA OF LOWER AMAZONIA: WILL THIS BE THE CENTURY WHEN WE GET IT TOGETTIER?

W. L. Overal¹ & A. Y. Harada¹, ¹Dept. of Zoology, Museu Paraense Emílio Goeldi, Caixa Postal 399, 66.017-970 Belém, Pará, Brazil, E-mail overal@museu-goeldi.br & ayharada@museu-goeldi.br

The Hymenoptera fauna of the lower Amazon is among the most diverse in the world, but our full appreciation on this high species richness is hampered by the still unconsolidated state of the taxonomy of many families and incomplete collecting throughout most of the region. At the same time that hymenopterans are increasingly seen as important indicator species for zoogeographical, ecological, and faunal studies, as well as for conservation, pollination, and biological control, the ranks of our taxonomists are being depleted by retirement or death. Incentives for taxonomists are marginal, and the Amazon currently boasts more resident molecular biologists than systematists. Since most end-users of hymenoptera taxonomy are untrained in morphology and taxonomy and require accurate species identification for access to the (often-scattered) associated biological information, dissemination of illustrated keys, check-lists, synoptic catalogs, and biological data bases through the internet would represent a major advance. Leaving aside the Symphyta (potentially identifiable in the Amazon) and Parasitica (not so identifiable), Amazon faunal studies are at least possible for the Bethylidae, Chrysididae (new book!), Tiphiidae, Scoliidae, Mutillidae (only 7 South American species with host records!), Formicidae (skip Crematogaster and Pheidole but try to do the Camponotus), Vespidae (Mischocyttarus now being revised), Eumenidae (with help from our friends), Pompilidae (avoiding the small species), Sphecoidea (with the big blue book), and Apoidea (if not too small, solitary, or unrevised). What has been lacking, for the most part, is scientific manpower (and concomitant financing and support). No complete faunal lists are available for any Amazonian locality, even the best collected ones, for any major hymenopteran family. The city of Belém, that served for over 300 years as the traditional portal to the Amazon for naturalists of all countries, does not have a complete list of its ant species, although this is in the works (>600 spp.) and will only be complete when the total surpasses the Manaus figure. Other Amazon ant faunas range upwards to 450 species, but the idea has taken root that beta, rather than alpha, diversity is what we should be looking at, since mosaics are surely occurring. Social wasp faunas are seen to be more locally diverse in areas of ecotonal contact between forest and savanna, and they are hard to sample during field trips of short duration. Not all bees come to baits, either, and Euglossini and Meliponini may not be representative of total apoid diversity in Amazon habitats. To avoid working in areas subject to human modification, researchers at the Goeldi Museum in Belém have begun to survey the hymenoptera of the Caxiuana National Forest. The future holds both promises and challenges. Index terms: Hymenoptera, Amazon, biodiversity, taxonomy,

[0397] COMPARATIVE ANT SPECIES DIVERSITIES IN INTACT AND LOGGED AMAZONIAN RAINFORES'IS

<u>S. M. Ketelhut</u> & A. Y. Harada, ¹, ¹Museu Paraense Emílio Goeldi, Depto. Zoologia, Entomologia. Cxp 399 - 66040-170. Belém, PA, Brazil. E-mail: sktelhut@inpa.gov.br

A comparative study of ant fauna communities was made in a primary forest and in two kinds of logging systems (Managed and Traditional) located in a tropical rainforest area, near Paragominas, Pará state, Brazil. In each area, ants were sampled using pitfall traps during December 1997 and March 1998 on six 200 m transects, separated from each other by 100 m. Differences in ant fauna diversity among the sites were tested using diversity indexes (Shannon, Simpson and Fisher's Alpha) and richness estimates protocols (e. g. Colwell & Coddington 1994). Species composition was evaluated through affinity analysis (Scheiner 1992) and similarity indexes (Jaccard and Morisita-Horn). A total of 134 ant species belonging to seven subfamilies and 42 genera could be identified in the entire area. Of these, 90 species were found in primary forest, 90 in managed and 84 in the traditionally logged forest. Differences between habitats could be detected comparing diversity and similarity indices among different transects. There were no differences in indexes when absolute values were compared for each site. Results from richness estimates protocols also indicate that ant faunas were similar between sites and suggest that ant faunas were still underestimated. The richness and abundance of ants were different between the months, and it does not affect the diversity patterns in the areas as a whole. High mosaic diversity could be detected using affinity analysis, and it is suggested that the communities were composed by very complex gradients. Thus, differences in ant composition would be due to heterogeneity at smaller scales.

Index terms: Logged systems, Hymenoptera, Formicidae, Biodiversity, Amazon, Estimates.

[0398] HOW FAR NORTH AND SOUTH DOES THE APIFAUNA OF AMAZONIA REACH, ESPECIALLY THE BEE SPECIES VISITING MASS-FLOWERING TREES

W. Engels^{1,4}, B. Harter^{1,4}, A. Köhler^{1,4}, W. Wilms^{1,2,4} V.L. Imperatriz-Fonseca². Betina Blochtein¹, R. Thiele^{3,4} & A. Zillikens^{1,4}, ¹LPB, PUCRS, Porto Alegre, Brazil; ²Depto. de Ecologia Geral, IB, USP, São Paulo, Brazil; ³COSEFORMA-GTZ, San José, Costa Rica; ⁴Inst. Zoology, Uni. Tübingen, D-72076 Tübingen, Germany, e-mail wolf.engels@unituebingen.de.

The mass-flowering syndrome is widely distributed amongst angiosperm trees in the Neotropics. In many rain forest habitats, these trees represent dominant species of the arboreal flora, and are often also important targets of timber logging. The flowers of these trees provide rich nectar and pollen resources for visitors which are mainly bees. However, the period of full blossom is always rather short, thus the question arises, which bees are using such resources and, at the same time, are pollinating the millions of flowers. To answer this question, canopy studies have to be carried out. We did this by using two approaches: netting bees at inflorescences by means of long poles from the ground, and climbing trees and performing observations and sampling within the canopy. Study sites were in the lowland rain forest of Costa Rica, and at different locations in the Brazilian Atlantic rain forest (Mata Atlântica), including the montane Araucaria forest of Rio Grande do Sul. The results show that highly abundant bees are the principal foragers on the flowers of mass-flowering trees, and that medium-sized stingless bees are the dominant visitors. Social bees are evidently the only force of pollinators available in sufficient numbers to provide pollen transport between conspecific tree individuals in the forest. We compare the spectrum of meliponids recorded on mass-flowering trees at the various sites north and especially south of the Amazon. Usually this guild of pollinators comprises less than ten species per site. The flowers of the many taxa of mass-flowering trees represent unspecialised florescences, mostly lacking bright colors, Studies on the bee-attracting flower signals were also carried out. The close relations between the trees and their pollinating bees in Neotropical rain forest ecosystems are interpreted as the result of diffuse coevolution. The biogeographical distribution of the bee taxa involved in the pollination of rain forest trees is discussed under aspects of evolution and ecosystem impact

Index terms: Meliponinae, mass-flowering trees, pollinating bees, Neotropical rain forests, diffuse coevolution

[0399] SOCIAL INSECTS AND THE KAYAPÓ INDIANS OF THE BRAZILIAN AMAZON: INDIGENOUS APPRECIATION AND NOMENCLATURE OF BIODIVERSITY

W. L. Overal¹ & D. A. Posey², ¹Dept. of Zoology, Museu Paraense Emílio Goeldi, Caixa Postal 399, 66.017-970 Belém, Pará, Brazil, E-mail overal@museu-goeldi.br. ²Oxford Centre for the Environment, Ethics & Society, Mansfield College, University of Oxford, Mansfield Road, Oxford OX1 3TF, U.K., E-mail darrell.posey@mansfield.ox.ac.uk

Among the Kayapó Indians of southern Pará state in the Brazilian Amazon, social insects are important in cosmogony (social wasps), mythology (termites), medicine (ants and wasps), agriculture (termites, ants and wasps), social organization (wasps), ritual (wasps), and warfare (wasps). Bee keeping and honey raids in the Kayapó village of Gorotire involve more than 15 species of stingless bees and a social wasp species. Informants were able to recognize and name 35 species of social wasps of the 68 species collected, although nest shape and size were needed clues to wasp identity in many cases. 42 species of ants were consistently given the same or similar names by informants, especially when habitat information was available. Only 4 common names were found for the numerous (>35) termite species present, but descriptive terms were often added to these names in order refer to specific forms. As was the case with social wasps, nest architecture is important in termite species recognition. Building on this taxonomic base, the Kayapó possess biological, behavioral, and ecological data on social insects demonstrably vaster and more detailed than those of acculturated (non-tribal) Amazonian rural dwellers. Their use of Azteca ants in fruit trees as control organisms for leaf-cutter ants (Atta), their use of termite nests (Nasutitermes spp.) as fertilizer, and their use of ant volatile compounds in human and veterinary medicine attest to their knowledge of social insect attributes. Keen observers of nature, they noted the arrival in the Amazon of the Africanized honey bee a full year before it was reported in the literature. The case of the Kayapó Indians is certainly not unique among Amazonian Indians, and it reinforces the urgent need for systematic soundings of indigenous and folk populations for information on the faunal elements with which they share the region. The inclusion of indigenous information in research (perhaps in the form of hypotheses to be tested) will require our stepping down from the high horse of ethnocentrism, but this is a small (and perhaps not the only) price to pay for the accumulated data base of peoples for whom natural history is a life-or-death matter.

Index terms: Amazon, Kayapó Indians, social insects, folk taxonomy.

[0400] THE AMAZONIAN TABANIDAE AND PIPUNCULIDAE (DIPTERA)

<u>J. A. Rafael¹</u> & A. L. Henriques², ¹Instituto Nacional de Pesquisas da Amazônia, Caixa Postal 478, 69011-970, Manaus, Amazonas, Brazil. ²Bolsista do CNPq. Email: jarafael@inpa.gov.br

Tabanidae. In the Neotropical region there are 65 genera and 1,172 catalogued species and subspecies, representing 47% of the 137 genera and 27% of the 4,300 species known worldwide. In the Amazon Basin 27 genera and 239 species representing 41% and 20% of the Neotropical genera and species were recorded. 156 species are endemic with the at the occidental half, 7 at the Central area, 7 at the oriental half and the remaining are restricted to one side of the Amazon River being 19 in the north and 11 in the south. In addition to the endemic species 83 recorded species also occur beyond the Amazon Basin, some of them widespread in the Neotropical region or in South America. The places in the Amazon Basin with more number of recorded species are 1) Ducke Reserve, Manaus with 80 species; 2) Tambopata, Peru, with 73 species and 3) Parque Nacional do Jau, low Rio Negro with 69 species. Some Amazonian tabanids have shown specific preference for hosts like caimans and birds. Pipunculidae. In the Neotropical region there are 16 genera and 235 species and subspecies, representing 69% of the 23 genera and 20% of the 1,200 species known worldwide. In the Amazon Basin it was registered 12 genera and 68 species, representing 75% of the genera and 30% of the species. Pipunculids are poorly represented in collections. Most Amazonian species were described in the last 15 years and are only known from their type localities. Less than 5% of all Amazonian species were recorded in other regions. Only one genus is endemic with two described species still not described. Biology and hosts are unknown.

Index terms: systematics, distribution, diversity, Amazon Basin.

[0402] ABUNDANCE, DIVERSITY AND SEASONALITY OF ARTHROPODA ASSOCIATED WITH THE SAPOTACEAE AND LECITIHIDACEAE TREE CANOPIES AT THE ADOLPHO DUCKE FOREST RESERVE, MANAUS, AMAZONAS, BRAZIL. PRELIMINARY FINDING

J. C. H. Gerrero, C. R. V. Fonseca, P. Hammond & N. E. Stork

ABSTRACT NOT RECEIVED

[0401] SPHINGIDAE OF THE BRAZILIAN AMAZON

C.S. Motta, INPA, CPEN, Caixa Postal 478, Manaus, Amazonas, Brasil 69011-970

In the Neotropical region there are about 200 genera and 1200 catalogued species of hawkmoths (Lepidoptera: Sphingidae) representing over 60% of the species known worldwide. Of the 124 species collected in the Brazilian Amazon, 116 species (from 28 genera) have been recorded in four areas in the state of Amazonas IItacoatiara, Jaú, Querari, Urucu]. The highest number of species was registered in the primary forest areas of Jaú (79 sp.), Urucu (78 sp.), Querari (69 sp.) and the lowest species diversity was in the disturbed forest area of Itacoatiara (63 sp.). The species of Dilophonotini predominated (55 sp.). The Macroglossini included 20 species of Xylophanes followed by the the Sphingini with 15 species of Manduca and 10 species of Isognathus. The species Manduca clarki, Manduca aff. brontes brontes, Perigonia stulta and Baniwa yavitensis were represented by only one specimen. Of the nine species known to be endemic to the Hylaea 4 were collected in the four areas of the state of Amazonas: Cocytius mortuorum (Urucu), Manduca clarki (Itacoatiara), Nyceryx stuarti (Jaú, Querari and Urucu) and Xylophanes cosmius obscurus (Urucu). Several species were collected at other sites within the Brazilian Amazon: Manduca prestoni (Rondônia), Madoryx b. bubastus (Rondonia and Anavilhanas), Nyceryx alophus (between Tonantins and Jutai), Eumorpha triangulum (Presidente Figueiredo), Xylophanes ploetzi (Alter do Chão and Manaus), X. sarae (Pico da Neblina), X. n. neoptolemus (Pacaraima) and Phanoxyla hystrix (Manaus). Of these species, M. prestoni and P. hystrix are also considered as endemic to the Amazon. Index Terms: Lepidoptera, Bombycoidea, hawkmoth, Amazonas, Brasil

[0403] LATIN AMERICAN ENTOMOLOGICAL SOCIETIES AT THE DAWN OF A NEW CENTURY—A TIME FOR INVENTORY

G. J. Hallman¹ & A. R. Panizzi², ¹United States Dept Agriculture, Agric. Research Service, 2301 S. International Blvd., Weslaco, TX 78596. E-mail ghallman@weslaco.ars.usda.gov. ²Centro Nacional de Pesquisa de Soja, EMBRAPA, Caixa Postal 231, Londrina, PR 86001-970, Brasil, E-mail panizzi@cnpso.embrapa.br.

Eight years ago we published an article in *American Entomologist* (38:22-32) on entomological societies in Latin America. At that time there were 15 societies, although some were inactive. Many published research journals and were very involved in educating interested parties about entomological topics, especially in economic areas. The highest per capita membership was about 28 members per million people in Peru, while most countries with entomological societies had about 10 members per million people.

During this symposium which explores what entomological societies are doing and might do to preserve biodiversity we revisit societies in the region. In the seven years before our 1992 article 3 new entomological societies were born, and the prospects for other societies forming in countries that did not have them looked good. But as this is written (Jan. 2000), we have not been able to verify that any new society has been established since the Asociacion de Entomologos de Costa Rica was in 1991. Worse, other societies have become inactive and membership has declined across the region. Given the great tasks facing entomologists in Latin America in such areas as pest control, preservation of biodiversity, and entomological nomenclature, the survival and constructive work of entomological societies where the bulk of entomological diversity occurs is a desirable objective.

Index words: Latin America, biodiversity

[0404] INSTITUTO NACIONAL DE BIODIVERSIDAD (INBIO) HELPING TO CONSERVE COSTA RICAN BIODIVERSITY

J. A. Ugalde-Gómez, Instituto Nacional de Biodiversidad, INBio, Apartado Postal 22-3100, Santo Domingo, Heredia, COSTA RICA, E-mail jugalde@inbio.ac.cr.

The Instituto Nacional de Biodiversidad (INBio) was established in 1989 as a non-profit scientific institution, with a social orientation and for the public welfare. His mission is to promote a new awareness of the value of biodiversity, and thereby achieve its conservation and use to improve the quality of life. All the programs: National Biodiversity Inventory, Bioprospecting, Information Management, Development for Conservation and Social Outreach are joint by a central process based in generation, processing and transference of knowledge, as well as the strategic alliances with national and international institutions and organizations, have contributed with the conservation of Costa Rican biodiversity. The National Biodiversity Inventory program is organized in Taxonomic Working Groups integrated by parataxonomists, technicians, curators and international taxonomists, all of them working together with the Ministry of Environment and Energy, specifically with the National Conservation Areas System (SINAC) which generate information about Costa Rican biodiversity in data bases and Basic Information Units at the species level, both with free access across Internet. Also scientific articles, field guides and educational materials are being produced in order to promote the use of biodiversity information in different areas such as: conservation, national planning, industry, education, science, agriculture, forestry, and ecology.

Index terms: Conservation, Latin America, Costa Rica.

[0406] BRAZILIAN ENTOMOLOGICAL SOCIETIES PRESERVING BIODIVERSITY

A. R. Panizzi', 'Centro Nacional de Pesquisa de Soja, EMBRAPA, Caixa Postal 231, Londrina, PR 86001-970, BRASIL, E-mail panizzi@cnpso.cmbrapa.br.

There are two entomological societies in Brazil. The first society is the Sociedade Brasileira de Entomologia (SBE) which was founded on July 17, 1937, by a small group of entomologists at the Instituto Biológico de São Paulo. There are currently 350 members. The SBE meets as part of the annual congress of the Sociedade Brasileira de Zoologia (SBZ). It publishes the Revista Brasileira de Entomologia three times a year, with a not fixed periodicity. It contains mostly, papers on taxonomy and biology. Approximately 50 articles are published each year in Portuguese, English, or Spanish. The Boletim da Sociedade Brasileira de Entomologia was published nine times from 1948 to 1958, and is now inactive. The second society, Sociedade Entomológica do Brasil (SEB) was founded on February 22, 1972, in Itabuna, Bahia. A number of attendants at an agricultural entomology meeting launched the society because they felt that the existing SBE dedicated little attention to economic entomology. The SEB quickly grew to become the largest entomological society in Latin America with about 1300 members. The SEB is divided in 17 regions which allows a high level of involvement by the members in the affairs of the society. A national congress is held every 18 months. A journal, Anais da Sociedade Entomológica do Brasil is published quarterly on a fixed periodicity (March. June, September, and December). The Society publishes also a newsletter (*Informativo da Sociedade Entomológica do Brasil – ISEB*) every four month, on April, August, and December, which contains SEB news, book reviews, editorial notes, etc. The contributions of the Brazilian entomological societies to promote biodiversity will be discussed. Our view is that both societies should interact with each other and with other organizations to promote preservation of biodiversity in the country and in the continent. Cataloguing insects, similar to the BIOTA-FAPESP project, that aims to record all the living organisms in the state of São Paulo, should be estimulated, and the societies should get involved with such projects. Also, issues related to biodiversity should be part of the constitutions of the societies, to promote this subject among the members and the public in general. Index terms: Entomological societies, Latin America, Brazil.

[0405] SOCIEDAD ENTOMOLÓGICA ARGENTINA AND THE PURSUIT OF ENTOMOLOGY

<u>M. Lizarralde de Grosso</u>, Instituto Superior de Entomología, Universidad Nacional de Tucumán, Miguel Lillo 205, 4000 Tucumán, Argentina. Tel. ++54-381 423-0056 FAX++54-381-423 5291. E-mail instililo@infovia.com.ar.

The Sociedad Entomológica Argentina (SEA) was founded in 1925 and since this time has been an active society; about one third of its members have postgraduate studies, mainly Ph.D.s, which enables them to attain sufficient human resources to manage advanced research programs. Many members of the SEA are from others countries such as Australia, Bolivia, Brazil, Colombia, Chile, Ecuador, Perú, Uruguay, and Venezuela. Most members work in universities and research centers of pure and applied entomology, especially in agriculture, medical, and veterinary areas. Entomology is the most developed zoological speciality in Argentina. The main research centers are: La Plata: Facultad de Ciencias Naturales y Museo de la Universidad Nacional de La Plata, Instituto de Limnología de La Plata (ILPLA), and Centro de Parásitos y Vectores (CEPAVE)-UNLP-CONICET. In Buenos Aires there are the Museo Argentino de Ciencias Naturales and the Universidad Nacional de Buenos Aires. In Tucumán: Instituto Superior de Entomología (INSUE), Universidad Nacional de Tucumán and Fundación Miguel Lillo. These are the principal foci for training of researchers, where most members are, and contain the three most important, in numbers and diversity, entomological collections in the country. There are also other institutions of entomological studies, with important developments occurring in recent years. Since 1987, the National Congress of Entomology has taken place every three years in Tucumán, Córdoba, Mendoza, and Mar del Plata, respectively. The next Congress will be in Buenos Aires in 2001. Argentine entomological activity is reflected in these events with such topics as biodiversity, biological control, medical and veterinary entomology, genetics, physiology, ethology, and ecology. Since 1925 the SEA has edited, once a year, the Revista de la Sociedad Entomológica Argentina, the oldest active entomological journal in Latin America, and also at the present, twice a year, a bulletin with additional information for the membership. SEA and its members also contribute to the development of biodiversity taking part in international meetings and publications. The SEA has a library located at the Museo de La Plata and maintains working relationships with a great number of institutions throughout the world, exchanging publications and pursuing funding.

Index terms: entomological societies, Latin America, biodiversity.

[0407] CONSERVATION OF THE BIODIVERSITY OF INSECTS IN CHILE

L. E. Parra, V. Jerez, T. Zaviezo, A. Cammouscight & D. Lanfranco, Casilla 21132, Santiago 2, Chile. Telephone: +56 2 6814095; Fax: +56 2 6817182; e-mail luparra@udec.el; URL: http://abulafia.ciencias.uchile.cl/sche.

The Chilean entomofauna is characterized by poor diversification of genera (many are monotypic), large number of species with primitive characters, high level of endemism, and prolonged geographic isolation. These characters, because of their scientific importance, constitute a unique attribute that promotes, as a priority, their study and In Chile, there are more than 12,000 described species, although an conservation. estimation of the undescribed species would total approximately 24,000. There are three important entomological collections that represent the diversity of the country's entomofauna: the Museo Nacional de Historia Natural and the Instituto de Entomología at the Universidad Metropolitana de Ciencias de la Educación, both located in Santiago, and the Museo de Zoología at the Universidad de Concepción in Concepción. The knowledge of the biodiversity of insects in Chile is dispersed throughout the literature, primarily in the Revista Chilena de Entomología, Acta Entomológica Chilena, Gayana Zoología, Boletín de la Sociedad de Biología de Concepción, Bosque and international journals. The members of the Chilean Entomological Society are the principal generators of information, represented by numerous published studies in diverse Chilean and international journals. Amoung books the efforts of Luis E. Peña standout. He published Los Insectos de Chile (2 editions) and recently Las Mariposas de Chile (the butterflies of Chile). Other important works are: González, 1989 Insectos y Acaros de Importancia Agrícola y Cuarentenaria (insects and mites of agricultural and quarantine importance) and Artigas, 1994 Entomología Económica contained in two volumes. Finally, in Simonetti et al., 1995 (eds.) Diversidad Biológica de Chile, the state of conservation and knowledge of the Chilean entomofauna is given. The Chilean Entomological Society promotes educational activities that tend to better understand, protect, and conserve the entomolauna of the country. Furthermore, Chile maintains a number of protected areas (national parks and reserves) dedicated to the conservation of the floristic and faunistic biodiversity including insects.

[0408] THE SOCIEDAD COLOMBIANA DE ENTOMOLOGIA PRESERVING BIODIVERSITY

M. T. Gonzalez, CENICAFE, Bogota, Colombia, E-mail: fcmgon@cafedecolombia.com.

The Sociedad Colombiana de Entomologia (SOCOLEN) was founded in 1973 by 26 members, and membership has grown to over 500. SOCOLEN has been a very active society during its 27 years of existence, carrying out an annual congress in various cities of the Republic and seminars, workshops, etc. on diverse topics during the year. To better serve entomological interests throughout Colombia, SOCOLEN is divided into 10 Regional Committees. The *Revista Colombiana de Entomologia*, currently in its 25th volume, publishes research articles on a broad array of entomological topics, while the *Entomologo* is an informative bulletin. Memoirs of annual congresses and proceedings of conferences are also printed. To stimulate entomological research several prizes are awarded annually. This talk will concentrate on how SOCOLEN's efforts positively affect biodiversity. Visit our web site at: http://www.socolen.com.co/index.html. Index words: entomological societies, Latin America, Colombia

[0410] SOCIEDAD ENTOMOLÓGICA DE PUERTO RICO PRESERVING BIODIVERSITY

M. F. Linberas & A. Pantoja, Gerente de Sistemas de Control de Vectores, HD Hudson Manuf, Co., Jacksonville, FL 32222-0156, E-mail Lluberas@aol.com; University of Puerto Rico-Mayaguez Campus, Department of Crop Protection, P.O. Box 9030, Mayaguez, Puerto Rico 00681, E-mail Pantoja: a_pantoja@rumac.upr.clu.edu.

This paper discusses the role, efforts, and accomplishments of members of the Sociedad Entomológica de Puerto Rico in studying and preserving the rich biodiversity of the neotropical Caribbean island of Puerto Rico. Index terms: Entomological societies, Latin America

[0409] BIODIVERSITY AND THE SOCIEDAD ENTOMOLOGICA DEL PERU

A. Lizárraga¹, L. Vuldiviezo² & G. Lamas³, ¹Ex President of The Sociedad Entomologica del Peru, Action Network for Alternatives to Pesticides, RAAA, Postal Address 1144 - Lima 11 - Peru, raaaper@terra.com.pe; ² President of The Sociedad Entomológica del Perú, National Program of Biologic Control - Servicio Nacional de Sanidad Agraria, SENASA, senasa@esan.com.pe; ³ Ex President of The Sociedad Entomológica del Perú, Natural History Museum, San Marcos National University, Postal Address 14-0434, Lima 14, Peru, gerardo@musm.edu.pe

The Sociedad Entomológica del Perú (Entomological Society of Peru) is based in Linua and currently has over 300 active members. Since its foundation in 1956, 41 scientific meetings have occurred and, 41 issues of the Revista Peruana de Entomología have continuously been published. In addition, 6 volumes of The Boletín Informativo have also been edited. The primary goal of The Entomological Society of Peru is disseminate information regarding entomological research through meetings and publications, stressing the importance of biodiversity and its preservation. Apparently, the first descriptions of insects in Peru were based on the collections of Humbolt and Bondpland in 1802. Since then, a great many researchers and investigators have made collections of insects in Peru, most of which were identified and preserved in European museums. With the inception of the Entomological Society of Perú, the importance of the entomological research in relation to Peruvian biodiversity has been promoted. One popular estimate is that there are 1,13 million species of insects in Peru, the most important orders of which are: Coleoptera, Hymenoptera, Lepidoptera, Diptera, Hemiptera + Homoptera and Orthoptera. The extensive number of species reported and estimated gives an idea of the vast importance of biodiversity in different Peruvian ecosystems. The History Natural Museum of San Marcos National University has made major studies of the group Lepidoptera. These reports, developed in relation to the diversity of species (especially of agricultural interest), have provided important contributions to the knowledge of this important insect order. Entomologists at the La Molina Agrarian National University have used these reports as a basis for entomological research. Other diverse universities, related to agronomy and biology, have also developed contributions, most of them of great importance toward establishing the magnitude of Biodiversity in Peru. Index terms: Peru, entomological societies biodiversity.

[0411] NATURAL HISTORY, CULTURE AND STATISTICS: CRITERIA FOR SELECTING BIOINDICATORS FOR MONITORING AND INVENTORY

D. L. Pearson, Dept. of Biology, Arizona State Univ., Tempe, AZ 85287-1501 USA

If bioindicators are to be used in conservation efforts, they must be chosen rigorously to meet both expectations of scientists and usefulness in communication with non-scientists. The level of natural history known for the proposed indicator, its usefulness to the public, a clear understanding of the need for indication, proper statistical methods, and an unambiguous way of reporting the results to scientific colleagues and the public are mandatory if bioindicators are going to be reliably used in planning and management. At a minimum, the proposed bioindicator must meet the criteria of: 1) established taxonomy, 2) natural history well known, 3) easily observed and/or manipulated, 4) broadly distributed, 5) biologically specialized, 6) some evidence of correlations of patterns with other related and unrelated taxa, and 7) some economic importance. Also, distinguishing whether the bioindicator is to be used in inventory, monitoring or some other use will dictate the significance of these criteria as well as how management plans will be reported to the scientific community and the public.

104121 PROSPECTS FOR MAXIMISING CONSERVATION OF MADAGASCAN BIODIVERSITY BASED ON KNOWN DISTRIBUTIONS AND GEOGRAPHY

D.C.Lees, Biogeography and Conservation Laboratory, The Natural History Museum, Cromwell Road, South Kensington, SW7 5BD.

It is often assumed that if we had highly detailed information on taxonomic groups, including the distribution and land-use of the dominant primate, we would be able to use that data to suggest an efficient and wise plan for conservation of the maximum number of species in the target, if not other taxa, in a minimum number of areas. Indeed, in many parts of the world and for limited taxon sets, there is evidently considerable redundancy and enough biodiversity information to render such a plan conceivable. In Madagascar, there is poor knowledge of most elements of biodiversity, there are outstanding levels of macro and micro-endemism and fragments of remaining forest are quite limited in extent, whilst many important areas that often connect the patchwork of existing reserves have no official protection. To rely on biodiversity data at all for conservation planning today, we are forced to use presently available, taxonomically and distributionally reliable data, with a bias towards better known groups, either directly or via models of their distribution that draw on spatially more reliable geographic data. Here, I examine the inter-predictive relationships between four invertebrate and six vertebrate groups with different range size frequency distributions and mobility responses to the landscape, and the form of their overall cumulative area representation curve. Differences in the distributional properties of different clades and levels of currently understood micro-endemism in certain Madagascan taxa suggest that such an indicator group approach is fatally flawed, and rather we need to assimilate biodiversity data, starting with already published data, in very many and different groups and to make predictive mapping more efficient and informative by capitalising on detailed geographical and human land-use data. I highlight a new regional databasing facility that is designed to help readily provide people and organisations in Madagascar with much needed baseline information in a spatially explicit context that draws on detailed geographic data, and to help promote the conservation of the island's extraordinary diversity in a rational way.

[0413] PLURALITY OF SPECIES, ECOLOGICAL GUILDS, SINGLE SPECIES AS BIOINDICATORS TO ASSESS RURAL LANDSCAPES: PROBLEMS AND TOOLS

M.G. Paoletti, Department of Biology, Padova University, 35100 Padova, Italy, E-mail paoletti@civ.bio.unipd.it.

Species number, abundance, ecology, physiology are among the key factors that permit bioindication. Developing an appropriate selection of organisms to assess landscape quality is the target of any project aimed at improving environmental quality and environmental health. The strategy is linked to the personal knowledge and sensibility, the available information and training. Adopting just a few specie or adopting many larger taxa, using ecological guilds, microcosms or directly study in the field is linked, in most cases, to personal sensibility and skill. Appropriate identification tools and good or good taxonomic expertise can make the adoption of plurality of species as target instrument of assessment. Morphotype sorting can be a very interesting tool especially in situation in which taxonomists and taxonomy tools are not easily available, this is the case for most areas to be assessed in the tropics. Ecological guilds can be appropriate in some cases where environmental impacts are very high. Making preliminary assessment in most cases can offer the best mix of ideas to properly operate. Discussion and practical considerations will be made regarding: on different input orchards and a power plant in Italy, of rural landscapes in China and forest-savanna cline in Amazonas, Venezuela. Comparison among different portions of the target landscape are the simplest way to work. Seasonal variability and spacial uncertainity make important the personal sensibility in planning and developing the project.

[0414] TESTING AN ECOLOGICAL BIOINDICATOR SYSTEM: DUNG BEETLES IN NORTHERN KWAZULU-NATAL, SOUTH AFRICA

M. A. McGeoch & B. J. van Rensburg, Dept. of Zoology and Entomology, Univ. of Pretoria, Pretoria 0002, South Africa, E-mail: mamcgeoch@zoology.up.ac.za

The use of terrestrial insects as indicators of habitat quality and environmental change has little empirical support in the form of taxa that have been quantitatively identified and then independently tested to confirm their usefulness as bioindicators. In addition, indicator species have mostly been assumed to fulfil both the role of indicator of environmental change, as well as detecting the direction in which change is occurring. We suggest that ecological indicator species are unlikely to provide information on the direction of change because of their high degree of habitat specificity and comparatively high vulnerability to environmental change. Rather, detector species, that span a range of environmental states, are likely to be better able to fulfil this role. Here we test the responses of dung beetle (Coleoptera: Scarabaeidae) indicator and detector species, previously identified in Tembe Elephant Park, South Africa, on an independent data set. Using the quantitative Indicator Value (IndVal) Method, a method for the selection of species indicative of the direction in which environmental change is occurring (detector species) is outlined and tested. IndVal was shown to be sensitive to inter-annual species abundance changes, although the IndVals of species with high indicator values of > 70 % changed comparatively little between studies. The indicator species first identified were largely supported by testing. Detector species, for which a third of the selected species responded as predicted, were shown to provide information complementary to that provided by indicator species, and are thus a potentially useful group of ecological bioindicator. A suite of dung beetle indicator and detectors species were thus confirmed as bioindicators for habitats in and around Tembe Elephant Park, and these species can now confidently be used for monitoring environmental change in the area. The testing of ecological indicators in this way is imperative to the progress of the field of bioindication.

Index terms: detector, environmental change, monitoring, indicator value.

[0415] INDICATOR GROUPS FOR BIODIVERSITY ASSESSMENT: RESULTS AND PERSPECTIVES OF A STRATEGY

G. Halffter¹ & C. E. Moreno², ¹Depto. Ecología y Comportamiento Animal, Instituto de Ecología A.C., A.P. 63, Xalapa, Ver. 91000, México, E-mail halffter@ecologia.edu.mx; Centro de Investigaciones Biológicas, Universidad Autónoma del Edo. de Hidalgo, A.P. 69 Plaza Juárez, Pachuca, Hgo. 42001, México, E-mail claudia@ecologia.edu.mx.

Species richness can be quantitatively expressed from different perspectives depending on the aspect (or function) under study, and on the spatial and temporal scales at which the study is carried out. In the XX ICE, in Florence (August 1996), the first author (G.H.) proposed a strategy to assess within community (alpha), between communities (beta) and landscape (gamma) diversities on the mesoscale through the use of indicator groups. Here, we present the first results of this approach and some perspectives of research derived from our work. To date, we have used three families of dung beetles: Scarabacidae (Scarabaeinae and Aphodiinae), Geotrupidae and Silphidae; as well as two families of neotropical bats (Microchiroptera: Phyllostomidae and Mormoopidae). Taking into account ecological processes at the landscape level, alpha diversity has shown to be a more difficult concept to measure than it was when communities were studied as isolated spatial units. Dispersal processes associated to landscape structure, such as movement of species from suitable adjacent areas to communities with low species richness (mass effect), may considerably increase alpha and decrease beta diversity. We have also found that some communities have high species turnover in time, a phenomenon that we have called "temporal beta diversity". When this occurs, alpha diversity measured as the mean species richness during sampling period is lower than the alpha diversity measured as the cumulative number of species during such sampling period. Mass effect and temporal beta diversity might be very frequent in non-stable communities. An indicator group strongly influenced by such stochastic processes is inadequate for monitoring biodiversity. Our results have encouraged us to redefine what alpha diversity really means and how should it be measured. This redefinition must consider the limits of communities, in terms of space and time. At the landscape level, gamma diversity should be assessed considering the proportional contribution of alpha and beta diversities. This approach gives the possibility of measuring and predicting the effects of alterations resulting from human activity in landscapes; whether these are modifications resulting in the fragmentation of communities or changes to them.

Index terms: Scarabaeidae; bioindicators; alpha, beta and gamma diversities.

[0416] EVALUATING PRACTICAL METHODS FOR SAMPLING INVERTEBRATE BIOINDICATORS

D. T. Jones & P. Eggleton, Department of Entomology, The Natural History Museum, Cromwell Road, London, SW7 5BD, UK. E-mail dtj@nhm.ac.uk.

Increasing effort is being directed towards investigating and evaluating the use of invertebrates as biological indicators (e.g. McGeoch, 1998; Paoletti, 1999). The basic requirement of a bioindicator is to indicate a relationship with another biotic or abiotic variable. Any relationship is, however, only as good as the sampling method employed to callect the data on the "target" group (i.e. the taxa being collected). If a sampling method cannot reproduce a reliable picture of the target group, then attempts to use the results to infer relationships with other variables is likely to lead to spurious conclusions. Therefore, an important preliminary question that must be addressed before a target group can be used as a bioindicator is: How well does a sampling protocol characterise the composition and structure of the target group? For practical purposes, a sampling protocol must also involve a trade-off between trying to minimise the size of the samples in order to reduce the time spent collecting, sorting, and identifying specimens, against the need for samples that are large enough to be representative of the local assemblage. We describe a transect sampling protocol designed to assess termite species richness and functional composition in tropical forests (Jones & Eggleton, 2000). Samples were calibrated against the total known local termite assemblage. The taxonomic and functional group composition of the transect samples did not differ significantly from the known local assemblage. Results suggest that the protocol is a robust, rapid and cost-effective sampling method that offers good replication and relatively low levels of pseudoturnover. Building on these lessons, we will present preliminary results from our Darwin Initiative project to develop and test rapid sampling protocols for beetles, ants and earthworms in tropical forests.

[0417] ASSESSING ANTHROPOGENIC IMPACTS ON BIODIVERSITY USING CARABIDS: A GLOBAL NETWORK

J. Niemelä & J. Kotze, Dept. of Ecology and Systematics, P.O. Box 17, FIN-00014 University of Helsinki, Finland. Niemelä, J., J. Kotze, A. Ashworth, P. Brandmayr, K. Desender, T. New, L. Penev, M. Samways, and J. Spence. 2000. The search for common anthropogenic impacts on biodiversity: a global network. J. Ins. Cons., in press.

Landscape change through human impact is a massive unplanned experiment creating modified land types across the world, yet we lack information on how these changes impact on biodiversity in various parts of the world. Thus, a global programme that assesses these human-impacted landscapes so that global patterns and effects can be distinguished from local ones is needed. However, the assessment of landscape modification is not the endpoint, but a means for making decisions as how to best manage the landscape for production, yet at the same time, maintaining biodiversity. My aim is to describe a global research and assessment programme that uses a common methodology (GLOBENET) (Niemelä et al. 2000). GLOBENET has the following objectives: (1) to use the same group of organisms (initially carabid beetles), one methodology (pitfall trapping), and the same human-influenced landscape (urban-rural gradient) in different parts of the world in studying the effects of human impact, (2) to develop simple tools and protocols for assessing ecological effects of human-caused landscape changes, which could help sustainably manage landscapes for biodiversity and for human requirements, and (3) to maintain a web-site as an information centre (http://www.helsinki.fi/science/globenet/). Evidence points to carabid beetles being sufficiently varied (morphologically, taxonomically, behaviourally and ecologically), abundant and sensitive to environmental changes worldwide to be used as bioindicators. Carabid assemblages from different countries will be analysed in the same way to determine common denominators (global and regional effects) as opposed to specific differences (local effects). Results so far include development of a standardised sampling protocol (Niemelä et al. 2000), and field work in three countries (Finland, Canada, Bulgaria). Results are presented by Johan Kotze in this congress, and they are available in the web site. To conclude, the initial GLOBENET programme will focus on providing consistent inventory and description of biological communities in an attempt to better understand biological diversity at landscape or larger scales. In the future, we hope to be able to expand the network and include as nany countries in the world as possible. Researchers interested in contributing to GLOBENET are advised to follow the Internet web-site for instructions and results. Key words: Carabidae, global change, bioindicators, biodiversity

[0418] CARABID BEETLES (COLEOPTERA, CARABIDAE) ACROSS URBAN-RURAL GRADIENTS IN BULGARIA, CANADA AND FINLAND; AN INTERNATIONAL COLLABORATIVE EFFORT

J. Niemelä¹, <u>D. J. Kotze</u>¹, L. Penev² & J. Spence³, ¹ Dept. of Ecology and Systematics, ^P O Box 17, FIN-00014, Univ. of Helsinki, Finland, ² Central Laboratory for General Ecology, 2 Gagarin Street, 1113 Sofia, Bulgaria, ³ Dept. of Biological Sciences, CW405A, Biological Sciences Building, Univ. of Alberta, Edmonton, Alberta, Canada.

Landscapes, worldwide, are changing rapidly through human intervention, and a need exists to assess these human actions on the native fauna and flora. GLOBENET, a global network of scientists evaluating human impacts on the environment, using a common methodology, has been established. Jari Niemelä will discuss the GLOBENET theoretical background and aims at this conference. GLOBENET has the following methodology: to sample carabid beetles, using standard size pitfall traps, across urban-rural gradients. For further information see http://www.helsinki.fi/science/globenet. In 1998 we collected arabid beetles across urban-rural gradients in Sofia (Bulgaria), Edmonton (Canada) and Helsinki (Finland). The highest number of carabid species were captured in Bulgaria, ca. 72 species in 7 035 individuals, followed by Canada (41 species in 15 543 individuals), and then Finland (25 species in 2 203 individuals). In the Canadian study, however, four species captured, representing 76.7% of total catch, were introductions from Europe (Carabus granulatus, C. nemoralis, Clivina fossor and Pterostichus melanarius). Consequently, analyses were performed on the 3 628 native individuals, but we also discuss the possible effects of these introductions on the native fauna. Standardised beetle abundance changed little across the three gradients, but rarefied species richness did change significantly across the Canadian gradient; here significantly more species were captured at the rural than urban end of the gradient. Biomass changes across these gradients were investigated. It is hypothesised that disturbed habitats support a carabid fauna of lower biomass. However, little evidence was found to support this statement as biomass changed without pattern across these urban-rural gradients. Three basic wing forms are identified in ground beetles; macropterous, brachypterous and dimorphic Although proportions of wing forms changed significantly from urban to rural environments for all three cities sampled, these changes were neither the same, nor consistent from one city to the next. These initial results demonstrate that human-induced landscape changes influence biodiversity in different ways, in different parts of the world Possible future avenues for research are discussed.

Key words: Urban-rural gradients, Carabidae, global landscape change

[0419] SUMMARY: SCIENTIFIC APPROACHES TO BIOINDICATION

M. A. McGeoch, Dept. of Zoology and Entomology, Univ. of Pretoria, Pretoria 0002, South Africa, E-mail: mamcgeoch@zoology.up.ac.za

Within 17 months, between August 1998 and January 2000, three independent reviews of bioindication appeared in the literature (McGeoch 1998, Caro & Doherty 1999, Hilty & Merenlander 2000). This suggests that the field of bioindication is ripe for a synthesis of past achievements, and that there is a need to set future directions for the field. Indeed, all three reviews concur strongly on three issues. First, the requirement for bioindicators is reemphasized, second the superiority of invertebrates over vertebrates as indicator taxa is acknowledged, and third, the field of bioindication is seen as lacking scientific rigour and well established methodologies. A symposium on scientific approaches to bioindication could therefore not be better timed. We have now moved beyond the debate on criteria for the selection of bioindicators, and it is largely agreed that the most appropriate criteria are prescribed by the specific objectives for which the bioindicator is to be used. Furthermore, it is recognised that multiple taxa will be needed to address not only the variety of alternative bioindication objectives, but frequently also singular objectives. Here multiple taxa provide complementary information and increased security, ensuring the detection or effective monitoring of environmental change. The focus of bioindication now lies on the clear definition of bioindication objectives, and the development of new and more quantitative methods for the identification, testing and application of bioindicators. As is evident from the papers presented in this Symposium, much closer scrutiny is being given to the quantitative assessment of the robustness of bioindicators. This is true irrespective of whether the broad objectives of bioindication concern identification of the level of a stressor in an environment, the impact of that stressor on biota, or reflection of the biodiversity of a given area. Recent developments in ecology, for example better understanding of mechanisms underlying species responses to disturbance, and models for the effective extrapolation of species densities across scales, are also likely to better inform the predictive tools that are so vital to bioindication. Comparative as well as more rigorous approaches detailed in this Symposium will enhance both the applied value of bioindicators and the confidence with which they can be used.

Index terms: methods for indication, environmental change, biodiversity.

Session 03 – BIOGEOGRAPHY AND BIODIVERSITY

[0420] TERMITE DIVERSITY AND LAND USE CHANGES: LESSONS FOR FUTURE GENERAL BIODIVERSITY STUDIES

<u>P. Eggleton</u>¹, ¹Dept. of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, E-mail: pe@nhm.ac.uk.

Termites are not only the most important arthropod decomposers in tropical forests, they are also extremely sensitive to the effects of forest clearance. Complete degradation of forests will often lead to the almost total destruction of termite assemblages, with a potentially enormous concomitant loss of ecosystem services. Termites would therefore seem to be extremely good target organisms both as indicators and as direct mediators of coclogical processes. In this talk I will critically evaluate the problems of using termites as indicators of land use change, especially those due to variation in sampling technique, analytical procedures and biogeographical history. Generalising to studies with a wider remit I conclude that many of the studies that assume simple disturbance responses in species richness are flawed, often by an overemphasis on catch-all parameters, especially species richness and diversity indices. Compositional (multivariate) approaches are likely to be much more informative and far more sensitive to the complex but subtle changes increasingly being observed in disturbed biotas.

Index terms: Isoptera, land use changes, species richness, analyses of assemblage composition

[0422] INSECTS AS INDICATORS OF CHANGING LAND USE IN ALPINE ENVIRONMENTS

J.R.Haslett, Inst. of Zoology, Univ. Salzburg, Hellbrunner Str. 34, A-5020 Salzburg, Austria, E-mail: john.haslett@sbg.ac.at.

Mountain environments are characteristically extremely heterogeneous over a wide range of spatial scales. These nested, complex habitat mosaics are being altered, often irreversibly, by changes in mountain land use. In Europe, problems arising from demands of agriculture and winter tourism are particularly prevalent. Here I explore responses of selected insects, particularly Orthoptera and Diptera, to variations in mountain habitat mosaic stucture in the Austrian and German Alps. Results reveal that insects may be sensitive to patch border complexity as well as to patch content, including microclimate. Individual behaviour, populations, and species assemblage structure may be affected. Key words: Diptera; Orthoptera; habitat mosaics; European Alps

[0421] CHANGES IN CARABID POPULATIONS IN RELATION TO HISTORICAL AND RECENT FOREST ECOLOGY

K. Desender, Dept. Entomology, RBINSc, Vautierstr. 29, B-1000 Brussels, Belgium, Email: kdesender@kbinirsnb.be

Most woodlands in Flanders (Belgium) nowadays are highly fragmented or degraded, mainly due to excessive human interference in the past. Forests now cover less than 10% of the total surface only, but are rather well known concerning their historical ecology. Several efforts have recently been directed towards increasing our knowledge on distribution, ecology and genetics of forest organisms, in particular ground beetles. A short review is given on carabid beetle diversity, ecological assemblages and population genetics in forests of Flanders. Within the context of studying effects of forest history (fragmentation and its effects on beetle diversity and population genetics), or forest quality in general (assemblages of ground beetles in archaeological as compared to recent samples, Red data book- species), several regional projects and impulse programmes have been launched, (some case studies will be illustrated on posters during the ICE). A recent baseline study deals with the occurrence and bio-indicative values of ground beetles from 56 forest stands, distributed in 40 forests. In another study, extensive data on the recent carabid beetle fauna occurring in woodlands of Flanders are compared to a unique archaeological dataset of a post-Roman forest. Integration of these data reveals that during medieval forest degradation and fragmentation, most woods must have been impoverished to a high extent with respect to their stenotopic woodland beetle fauna. Typical woodland beetles show a reduced dispersal power (constant brachyptery) and appear to be powerful indicators for larger ancient woods. A next case study has evaluated beetle diversity in relation to forest size (fragmentation) and history. Apparently, ground beetle diversity has increased in smaller forest fragments, mainly due to increasing influences of surrounding habitats (edge effects). Larger ancient forests therefore yield lower diversity estimates. although having much higher values for conservation. Finally, we have recently used several carabids as model organisms in population genetic studies on forest fragmentation. Population genetic results invariably show significant genetic differentiation between populations. Some of the brachypterous species show geographical isolation by distance. High FST-values are obtained for some rare and brachypterous species. Smaller values of genetic differentiation are found in common and more mobile species from inundation and valley forests. Genetic erosion in small populations is indicated for some very rare and brachypterous carabids, which are known indicators for ancient forests. Based on our results, a number of recommendations can be given for regional nature conservation. Index terms: fragmentation, ecological indicators, diversity, population genetics

[0423] BUTTERFLIES AS INDICATORS FOR CONSERVATION IN FRAGMENTED LANDSCAPES IN THE NEOTROPICS

K. S. Brown Jr, Dept. De Zoologia and Museu de História Natural, Inst. de Biologia, Univ. Estadual de Campinas, C.P. 6109, Cidade Universitária, Campinas, SP 13.083-970 BRAZIL. Financial support: CNPq, FAPESP, CIFOR, PDBFF, BSP.

Insects, the most diverse ecotaxonomic group of macroorganisms, dominate most Neotropical environments. A single locality can have nearly 2000 recognized species of butterflies, 300 of dragonflies and 500 of ants (three better-studied groups with wide niche variations in food, space, time, chemistry, and structure). Fast-breeding insects with short generation time, readily observed, easily recognized, and quickly evaluated for abundance and variation, are especially useful for rapidly monitoring directional changes in the local resources and diversity. In low-productivity systems in the deep tropics (Manaus), rich systems near the Andes (Rondônia and Acre), and complex landscapes in the Atlantic forests, fragmentation and diversity patterns have been studied over several decades, using butterflies and other insects. In general, species richness increases locally with mild disturbance, probably as a result of multiplication of niches and their occupants. Certain types of species disappear early, but richness only decreases when anthropic intervention exceeds natural levels of disturbance (often involving 10-30% of the system, sometimes much greater in bamboo forests, mountainsides and river valleys). Genetic and species diversity depend on landscape or habitat heterogeneity in almost all groups and sites examined, while resource richness may even decrease species diversity. The size of a fragment is less relevant than edge effects and habitat diversification in predicting local richness, persistence, and redundancy patterns. Factors that contribute to heterogeneity or connectivity (especially topography, climate, and disturbance) show clear correlation with the richness of insects, while other factors, including vegetation, soils, latitude, and permanent surface water, have low predictive values. This is typical of disturbance- or heterogeneity-driven diversification on many spatial and temporal scales, with groups responding, through their abundance, disappearance, or immigration, to changes in microenvironment of a fragment or a habitat patch. The monitoring of these indicator groups, though not sufficient per se, is a necessary and effective component in effective landscape conservation in the Neotropics.

Index terms: Richness, heterogeneity, resources, diversification, disturbance.

[0424] TERMITES AS INDICATORS OF HABITAT FRAGMENTATION IN THE CERRADO IN BRAZIL

<u>O. DeSouza</u>, Depto. Biologia Animal., Univ. Fed. Viçosa, 36571-000 Viçosa MG, Brazil, E-mail: og.souza@mail.ufv.br

Being detritivores, termites (Insecta: Isoptera) neither control directly the rate at which their resources are made available, nor restrict the ability of the resources to regenerate. Consequently, they do not mask the ecosystem depletion caused by any sort of ecological pressure, and, therefore are theoretically reliable bioindicators. A field test is performed aiming to show that changes in termite community/population parameters vary consistently with environmental alterations promoted by habitat fragmentation in Brazilian savanna ("Cerrado"). In addition, other criteria for selection of bioindicators are objectively evaluated using termites. It is shown that termites respond to environmental stresses caused by habitat fragmentation in a readily detectable and statistically tractable way. Moreover, data collection for such analyses can be simple, quick, and inexpensive. In addition, termites present wide geographical range, covering precisely the areas of the globe where habitat fragmentation is an important issue. Finally, some termite populations may attain significant pest status, which could ease the quest for sponsorship of scientific research. Termites, however, present some traits which pose problems for their use as bioindicators. After balancing the pros and cons, it is concluded that termites are a reliable taxon to be used as bioindicators of habitat fragmentation and, possibly, bioindicators of more general environmental stresses.

Index terms: Isoptera, bioindicators, environmental stress

[0425] INSECTS AS INDICATORS OF SUBTLE, CLIMATE-INDUCED HABITAT FRAGMENTATION

<u>G. J. Masters</u>¹, V. K. Brown¹, I. P. Clarke¹, S. P. Riberio², R. G. Booth¹ & J. B. Whittaker³, ¹CABI Bioscience, UK Centre, Silwood Park, Ascot, Berkshire, SL5 7TA, UK, E-mail: g.masters@cabi.org; ²Dept. de Biologia Geral/ICB, Universidade Federal de Minas Gerais, CP 486-CEP 30160-970, Belo Horizonte, MG, Brazil & ³Institute of Environmental & Biological Sciences, Lancaster University, Lancaster, LA1 4YQ, UK.

Climate can have direct effects on insects (e.g. temperature-dependent phenological change) and indirect effects, where the response is mediated by the host plant or the immediate biotic community. Variability in macro- or microclimate can lead to subtle physiological responses within host plants and/or changes in their community structure and function, with knock-on effects for the associated insects. Insects are good biological indicators of climate-induced alterations in their host plants, through their relatively short generation times, life-history strategies and mobility/dispersal. Additionally, the majority of insect groups can be easily monitored at regular intervals. A manipulative field experiment, using novel, non-intrusive technology to change local climate, was initiated in 1993 and is on-going. Two climate change scenarios were simulated in the field; warmer winters (by 3°C from Nov. to the following April) with either dryer or wetter summers (complete drought during July and Aug. and 20% supplementation of the long-term average rainfall, from June to Sept. respectively). These treatments have produced a dramatic fragmentation of the grassland habitat, with adjacent plots having very different communities. Insect populations have been monitored throughout this period; in particular the Auchenorrhyncha, leaf-miners, Collembola and Coleoptera, and data from these groups will be used to illustrate climate-induced fragmentation of the habitat. Wetter summers led to an increase in insect abundance, tracking vegetation cover. However, summer drought led to certain insect groups maintaining or increasing their abundance while the vegetation suffered a decline. This was attributed to drought stress leading to greater nutrient availability. All landscapes have inherent spatial heterogeneity, which will lead to variability in the impact of climate. At a local scale, landscapes will have patches that are, for example, wetter/dryer and warmer/colder. Certain insect species will be sensitive to this variation, and thus could be candidates for biological indicators of climate-induced change within the landscape.

Index terms: calcareous grassland, climate change, drought stress, eco-physiology, spatial heterogeneity

[0426] INSECTS AS INDICATORS OF THE RESTORATION OF AGRICULTURAL LAND

S. R. Mortimer, R. G. Booth & V. K. Brown, CABI Bioscience, Silwood Park, Ascot, Berkshire, SL5 7TA, UK, E-mail: s.mortimer@cabi.org

Much of Europe's biological diversity is associated with agricultural ecosystems. Increases in the intensity of agricultural management in recent decades have led to erosion of this biodiversity. In particular, increases in agrochemical inputs and the widespread use of forage crops have led to the destruction of large areas of species-rich grassland. Recent policy changes (Convention on Biological Diversity, EU Agri-environment Regulation, EU Habitats Directive) have provided incentives for restoration of these habitats associated with low intensity agricultural practices. Insects make good biological indicators of changing agricultural land use as a result of their short life-cycles, mobility and sensitivity to small scale environmental conditions. Indeed, insects can be better indicators of the health of a plant community than the plant species themselves. The insect fauna is a product of both plant community composition and vegetation structure. Therefore, changes in management (e.g. grazing pressure) which result in alterations in canopy structure may affect the insect community long before changes in plant community composition are manifested. However, the presence of adults does not mean that a population exists at the site. Whereas plant species are comparatively easy to identify, with insect taxa there is a trade-off between ease of identification and their value in predicting the success of a restoration scheme. Approaches include the comparison of insect assemblages at restoration sites with those of existing areas of pristine habitat using similarity indices or multivariate analysis techniques. Data on the species composition of the fauna of particular insect groups can be used to identify key environmental or management variables which promote the restoration of the community. Such approaches allow recommendations to be made on the most appropriate management for a particular site, and also allow targeting of resources for restoration schemes on those sites likely to yield the best results. Multivariate techniques can also be used to define potential indicator species, which must combine ease of identification with predictive power, allowing evaluation of the success of restoration management. The use of insects as indicators of the success of restoration management will be illustrated using examples from the restoration of lowland calcareous grasslands in the UK. Restoration management scenarios include the diversification of agriculturally-improved grassland, the re-creation of grasslands on ex-arable land and the restoration of abandoned grasslands after scrub encroachment.

Index terms: agro-ecosystems, biodiversity, calcareous grassland, conservation management, habitat management.

[0427] AN EVALUATION OF ARTHROPODS FOR POSSIBLE USE IN COMPLETION CRITERIA FOR MINESITE REHABILITATION

J. D. Majer¹ & L. Bisevac¹, ¹School of Environmental Biology, Curtin University of Technology, GPO Box U 1987, Perth WA 6845, Australia. E-mail imajerj@info.curtin.edu.au.

Completion Criteria, also known as Success Indicators, are measures used to help identify when minesite rehabilitation has reached a benchmark standard in order to allow it to be relinquished by the mining company. Appropriate levels must be attained before declaring the restoration a success and, where relevant, release of bonds. The most common approach to using such criteria for rehabilitation of former minesites is based on physical and soil factors and also various measures of plant communities in the area. Fauna is not usually measured, since animals are presumed to return with the re-establishment of flora; the casualty of this relationship has seldom been demonstrated. Furthermore, if fauna is included, generally only vertebrate animals are considered. As explained elsewhere in this Symposium, invertebrates are ideally suited for conveying information about the environmental health of an area. There is therefore an opportunity to use measurements of invertebrates as indicators of the success of rehabilitation and to include these in the schedule of Completion Criteria. This presentation makes a comparison of the logistics of performing: 1) vegetation, 2) vertebrate and 3) invertebrate surveys in the monitoring of rehabilitation. Using data from the Iluka mineral sand mine at Eneabba, Western Australia, it presents evidence that invertebrates can provide a cost-effective means of generating information on the environmental status of an area.

[0430]CONSERVATION OF GRASSLAND BUTTERFLIES IN AN URBAN LANDSCAPE IN THE UK

B.C.Wood¹ & A.S.Pullin², ¹School of Biosciences, Univ. of Birmingham, Edgbaston, Birmingham, B15 2TT, UK, Email B.C.Wood@bham.ac.uk.

Urban green areas are a valuable refuge for wildlife in cities. As urban development increases, green space is often reduced in area and fragmented into smaller, more isolated patches. Although permanent green space exists in most cities, some of the urban landscape is in a dynamic state of flux, with patches being continually created whilst others are lost. Insects use these patches as both stable breeding habitats and as transient patches facilitating dispersal. This study investigates a suite of four grassland butterfly species, along putative wildlife corridors, in the fragmented network of grassland habitat in two conurbations in the West Midlands, UK. These butterfly species range in mobility from the highly mobile Pieris napi, to the intermediary Maniola jurtina and Pyronia tithonus, and the sedentary Coenonympha pamphilus. Allozyme electrophoresis was used to determine the extent of geographic structuring and the level of gene flow between populations along and between habitat corridors. It was hypothesised that lowest levels of gene flow and therefore greatest geographic structuring would exist between populations of the most sedentary species, C. pamphilus and no geographic structuring would be found between the highly mobile *P. napi* populations, at this spatial scale. Little geographic structuring was found for all species, although higher mean Fst values were found for C. pamphilus and P. tithonus than P. napi and M. jurtina. Bootstrapped Reynold's distance measures (generated from allele frequencies) between populations and resulting unrooted consensus neighbour-joining trees show that populations are no more connected when situated on the same putative habitat corridor, than when situated on different corridors. No correlation was found between geographic distance and the genetic distance between populations. These results suggest that the distribution of these butterfly species is governed by the distribution and persistence of suitable habitat, rather than the relative mobility of species and the connectivity or isolation of habitat patches. Conservation strategies for these grassland species in the urban landscape, therefore, should focus on the appropriate management and creation of suitable habitat for these species.

[0429] HOST-SPECIFICITY IN MACULINEA ALCON: A LARGE BLUE BUTTERFLY CONSERVATION ISSUE IN EUROPE

D.R. Nash¹, T.D. Als², R. Maile³, H. Jungnickel³ & <u>J.I. Boomsma¹</u>, ¹Dept. Population Ecology, Univ. of Copenhagen, Unversitetsparken 15, DK-2100 Copenhagen, Denmark, E-Mail DRNash@zi.ku.dk; ²Dept. Genetics and Ecology, Univ. of Aarhus, DK-8000 Aarhus C, Denmark. ³Dept. Chemistry, University of Keele, Keele, Staffordshire. ST5 5BG. UK.

The large blue butterflies (genus Maculinea) are rare, endangered or locally extinct throughout Europe. All large blue butterflies have an unusual life-cycle. They initially feed on the flowers of one or a few specific host plants, but in the last larval instar they become aphytophagous parasites of ant colonies of the genus Myrmica. The combined requirement for specific host plants and specific host ants is a major restriction on the suitable habitats available for these butterflies, and their socially parasitic lifestyle puts a further restriction on population sizes. Recent changes in agricultural land use have led to the restriction of suitable habitat to small, widely dispersed patches, and there have been frequent local extinctions, even in apparently suitable habitat. There is therefore currently much conservation effort to preserve and expand existing habitat and to reintroduce large blue butterflies into areas from which populations have become extinct. The key to the success of these endeavours is likely to lie in the understanding of the host ant specificity of large blue butterflies. Reintroduction into areas that are populated with, or measures that encourage, the wrong species of Myrmica are doomed to failure. We have been studying the population ecology and host specificity of the Alcon blue butterfly, Maculinea alcon. This species is unusual in that it is known to use different Myrmica species as host in different parts of Europe. Danish populations of M. alcon are particularly interesting because they lie between populations in Sweden that are known to use exclusively Myrmica rubra as a host, and those in The Netherlands that use Myrmica ruginodis. Our work has shown that both Myrmica rubra and Myrmica ruginodis are used as hosts in Denmark, but not in a simple cline as we had originally predicted. The majority of Danish populations seem to use both host ant species simultaneously. We have examined the surface hydrocarbons found on caterpillars of M. alcon and those on the their host ants. From this it seems that *M. alcon* caterpillars gain access to, and survive in, their host ant nests by mimicking the surface chemistry of the host ant larvae. Different populations of the butterfly differ in how closely they match the larvae of the different host species, and this is reflected in their host use in the field. Cross-infection experiments have demonstrated some local adaptation to host ants. These results have implications both for the conservation of large blue butterflies and for studies of parasite-host coevolution in general.

[0431] CONSERVATION GENETICS OF A THREATENED EUROPEAN BUTTERFLY EURODRYAS AURINIA IN THE FRAGMENTED AGRICULTURAL LANDSCAPE OF THE UK

D. A. Joyce & A. S. Pullin¹, ¹ School of Biosciences, The University of Birmingham, Edgbaston, Birmingham B15 2TT, UK. E-mail d.a.joyce@bham.ac.uk.

Euphydryas aurinia is protected in Europe under the Bern Convention after a dramatic decline throughout the continent. The UK is thought to be a major stronghold for the species, but even here it is declining at the rate of at least 11.5% per decade. This is due to loss of suitable habitat, either through destruction or mismanagement. The remaining populations are separated from one another by large expanses of unsuitable habitat leading to a sparse distribution of fragmented populations of the butterfly. Our work aimed to investigate the genetic diversity in the remaining UK population to assess the effect that fragmentation of habitat is having on the population structure and levels of gene flow in the species. We examined the structure of the UK population from a historical perspective using allozyme electrophoresis and mitochondrial DNA to see whether a) the species exhibited geographical structuring of genetic diversity, and b) we could infer anything about the post-glacial colonisation of the butterfly into the UK. Mitochondrial cytochrome b sequence data (400 base pairs) from 63 individuals, revealed low haplotype diversity throughout the UK. This included two individuals from an extinct population that we were able to sample using museum specimens. We compared data obtained from French and Portuguese butterflies and concluded that colonisation is likely to have been one event possibly from the Iberian peninsula. We can therefore treat E. aurinia in the UK as a single ESU. Allozyme data (11 loci, mean n = 20) showed that there was no isolation by distance, and very few populations contained private alleles. There seems to be a history of extensive gene flow in the species, but alleles at all loci did significantly differ in frequencies between populations, likely to be an effect of the relatively recent isolation of populations from one another. Also, populations were found to be most closely related to those geographically nearest to them, suggesting there has been gene flow between them. Heterozygosity levels are lower than would be expected if the population was mating entirely at random. Our evidence suggests there was once far more gene flow than in recent times, as would be expected at a time when agriculture was less intensive. It seems likely, especially in the light of the population fluctuations and regular bottlenecks that E. aurinia colonies are known to undergo, that gene flow is extremely important to maintain diversity in populations and prevent inbreeding. It is therefore vital that fragmentation of remaining populations is halted, and habitat restoration / creation considered a priority in order to counteract the negative effect that further isolation will have.

Index terms: Myrmica, Parasitism, Mimicry, Coevolution.

[0432] LANDSCAPE MANAGEMENT FOR THE LARGE COPPER BUTTERFLY, LYCAENA DISPAR BATAVUS

A.S. Pullin & C.N. Nicholls, School of Biosciences, The University of Birmingham, Edgbaston, Birmingham B15 2TT, UK. E-mail: a.s.pullin@bham.ac.uk

A threatened species throughout Europe, L. dispar has declined rapidly over much of its range, particularly in northern regions where the univoltine subspecies L. dispar batavas occurs. The latter's wetland habitat is amongst the most severely degraded and urgent need for conservation action is recognised by the species inclusion in appendix II of the Berne Convention and in the European Union's Habitats Directive. Field research has identified elements of the ecology of *L. dispar batavus* that suggest a more extensive form of conservation management is required than the site-based approach used successfully with some other butterfly species. Site management to provide open fenland areas and sufficient abundance of its larval foodplant, *Rumex hydrolapathum* is vital but this is unlikely to be enough. The species occurs at low density and is capable of rapid dispersal, appearing to have an opportunistic strategy enabling exploitation of ephemeral open wetland habitats. Consequently populations are unlikely to be stable, local extinctions will be frequent and must be matched by colonisation. This suggests that conservation and restoration will require networks of suitable habitat connected by 'corridors/stepping stones' facilitating colonisation. This may be a general problem to be faced in conserving many rapidly declining butterflies in European agricultural landscapes. Using one of the last remaining sites of L. dispar batavus, the Weerribben National Park (The Netherlands) as a habitat template, comparative studies carried out on a hierarchy of spatial scales has enabled an assessment of contemporary habitat suitability at prospective re-introduction sites in the Broadland region of eastern England. Evaluation of preliminary results suggest that currently Broadland provides insufficient amounts of open fenland that characterizes much of the butterfly's native habitat, and that those suitable areas that do exist are probably too small and too isolated to support a viable population. Targeted restoration management, based on identification of key habitat features, should, nevertheless redress this situation, eventually enabling implementation of a full-scale re-introduction programme.

[0437] HETEROPTERA

<u>C. W. Schaefer</u>, Department of Ecology and Evolutionary Biology University of Connecticut U-43 Storrs CT 06269-3043 USA. schaefer@uconnvm.uconn.edu

The number of described (36,700) and of undescribed (25,000) species in the hemipteran suborder Heteroptera were very roughly estimated from catalogs and from responses by authorities to my inquiries. Of these species, 55% belong to the infraorder Cimicomorpha, and 35% to Pentatomomorpha (including Aradidae); the remaining 10% of species are divided unequally among the remaining five infraorders. The cimicomorphan families Miridae and Reduviidae are the largest (10,000 and 6500 species respectively); the pentatomomorphan families Pentatomidae and Lygaeidae are "tied" for third, with about 4150 species each. Considerable progress has been made towards cataloging heteropteran species, and this in turn has led to some fine systematic and phylogenetic work. However, the biologies (including immature stages) and ecology of most species are completely unknown. There are far too few workers on heteropteran biology, and the number diminishes every year. There are even fewer working on systematics, and the remarkable progress made so far is the result of the fine work of these few students of Heteroptera.

[0440] A NEW PROGRAM FOR SYSTEMATICS: THE CONVENTION ON BIOLOGICAL DIVERSITY'S GLOBAL TAXONOMY INITIATIVE (GTI)

<u>I. D. Cresswell</u>, United Nations Convention on Biological Diversity Secretariat, 393 St. Jacques Street, Suite 300, Montreal, Quebec H2Y 1N9, CANADA, E-mail ian.cresswell@biodiv.org.

The lack of taxonomic knowledge of biological diversity has been recognized worldwide as a significant problem in decision-making for conservation and sustainable use of our natural resources. In response the Convention on Biological Diversity (CBD) has created the Global Taxonomy Initiative (GTI) to facilitate the filling of known gaps in systematics, the training of new taxonomists and curators, and finding new ways of using our knowledge base to increase our ability to conserve, use and share the benefits of our biological diversity. The need for fundamental taxonomic knowledge of biological diversity to underpin the key objectives of the CBD is wide ranging. The CBD deals with diversity at all levels of the biological hierarchy; from genes, species, populations, communities, ecosystems to landscapes. The GTI must assist international funding agencies, national and sub-national governments, and non-government bodies address the need for adequate taxonomy as part of the worldwide demand for up-to-date biodiversity information. To do this requires the advancement and renewal of taxonomy associated with the protection and maintenance of our natural heritage. For the GTI to be effective in a timely way a major increase in partnerships need to be quickly formed between the world's natural history institutions in the developed and developing worlds. Increasing the world's taxonomic activity will need to be focused to ensure the results are not only scientifically correct but also provide practical, implementable information that is available to managers and decision makers. The developing training programmes, the strengthening of infrastructure for biological collections in countries of origin, the building the capacity for taxonomic research, and increasing the worldwide availability of taxonomic information are high priorities. The overall need has been identified and a new commitment to action has been agreed. Yet this paper asks more questions than it answers: what should be our work priorities, how should we get agreement on who does what, how can each individual make a difference to the overall goals of conservation and sustainable use? This paper will present the decisions from the 5^{th} meeting of the Conference of the Parties (the political body of the Convention) held in Nairobi, May 2000, and will attempt to illustrate the way forward, including how the ICE can help implement the GTI.

[0441] THE SIGNIFICANCE OF INSECTS AND OTHER INVERTEBRATES IN MULTILATERAL ENVIRONMENTAL AGREEMENTS

N. M. Collin, World Conservation Monitoring Centre, 219 Huntingdon Rd, Cambridge CB3 0DL, UK

The five key multilateral environmental agreements (MEAs) concerning global biodiversity are the Convention on International Trade in Endangered Species (CITES); the Migratory Species Convention (Bonn Convention); the International Convention on Wetlands (Ramsar Convention); the World Heritage Convention; and the Convention on Biological Diversity (CBD). They seek respectively to maintain wildlife trade within sustainable limits; to protect populations and key habitats of migratory species; to identify and protect key wetlands of the world, including coastal areas; to identify and manage the world's principal natural and cultural sites; and to conserve, sustainably use and share the benefits arising from biodiversity. Insects and other invertebrates constitute the bulk of the world's biodiversity. But is this sufficiently recognised in these conventions? The author analyses the significance of insects and other invertebrates in the conventions, demonstrating that explicitly they comprise only a small part of the decisions and species listings (e.g. in CITES and the Bonn Convention), but that their importance is implicitly recognised. Scientific knowledge of insects and other invertebrates should play a larger role in implementing MEAs, but the entomological literature may be unsuited to analysis and presentation to policy-makers. Could this be improved? MEAs focus on both conservation and sustainable use. Nations wish to protect insects and other invertebrates for their own sakes, but also for their roles in maintaining ecosystem services and as potential sources of useful products and revenues. Entomologists should present their results accordingly. Research proposals need to speak directly to the aims of the MEAs. Government policy-makers need research that helps them directly to implement MEAs nationally. Entomologists should study national reports on MEAs and present their research in ways that serve these reporting needs. Insects and other invertebrates are undoubtedly fundamental to the ecological processes that MEAs seek to maintain. This must be presented more convincingly and accessibly, through use of spatial data, crosscomparison with other groups and through inclusion in conservation priority analyses being executed around the world. This will benefit not only the successful implementation of MEAs, but in turn increase the flow of research support to the entomological community.

[0443] BIOSPHERE RESERVES: A MODEL FOR THE ROLE OF TAXONOMIC SCIENCE IN BIODIVERSITY CONSERVATION

<u>P. Bridgewater</u>, Division of Ecological Sciences, UNESCO, 1 rue Miollis, Paris 75732 CEDEX, France

To manage, conserve, use and share biodiversity we must understand it - and that involves increasing efforts in taxonomy. Taxonomy provides this reference system for all known life. While we have thus the scientific framework, we are still a long way from knowing all the elements. Consequently, the governments of the world that recognize the Convention on Biological Diversity (CBD) have acknowledged the existence of a taxonomic impediment to sound management and conservation of biodiversity. Solving the taxonomic impediment is also essential to develop a balanced approach to protected area establishment and management, as without a strong taxonomic base protected areas simply remain ineffective paper proclamations. In the context of biodiversity conservation generally, such a balanced approach can be achieved through the ecosystem approach adopted by the CBD. The UNESCO-Man and Biosphere program seeks to implement the ecosystem approach at global, regional and national levels. A major objective of the program is the development of a World Network of Biosphere Reserves, which provides an integrating approach to biodiversity, through developing identification and monitoring of, and incentives for, the conservation, management and use of biodiversity. Our management of nature gives expression to our many human cultures. The taxonomic perspective, yielding a detailed understanding of biodiversity, helps comprehend how, in turn, the environment reshapes human culture through feedback processes. Throughout the world most landscapes are *biocultural* landscapes – blends of human activity with the expression of biodiversity. Biosphere Reserves are an on-ground attempt to help us understand better how human cultural activity has shaped the biodiversity of today. Solutions to key taxonomic impediments will require necessary funding to maintain existing collections, liberate information from them, and provide capacity building in developing countries, where national collections are absent, poor in quality and lack necessary maintenance standards. This also means activity at all levels of the taxonomic hierarchy, across all Kingdoms and subsidiary divisions. Blending people and nature, Biosphere Reserves are unique models to help resolve taxonomic impediments, while also delivering conservation outcomes.

[0444] ALIEN BUGS IN INTERNATIONAL CONVENTIONS

I.K. Waage, CABI Bioscience, Silwood Park, Ascot, SL5 7TA, UK, E-mail: j.waage@CABI.org

Article 8h of the Convention on Biological Diversity calls on countries to prevent, eradicate or control alien invasive species which threaten the environment. This has generated many new initiatives on alien invasive species, including the global Invasive Species Programme, which is described. Entomologically-based programmes of eradication, chemical and biological control of alien insects and weeds provide both models and cautionary tales in addressing this Convention obligation. There are exciting challenges in integrating existing agricultural and environmental Conventions into a common biosecurity approach to alien pest management, and specific issues to address, including the introduction of alien organisms for biological control. [0446 CHALLENGES AND OPPORTUNITIES IN UNDERSTANDING AND UTILIZING AFRICAN INSECT DIVERSITY

<u>S. E. Miller</u>, National Museum of Natural History, Smithsonian Institution, Washington, D.C. 20560-0105 USA and International Centre of Insect Physiology and Ecology, Box 30772, Nairobi, Kenya

About 100,000 species of insects have been described from Sub-Saharan Africa. Because of the colonial history, Africa, in comparison to other tropical regions, is probably better known, but the information is harder to find. Few centres of expertise on insect diversity and systematics exist in tropical Africa, while most of the large collections are in South Africa, Europe and the United States. Recent surveys of in-country resources by ICIPE, CABI, and BioNET International show that human resources are also thinly distributed in tropical Africa. Yet, there is tremendous need for basic information on insect diversity for pest management related to plant, livestock and human health, as well as conservation and environmental management. Invasive (alien) species represent a newly recognised threat that cuts across traditional sectors. Recent work in Africa by several organisations shows the potential of different approaches to these challenges, including compilation and synthesis of pre-existing data and research targeted at strategic needs. Information can also be applied in novel ways to promote environmentally friendly income generating schemes such as silk worms, honey bees, ecotourism, butterfly farming and bioprospecting. The Global Taxonomy Initiative of the Convention on Biological Diversity provides an opportunity to expand these experiments to better meet the needs. Index terms: Africa, biodiversity, conservation, taxonomy, systematics

[0445] OVERCOMING THE TAXONOMIC IMPEDIMENT TO SUSTAINABLE DEVELOPMENT - BIONET-INTERNATIONAL, THE GLOBAL NETWORK FOR TAXONOMY

N. King, BioNet-International, Bakeham Lane, Egham, Surrey TW20 9TY, UK, T: +44 1491 829036/7/8, F: +44 1491 829082/100, e: bionet@cabi.org; n.king@cabi.org, http://www.bionet-intl.org

BioNet-International is a global network for capacity building in biosystematics for sustainable development. The network is comprised of a number of inter-linked regional LOOPs (Locally Organised and Operated Partnerships) of developing country institutions, supported by a consortium of developed country institutions. Its purpose, through South-South cooperation and North-South partnerships for institutional strengthening and human resource development, is to enable developing countries to achieve self-reliance in taxonomy to support regional and national programmes for eradication of poverty via sustainable agricultural development and use of natural resources, and conservation of biodiversity (including implementation of the Convention on Biological Diversity). The networks' success is attributable to two key components. The first is local ownership of the process, including governmental endorsement of the need for such a capacity building network whereby needs are identified and prioritised by member countries themselves. The second is a tried and tested mechanism whereby a lack of individual country capacity is overcome by pooling, optimising and sharing regional capacity on a reciprocal basis between member countries. It provides a very useful model for other capacity building initiatives in developing countries, as well as for North-South and South-South collaborative partnerships for capacity building.

Index Terms: capacity building, networks, south-south, north-south, partnerships, biosystematics, taxonomy

[0447] WEEVIL DIVERSITY IN AFRICA: EXTRAPOLATIONS FROM HOST SURVEYS AND SYSTEMATIC STUDY (COLEOPTERA: CURCULIONOIDEA)

R. G. Oberpricler, CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, AUSTRALIA. E-mail Rolf.Oberprieler@ento.csiro.au.

Estimation of the species richness of diverse and speciose groups is notoriously difficult. In phytophagous taxa, this usually involves some assumption of host specificity that is generally not testable at current levels of information. Relatively intensive sampling and systematic study of the weevil fauna of southern Africa during the last two decades allows a more accurate estimate of total species numbers in that region and also extrapolation of the world species richness of Curculionoidea. In a selection of taxa with narrow host specificity, species numbers after targeted sampling and taxonomic study increased about 5-fold, while those of some non-hostspecific (oligophagous to polyphagous, but generally habitat-specific) taxa increased 3-fold. In the former category, projection of the narrow host specificity to remaining (unsampled but suitable) host species indicates a total species richness of about 17 times the number of currently described species. In the latter category, total species numbers are estimated at about 5 times those of described species. By contrast, the total species richness of larger, terrestrial and better-sampled weevils is unlikely to reach double the number of currently described species. In consideration of the large and mostly host-specific but poorly sampled and studied southern African fauna of Ange and mostly noarspectre out poorly simple and build and the second secon species is likely. This calculates to about 13500 species for the region and 40000 for the entire African weevil fauna. The same ratio estimates the Australian weevil fauna at 20000 species (4192 described) and the South American and Oriental faunas at about 50000 each. With the smaller and better known faunas of North America and the Palacarctic region estimated at about 10000 each, the total world weevil species richness calculates to about 180000, or 3 times the number currently described. With weevils constituting about 20% of the entire world beetle fauna (18.7% in Australia), a total Coleoptera species richness of 900000 is indicated. This southern Africa case study therefore suggests a world weevil and beetle fauna of approximately 0.2 and 1.0 million species, respectively. Index terms: weevil and beetle species numbers

[0448] CARABIDS OF AFRICA: THE STATE OF THE ART, WITH BIOGEOGRAPHICAL HIGHLIGHTS (COLEOPTERA)

<u>A. V. Taglianti</u>, Dipartimento di Biologia Animale e dell'Uomo, Università di Roma "La Sapienza", Viale dell'Università, 32, I-00185 Roma. E-mail: vignataglian@axrma.uniromal.it

The carabidology of the Afrotropical Region is represented in the last two centuries mainly by French entomologists. The major contributions was those by C. Alluaud, R. Jeannel, L. Burgeon and particularly P. Basilewsky. So far, a definitive assessment at the specific level is not available for the whole African Region: the carabid fauna is rich although not comparable to that of other major biogeographical regions, particularly of the Holarctic one. For the major taxa (tribes/subfamilies) of carabids s.s. (tiger-beetles and Paussinae excluded) the estimates are more reliable. A total of 115 major taxa (49 in a lumper vision) out of 173 (79) recognised in the world Carabidae, represent nearly 60% of the world fauna. The nearly 15 endemic groups (13%) include very basal lineages. Although several widespread groups, such as Carabini, Cychrini, Nebriinae, Broscini, Patrobinae and many subtribes of Pterostichini are lacking, others display a remarkable radiation in Africa: Agonini, Oodinae, Callistinae, Panagaeinae, Lebiinae and Zuphiinae. This pattern can be reasonably explained as the result of very ancient radiation(s) in Gondwana, with several (albeit not numerous) colonizations by elements originating from subsequent Angarian radiations. At regional level good knowledge has been gathered for Southern and Eastern Africa. Particularly for the eastern regions (Ethiopia, Somalia and Tanzania) up-to-date check-lists are herein discussed. The fauna of this area seems to be the most highly diversified in Africa. For instance the nearly 800 species listed from Tanzania, include forest, savannah, mountain and desert elements, being thus evidently correlated with the landscape complexity. While the forest elements are mostly shared with Central and Western Africa, the others are endemics (ca. 30%) or with southern affinity; a significant Palaearcite component is present in the mountain areas. Index terms: Carabidae, biogeography, diversity.

[0449] DISTRIBUTION PATTERNS AND HOST PLANT RELATIONSHIPS WITHIN THE GENUS CERATITIS MACLEAY (DIPTERA: TEPHRITIDAE) IN AFRICA

M. De Meyer, Entomology Section, Koninklijk Museum voor Midden Afrika, Leuvensesteenweg 13, B-3080 Tervuren, Belgium, E-mail demeyer@africamuseum.be.

The Afrotropical genus Ceratitis MacLeay comprises about 80 species. Data indicate that the group as a whole, infests a wide spectrum of host plants. A number of well defined clades within the genus are however restricted to a narrow range of hosts, usually confined to a particular genus or family. These oligophagous or stenophagous clades are often confined in their distribution. Their distribution is compared with the known host plant range, and discussed in this respect. Polyphagous Ceratitis species (such as C. anonae, C. capitata, C. cosyra, C. fasciventris, C. punctata and C. rosa), attack a variety of exotic commercial and indigenous wild fruits. Different distribution patterns for those particular pest species are however observed. This implies that other hitherto unknown environmental parameters must definit their known distribution. The different patterns found are compared and discussed. Particular clades within the genus are phylogenetically well resolved. For these groups, the phylogeny is associated with the observed occurrence of the particular species within the clades.

Index terms: fruit fly, pest species, oligophagous, stenophagous, polyphagous

[0450] THE CADDISFLIES (TRICHOPTERA) OF LARGE RIVERS IN NAMIBIA: UNIFORMITY OR DIFFERENT FAUNAS?

<u>W. Mey</u>, Museum fuer Naturkunde, Humboldt-Universitaet, Invalidenstr. 43, D - 10115 Berlin, Germany.

The only perennial rivers in Namibia are those flowing along the northern and southern borders: Cunene, Kavango, Kvando, Zambezi and Orange. The caddisfly fauna of these large rivers is poorly known. Intensive collecting of aquatic insects has been performed during the first Namibian-German Expedition 1992 at different sites on the Kavango river (= Popa Falls), Kvando river (= Nakatwa) and Zambezi (= Katima Mulilo). The insects were attracted by mercury-vapour lamps run by a generator as the power unit. The lamps were in operation at each site for 4 hours after sunset in 4 consecutive nights. A total of 82 Trichoptera species were collected. More than 50 species are found in Namibia for the first time. Most of them are widespread afrotropical species. A qualitative comparison of the compiled species lists of the three rivers reveal, that: The potamobiontic caddisfly fauna of the investigated rivers is quite homogeneous. 1) The rapids at Popa Falls of the Kavango are the locality with the highest species diversity. This is due largely to the rocky riverbed which generates a large number of additional habitats for the larvae, 2) The faunal composition is dominated by species of the families Hydroptilidae, Hydropsychidae and Leptoceridae. A remarkable feature is the sympatric occurrence of many congeneric species (e.g. Hydroptila Dalman, Cheumatopsyche Wallengren, Ecnomus McLachlan, Oecetis McLachlan). The results are discussed concerning the differences of distributional patterns between aquatic and terrestrial faunas and its relevance to define hydrobiological regions.

Index terms: Trichoptera, riverine fauna, Africa, Namibia

[0451] BIODIVERSITY MEASUREMENT: THE SOUTH AFRICAN GRASSLAND INSECT EXAMPLE

<u>S. vdM. Louw</u>¹ & M. T. Seaman², ¹Dept of Zoology & Entomology, Univ. of the Orange Free State, P. O. Box 339, Bloemfontein 9300, South Africa. E-mail: LouwSvdM@dre.nw.uovs.ac.za; ²Centre for Environmental Management, Univ. of the Orange Free State, P. O. Box 339, Bloemfontein 9300, South Africa. E-mail: SeamanMT@dre.nw.uovs.ac.za

A bio-monitoring strategy for grassland ecosystems, central to which is a scoring system that optimizes accuracy and speed, is long overdue. While such systems have long been under development for rivers and other aquatic ecosystems, bio-monitoring of terrestrial ecosystems remains a cumbersome process. While the 'health' of a grassland habitat could be measured via the biodiversity of grasses themselves, or via faunal groups such as birds or mammals, we consider grassland insects to be a most appropriate group. This choice is based on the simplicity of sampling, the inherent species richness of insects themselves and the symptomatic nature of such a diverse group of consumers. On the other hand, we recognised that large numbers of species and identification problems could jeopardize analysis. Our solution is the use of functional feeding groups (FFG's) as operational units and we argue that FFG's are not biased and do not skew the analysis, but instead only reflect actual niche occupation. In a recent case study during the winter in the central Free State province of South Africa, 26 FFG's were identified, enabling us to identify adequate sample size and alpha and beta diversity with relative ease. FFG's were awarded values on a five-point scoring system that was linked to the probability of occurrence in a 'healthy' system. Resultant scores provide benchmark values that will allow comparison and evaluation over successive years. With this we propose to trigger the further development of a South African Grassland Scoring System (SAGraSS). Such a system would provide rapid, repeatable and user-friendly insect-based bio-monitoring methodologies for scientists, para-taxonomists, environmental impact assessment practitioners environmental managers alike.

Index terms: Bio-monitoring, functional feeding groups, SAGraSS.

[0452] BIOGEOGRAPHY AND RELATIONSHIPS OF AFROTROPICAL ACROCERIDAE (DIPTERA) TRUE ENDOPARASITOIDS OF SPIDERS

E.I. Schlinger, The World Spider-Parasitoid Laboratory, 1944 Edison Street, Santa Ynez, CA 93460 USA, E-mail: acrofly@silcom.com.

At present the Afrotropical Region contains no less than 60 species of *Acroceridae*, placed in 16 genera representing all three recognized subfamilies of *Acroceridae*. The relationships of these taxa will be discussed with particular reference to Madagascar and to the Neotropical Region. Biogeographic patterns of selected groups will be detailed on Gondwanan maps and compared with recent maps to clarify distribution assumptions of both the acrocerid parasitoids and their host spiders. Talk will be illustrated with colored slides of recent paintings of these colorful flies.

Index Terms: Acroceridae, Araneae, parasitoids, Gondwana

[0454] PHYLOGENY AND HOST-PLANT RELATIONSHIPS OF THE PECTINIVALVINAE (LEPIDOPTERA: NEPTICULIDAE)

R.J.B. Hoare, Landcare Research, Private Bag 92170, Auckland, New Zealand.

The Nepticulidae are a worldwide family of tiny moths, whose larvae mine in the leaves, stems or fruit of a wide range of angiosperm plants. Usually a single species of moth is restricted to a single host-plant species or to a few species in the same host genus. However, at the generic level this specificity tends to break down, and speciose lineages such as Stigmella attack a wide range of host-plant families. Two subfamilies are recognized within the Nepticulidae, the worldwide Nepticulinae, and the Pectinivalvinae, which have only been recorded from Australia. The type genus of Pectinivalvinae, Pectinivalva, is very common throughout Australia, and at least 160 species are known, with many more undoubtedly remaining to be discovered. All known host-plants for Pectinivalva belong to the Myrtaceae. A cladistic analysis of representative members of the genus revealed that it falls into three well-supported monophyletic groups, each with a more or less characteristic host-plant range. More basal members of two of the three groups are restricted to rainforest Myrtaceae, and it is suggested that these groups may have diversified onto the sclerophyllous myrtaceous flora that now dominates Australia as the climate dried out during the Miocene. The only other recognized genus of Pectinivalvinae is the recently described Roscidotoga, which is sister to Pectinivalva. Roscidotoga contains three known species, whose larvae feed on Cunoniaceae and Elaeocarpaceae, two related plant families in the Oxalidales. Like the Myrtaceae, these families are considered to be ancient elements of the Australian flora, which would have been present in Gondwanan times, before the break-up of the southern continents, and the relationship of the nepticulids with them is probably equally ancient. The two pectinivalvine genera are considered likely to be early Cretaceous in origin, and the possible reasons for their apparent absence from continents other than Australia will be discussed.

Index terms: Pectinivalva, Roscidotoga, Cunoniaceae, Myrtaceae, Gondwana.

[0453] BIOGEOGRAPHY OF AFROTROPICAL *MONOLEPTA* AND RELATED TAXA (CHRYSOMELIDAE; COLEOPTERA)

T. Wagner, Zoologisches Forschungsinstitut und Museum Alexander Koenig, Adenauerallee 160, D-53113 Bonn, Germany.

In recent studies on canopy arthropods in East African forests, *Monolepta* and related taxa (Galerucinae, Chrysomelidae), were found as an abundant and species rich group of canopy dwelling leaf beetles. Classification and taxonomic status of this group is very unsatisfactory, and a revision was started. About 300 species were described in *Monolepta*, *Candezea*, and *Barombiella*, mostly between 1880 and 1940. Genus names were not used constistently by the plural authors, and consequently previous allocation was para- and polyphyletic. The phylogenetic revision also allows insights into biogeographical aspects of this group. Highest species richness and high degree of endemism was found along the Central and East African Rift system, and especially in the Ethiopian Highlands. Lower centres of endemism are the Cape Region and the montane area of Cameroon. Speciation processes were probably strongly influenced by habitat disjunction during the strong quarternary climatical change in Africa. Index items: Africa, revision, speciation.

[0455] SPECIES DIVERSITY OF AMAZON RAINFOREST FRUIT-FEEDING NYMPHALID BUTTERFLIES: EFFECTS OF SPACE, TIME AND DISTURBANCE

P. J. DeVries, Center for Biodiversity Studies, Milwaukee Public Museum, 800 West Wells St., Milwaukee, Wisconsin 53233, USA

Butterfly diversity studies have been important to our understanding of community ecology and conservation biology, but they seldom measure diversity in multiple dimensions of space and time, or employ sampling methods that are comparable among areas. We used a standardized, long-term sampling regime in the canopy and understory at monthly intervals to show that in Amazonian forests fruit-feeding nymphalids are not randomly distributed in space and time. Partitioning total species diversity into additive components within and among community subdivisions (vertical, horizontal and temporal dimensions) showed that significant diversity existed in each dimension. We show that samples from a single habitat, height and time contain only a small fraction of the total community species richness, and temporal variation is an extremely important factor affecting measures of tropical species diversity. There is strong evidence that fruit-feeding nymphalid communities are divided equally between the canopy and in the understory, and that the species composition of the canopy and understory are distinct, therefore demonstrating the necessity of accounting for the vertical dimension when measuring forest diversity. Individual abundance and observed species richness was greater in more disturbed habitats, but due to disparate sample sizes, rarefaction analysis showed that such differences can be seriously misleading. Our study demonstrates the feasibility and necessity of performing long-term sampling in multiple dimensions for conservation. We emphasizes the need for similar data sets from other sites to accurately understand and compare species richness and diversity in tropical forest communities.

[0456] EUPTYCHINE SATYRID BUTTERFLIES: BIODIVERSITY, NOMENCLATURAL FRUSTRATION AND FUTURE PROMISE

L. D. Miller, Allyn Museum of Entomology, Florida Museum of Natural History, University of Florida, 3621 Bay Shore Rd., Sarasota, FL 34234, USA, E-mail c/o jmiller@virtu.sar.usf.edu.

Euptychiine Satyridae are a highly diverse group, centered in the Amazonian region, but with representative species being found from southernmost Canada to northern Argentina. These insects are usually drab, frequently are not attractive specimens and are under-collected by even knowledgable workers. There are nearly 300 species, apportioned among 30-40 genera, and these still remain to be categorized. Many species are widespread, perhaps reflecting a more catholic taste in foodplants, but other species are much more specialized in their choice of foodplant, as well as ecologically separate. They also may be isolated geographically; thus, there is a Mexican group of species, a southeastern Brasilian isolate and one centered in the sub-Andean part of Amazonia. That they are difficult to determine with certainty, is attested to by several species being recognized in various collections under a single name, even though these collections are internally consistent in their identifications. Often names are misapplied, and the same species may masquerade under several names, such as in Taygetis cleopatra C. & R. Felder, where most collections have this species identified as T. xenana Butler, a junior synonym, and the name cleopatra is applied to a form of T. laches (Fabricius). Similarly, confusion exists with the aberrant south Brasilian Coenoptychia boulleti Le Cerf, which was described three times in four years under three different generic names. Once these taxonomic problems are resolved, the way is cleared to allow these insects to serve as the excellent ecological indicator species that the admittedly limited biological data indicate they are.

Index terms: endemism, ecological indicators, Coenoptychia, Taygetis,,

[0458] PATTERNS OF BIODIVERSITY IN THE NEOTROPICAL CASTNIIDAE (LEPIDOPTERA)

J. Y. Miller, Dept. of Natural History, Allyn Museum of Entomology, Florida Museum of Natural History, University of Florida, 3621 Bay Shore Road, Sarasota, FL 34234, USA, E-mail jmiller@virtu.sar.usf.edu

The Castniidae are a pantropical group, geographically distributed in Australia, southeast Asia, and throughout the neotropics from Mexico to Argentina. Since several morphological features are usually attributable to both butterflies and moths in representative species, this family is exceedingly significant and has been considered a possible ancestral group for the Lepidoptera. There are currently 32 genera and 106 species recognized in the neotropical subfamily Castniinae, with a wide array of wing coloration and patterns, including some species involved in diverse minuery complexes. The larvae feed internally and are principally associated with monocotyledenous plants of economic importance (Musaceae, Arecaceae, Bromeliaceae, Orchidaceae), but detailed information on life history for most taxa is quite limited. With the exception of those species commonly associated with Poaceae (sugar cane) and Musaceae (plantino, banana), foodplant and other ecological requirements appear to be quite specialized. Most taxa are associated with semi-deciduous, humid, or tropical rainforests with a variety of available habitats and nicrohabitats. Based on recent field work and other comprehensive biodiversity studies, particularly in Lepidoptyera and associated plant groups, current distribution records suggest that the Castniinae are excellent bioindicators of areas of high species diversity and endemism in the neotropics. The majority of the taxa are represented geographically in Brazil (61%) with 7% found in Mexico and 4% in Argentina respectively. The significance of biodiversity patterns in the Castniinae in light of the current evidence and potential studies will be discussed. Index terms: endemism, rainforests, monocots

[0457] BIODIVERSITY OF PAPILIONOIDEA FROM MEXICO

A. Luis-Martinez, J. Llorente-Bousquets & L Vargas-Fernandez, Museo de Zoología, Facultad de Ciencias, UNAM. Ap. Postal 70-399, C.P. 04510 Mexico, D.F. MEXICO.Email: alm@hp.fciencias.unam.mx

In Mexico, studies on butterflies go back to the last century (Biologia Centrali-Americana) and since then knowledge has advanced significantly. More than 2000 subspecies included in 1,600 species grouped in five families, 20 subfamilies, 50 tribes and almost 500 genera have been already recognized. This information has appeared in more than one hundred monographs and books and in many papers published in at least 12 major periodical journals. The main synthetic results of this work are: (1) Mexico holds 10% of the Rophalocera of the world and ranks among the ten most rich countries in butterflies; (2) our country and neighbouring areas hold paleo and neoendemic groups of great interest, some of them relictuals, mainly in xeric parts of the north and west and in the mountain areas of the south; (3) the richness pattern is independent of the endemism pattern because the richest areas are tropical humid lowlands; (4) the areas with higher endemism and richness are those with the greatest physiographic, climatic and vegetational heterogeneity (e. g. Los Tuxtlas, Vercaruz and Sierra de Juárez, Oaxaca, each one with about 35% of the species richness), the conservation of butterfly diversity depends on habitat conservation because slight changes may induce local extinctions, but we still lack in depth and long term studies about these problems; and (5) Mexico presents several insular intracontinental patterns, which are the product of the disjunct and heterogeneity distribution of xeric and humid parts, which are the result from the complex biogeographical history of the country. Papilionoidea, Mexico, Biodiversity, Biogeography, Endemism

[0459] DIVERSITY OF PYRALOIDEA MOTHS ALONG A GRADIENT OF RAINFOREST DISTURBANCE IN NORTHERN BORNEO

<u>C. H. Schulze</u> & K. Fiedler, Dept. of Animal Ecology I, Univ. of Bayreuth, D-95440 Bayreuth, Germany, E-mail: christian.schulze@uni-bayreuth.de.

In this study we used Pyraloidea moths as target group to estimate the impact of human disturbance on a species-rich group of herbivores. To analyse patterns of diversity and abundance structure, we attracted moths by light at selected sites across a gradient of habitats, ranging from primary rainforest across different secondary forest types to cultivated areas. The study was conducted at Mt Kinabalu Park (Sabah, East Malaysia) because this reserve and its surroundings offers a wide range of habitats in a relatively small area. Therefore, geographical effects should not play a major role for explaining differences in species composition of studied sites. Sampling took place in 1997 and 1998 and covered different months of the year with different rainfall conditions. The Crambidae subfamily Acentropinae was analysed separately because the aquatic life habits of its larval stages may cause a different response of this taxon. On subfamily level, by far the most abundant and species-rich taxon at all sites was the subfamily Pyraustinae which represented 88.3-97.5% of all sampled non-Acentropinae specimens and 69.8-89.1% of the recorded species total. Williams' α for Pyraloidea (excluding Acentropinae) varied between 3.7 and 131.0. Highest alpha-diversity was found at the primary forest (α =131.0) and the old secondary forest sites (α =98.6 to 118.6). However, also at sites in cultivated areas with small patches of secondary scrub vegetation still a high diversity could be found (α =51.9 to 80.9). In contrast, diversity decreased dramatically at sites located within oil palm plantations (α =8.3) and cultivated meadow fields (α =3.7). In particular, the Pyralidae subfamily Epipaschiinae responded strongly to disturbance. While the number of recorded species decreased from 38 (canopy) and 29 (understorey) species, respectively, at the primary forest site to 3-15 at secondary forests and cultivated sites, the decrease in abundance was even more pronounced. At sites within large cultivated areas no Epipaschiinae moths could be recorded at all. Acentropinae diversity was not reduced at disturbed sites except of sampling plots in an oil palm plantation and a meadow field. Although environmental conditions in streams may strongly be affected by forest disturbance, we did not observe effects on the diversity of these aquatic moths at our sites close to (intact) forests. In general, as found in earlier studies, even within one taxon like the Pyraloidea, the diversity of different subtaxa responded in different ways to human disturbance. Since even strongly disturbed habitats in proximity to remaining forests exhibited a high diversity of Pyraloidea moths, this emphazises the potential of such areas to serve as buffer zones around nature reserves as well as for maintaining a high fraction of diversity in tropical cultivated landscapes.

Index terms: Epipaschiinae, Pyraustinae, Acentropinae, diversity, Malaysia

[0460] RICHNESS HOTSPOTS AND RARITY HOTSPOTS OF MEXICAN SATURNIIDAE (INSECTA: LEPIDOPTERA)

M. Balcázar-Lara¹ & I. J. Kitching², ¹Fac. de Ciencias, U. de Colima, Apdo. Postal No. 11, Colima, C. P. 28000, MEXICO, E-mail mabl@servidor.unam.mx; ²Department of ²Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, U. K., Email iik@nhm.ac.uk.

Distribution maps for 115 endemic or quasi-endemic Saturniidae of Mexico were developed in order to find and study hotspots of richness and hotspots of range-size rarity. This information is necessary for finding sets of complementary areas which combined would include the greatest species richness. These previous figures are among the most often used in biodiversity conservation for choosing areas for in situ conservation management. The selected group Saturniidae, is among the best known groups of Lepidoptera in particular, and Insecta in general, in Mesoamerica from the point of view of its taxonomy. In addition, this family is specially rich in endemics in Mexico with about 8% of all the taxa described for the world. Species richness for the taxa studied were scored among 10 minute grid squares in Mexico, and analyzed using the program WorldMap ver. 4.19. The grid cells chosen by the richness hotspots method are in five mountainous areas. The first one is mainly along the Transvolcanic Axe in central Mexico, at medium altitudes on the southern slopes, close to or where it merges with the Balsas River basin. The next two areas are in the Oriental and Southern Sierra Madre, in both cases, the richest grids are those associated with cloud forest. The Highlands of Chiapas and the Sierra the Juárez in Northern Oaxaca State, again show the same pattern, but in both cases in ecotonal areas with the oak and pine forests. When we analyzed the rarity by inverse range size, a very similar pattern to that of the richness emerged, with one main difference: the cape area in Baja California.

Index terms: biodiversity, Mexico, distribution, endemics

104621 PRELIMINARY LIST OF STINGLESS BEES (APIDAE, MELIPONINAE) OCURRING IN ECOSSYSTEMS OF MARANHÃO STATE, BRAZIL

P. M. C. Albuquerque¹ & M. M. C. Rêgo¹, ¹Dept. of Biology, Univ. of Maranhão, Av. dos Portugueses, Campus do Bacanga, São Luís, Maranhão, 65080-040, Brazil, E-mail palbug@elo.com.br

Although many surveys of bee fauna have been done in various Brazilian regions, the great part of bee fauna diversity in the neotropical region remains nearly unknown. Differing from other Brazilian states, Maranhão is located in a transitional region between the amazon forest, in the cerrado vegetation of the central plateau and the caatinga of the Northeast. Due to this factor it has acquired great ecological importance. There is superposition and interactions among faunistic characteristics of these three regions leading to a phytogeographic mosaic. From a large previous work about the structure of bee communities involving diversity, relative abundance, phenology and interaction in floral resource utilization in varied ecosystems of Maranhão, a preliminary list of Meliponinae species that occur in the state was prepared. The main objective is to illustrate the taxonomic diversity of the region. Data from six surveys that used standardized and systematics samples performed in sand dunes, cerrado, secondary forest, pre-amazon forest and western low land of Maranhão were included. Alongside the data obtained in these surveys other specimens collected in the state were also analyzed and are available in the Biology department's collection - Federal University of Maranhão, Brazil The composition of species was as follows: Melipona compressipes fasciculata, M. puncticollis, M. rufiventris, M. melanoventer, Tetragona dorsalis, T. clavipes, T. truncata, Trigona fuscipennis, T. pallens, T. amalthea, T. branneri, T. fulviventris, T. spinipes, T. recursa, T. dallatorreana, T. williana, Cephalotrigona capitata, Celetrigona longicornis, Ptilotrigona heideri, Scaptotrigona flavisetis, Frieseomelitta aff. portoi, F. silvestrii, F. flavicornis, Partamona pearsoni, P. testacea, P. cupira, Oxytrigona tataira, Tetragonisca angustula, Scaura latitarsis, S. longula, Trigonisca nataliae, T. pediculana, T. ceophloei, Geotrigona aequinoctialis, G. aff. mombuca, Nannotrigona punctata, Plebeia alvarengai, P. minima. Apart from these species there are many others not yet identified belonging to the genders Aparatrigona, Leurotrigona, Melikerria and some new species. Index terms: Diversity, relative abundance, Meliponini.

GENUS AUSTROZELE BIOGEOGRAPHY OF THE THE [0461] (HYMENOPTERA: BRACONIDAE: MACROCENTRINAE)

C. van Achterberg, Curator of Hymenoptera & Diptera, Afdeling Entomologie, Nationaal Natuurhistorisch Museum, Postbus 9517, 2300 RA Leiden, Netherlands. E-mail: achterberg@naturalis.nnm.nl

The genus Austrozele Roman is medium-sized and has a mainly Palaeotropical distribution with some species in the Palacarctic and Nearctic regions. The members are nocturnal ("ophionoid facies") of which some are common and are at least some are parasitoids of pests, e.g. of Spodoptera exigua Hübner. The genus has been radiating recently; the species are very similar and vicariancy seems to have played a very limited rôle. Currently the genus is revised, up to now 32 species are known, which are mostly still undescribed and most species occur in the Indo-Australian region. The phylogeny and the dispersal events are discussed.

Index terms: biogeography, Braconidae, Macrocentrinae, Austrozele.

[0463] BIODIVERSITY OF AGROMYZIDAE IN CEREAL AND GRASS FIELDS AND THEIR BOUNDARIES

A. Andersen & II. Sjursen, The Norwegian Crop Research Inst., Plant Protection Centre, Høgskolev. 7, 1432 Ås, Norway.

The present is a preliminary report on a project running in spring barley and grass fields in southeastern Norway 1998-2000. Each year 5 fields on 3 farms are investigated: one cereal field on a conventional farm growing only cereals, one cereal field and one grass field on a conventional farm growing cereals and grasses, and one cereal field and one grass field on a biological farm. Three new farms are chosen every year, so a total of 15 fields will be investigated in the project. In each field 3 lines of 5 1x10m plots each are set up from the boundary and 30m into the field. In all the plots and along the boundaries of the chosen fields the agromyzids are caught with a net in a standardized way several times during the growing season. The following are some tendencies in the material from the first two years. A total of 7225 (1459 + 5766) specimens were caught, of which 6099 (84.4 %) belonged to the cereal and grass pest species Chromatomyia fuscula. Seventy-five species have been identified, of which 26 were caught both years. Twenty-five species (67 %) belonging to the following 5 genera were feeding in Gramineae: Agromyza (8 species), Cerodontha (8 species), Chromatomyia (3 species), Liriomyza (5 species) and Pseudonapomyza (1 species). Non-Gramineae feeding species were almost absent in the fields themselves, even if a large number of weed species occurred. In all, only 56 specimens (1.2%) of non-Gramineae feeders were caught in the fields. There was a tendency towards more non-Gramineae feeders in the biological fields (2.1%) than in the conventional fields (0.9 %). The non-Gramineae feeders dominated less in the boundaries. probably due to a large variety of plant species present there. In the two years 32.5 and 85.5 % of the specimens caught in the boundaries were Gramineae-feeders. The plant species in all the plots have been identified, and the distibution of the different agromyzid species will be compared with the distribution of their host plants. Index terms: Chromatomyia fuscula, Agromyza spp., biological farming.

Symposium and Poster Session

[0464] SIMPLIFYING ANT MONITORING: A CASE STUDY FROM THE AUSTRALIAN SEMI-ARID TROPICS

A. N. Andersen, Tropical Savannas Cooperative Research Centre, CSIRO Tropical Ecosystems Research Centre, PMB 44 Winnellie, NT, 0822, Australia. E-mail: Alan.Andersen@terc.csiro.au

Despite widespread recognition of the value of insects as bio-indicators, insects are usually ignored in land monitoring programs. This is largely because insect consuses traditionally involve specialist sampling techniques, the sorting of large numbers of specimens, and the identification of many taxonomically challenging species. My presentation will report on the reliability of results from a simplified ant sampling protocol that is readily incorporated into routine wildlife surveys. Ants are exceptionally diverse and abundant in Australia, and are the most widely used group of invertebrate indicators. A comprehensive ant sampling program was conducted as part of an assessment of the biodiversity impacts of SO2 emissions from a large copper and lead smelter at Mt Isa in northwestern Queensland, yielding a total of 174 species from 24 genera. The key findings were: 1.The two regionally dominant landforms support distinct ant faunas, with plain habitats being considerably richer in species than rocky ridges; 2. Ant species richness increases with distance from the smelter, corresponding with decreased levels of SO2; 3. Several common species show clear abundance patterns in relation to SO2, with some decreasing and others increasing; 4. Eyrean (arid-adapted) taxa were especially sensitive to SO2; 5. Ant functional group composition showed relatively little change in relation to SO2. Routine sampling of vertebrates was conducted as part of the broader assessment program, and included large, bucket-sized pitfall traps with drift fences. Ants were also collected from these traps to see if such greatly simplified sampling was sufficient to provide useful results. The sorting of morphospecies was also greatly simplified by considering only large (>4 mm) species, and analysis was simplified by considering only site presence/absence data. In this manner, the inclusion of ants in the assessment process required less than 10% of the effort demanded by the specialist ant sampling program. The extent to which these results recapitulate the findings from the comprehensive ant survey will be reported. Preliminary analyses indicate that the incidental captures of large species from vertebrate pitfall traps gave most if not all the key findings provided by the comprehensive ant sampling program. It therefore appears feasible to incorporate ant sampling in wildlife surveys as part of routine land monitoring and assessment programs.

[0465] BIOTYPIC AND GENOTYPIC DIVERSITY OF GREENBUGS: HOST ADAPTED OR CULTIVAR SELECTED

J. A. Anstead¹, **J. D. Burd² & K. A. Shufran²**, ¹Oklahoma State Univ., 127 Noble Research Center, Stillwater, OK, USA, 74078. E-mail janstead@pswcrl.ars.usda.gov; ²USDA-ARS, Plant Science and Water Conservation Lab., 1301 N. Western Rd., Stillwater, OK, USA, 74075.

Greenbugs are a considerable agricultural pest worldwide. They are limited to the graminae and cause economic damage on a wide range of crops including wheat, barley, sorghum, rice and rye. Greenbugs also utilize a large number of non-cultivated hosts. A number of host plant resistance sources against greenbug feeding damage have been found. However each has been overcome by the emergence of greenbugs able to overcome this resistance. Traditional theory suggested that these biotypes evolved in response to the selection pressure exerted by resistant cultivars in the field. Recent evidence suggest that this is not the case and it is hypothesized that variability in virulence to resistant lines plants pre-existed among greenbug populations on non-cultivated hosts. Greenbugs were collected from a number of cultivated and non-cultivated hosts in the central plains of the U.S. and clonal laboratory colonies were started with single aphids. They were biotyped using standard plant differentials. A 1.0kb portion of the mitochondrial Cytochrome Oxidase Subunit I gene was extracted, PCR amplified and sequenced. The DNA sequence data were subjected to maximum likelihood analysis and dendrograms were produced using the PAUP statistical package. These data supported previous conclusions that the greenbug species could be separated into 3 clades based on mitochondrial sequences. The distances between the clades appear to indicate divergence times of over 1 million years. Biotype I was found in all three clades indicating there is exchange of genes conditioning for virulence, and that biotypic status did not drive the divergence of these clades. A single clade contained almost all the greenbugs collected from crop hosts, indicating only a subset of the population is present in cropping systems. All 3 clades had substantial differences in their non-cultivated host range. This study conclusively shows that the deployment of resistant crop lines did not drive the formation of biotypes. It shows that divergence within this species was probably driven by non-cultivated host plant use, and that the greenbug species complex is comprised of a group of sub-populations adapted to different host species.

Index Terms: Schizaphis graminum, Biotype, COI, host plant resistance

[0466] DIFFERENT SEED TREATMENTS TO CONTROL THRIPS FRANKLINIELLA SCHULTZEI (THYSANOPTERA: THRIPIDAE), APHIDS APHIS GOSSYPII (HOMOPTERA: APHIDIDAE), VEGETATIVE DEVELOPMENT AND YIELD OF COTTON CROP

<u>S. Bellettini</u>, Departamento de Fitotecnia, Fundação Faculdade de Agronomia "Luiz, Meneghel", Br 369 km 54 C.P. 261 CEP 86360-000 Bandeirantes-PR, E-mail: bellettini@ffalm.br

It were evaluated, in Bandeirantes City-PR, different seed treatments to control thrips and aphids; vegetative development and yield of cotton crop. It were used following treatments and doses as a.i./100 kg of seeds: thiamethoxan (Cruiser 700 WS) 150, 210 and 300 g; imidacloprid (Gaucho) 140 g; carbofuran (Furadan 350 TS) 700 g; acephate (Orthene 750 BR) 750 g and control (with no insecticide). Experimental design was randomized blocks with 7 treatments, 4 replications and plots with 27 m². Evaluations were done by counting alive thrips number at 10, 15, 20, 25 and 30 days, on 10 randomized plants per plot; the number of alive aphids at 15, 20, 25, 30 and 35 days on 10 top randomized leaves per plot; plants height at 10, 20, 30, 40, 80 and 120 days after emergence, on 10 marked plants per plot and cotton seed production. Different treatments showed efficiency higher than 81% on thrips control till 30 days and 82% on aphids till 35 days after plants emergence. Insecticides thiamethoxan (Cruiser 700 WS) 210 e 300 g and imidacloprid (Gaucho) 140 g showed efficiency from 90 till 97,3% at evaluations, on thrips and aphids control. Treatments thiamethoxan (Cruiser 700 WS) 210 and 300 g and imidacloprid (Gaucho) 140 g showed 9,3; 17,3 and 11,8% heigher on plants height and 26,1: 30,7 and 25,9% on cotton seeds production, respectively, comparing with control. Used insecticides and doses had no plants toxicity. Index terms: cotton crop; thrips; aphids; chemical control.

[0467] INTRASPECIFIC GEOGRAPHIC VARIATION IN HOST-PLANT UTILIZATION OF BUTTERFLIES

¹<u>A. Bergstrom</u> & ¹S. Nylin, ¹Dept of Zoology, Stockholm Univ., SE-106 91 Stockholm, Sweden. Email anders.bergstrom@zoologi.su.se.

Traditionally, host-plant repertoires of butterflies have been thought of as being very conservative. Recent studies though have, on the contrary, shown that host-plant shifts can be very rapid under certain conditions, leading to high levels of intraspecific geographic variation in host-plant use. In my talk I will present examples on species that have shown rapid evolution of host-plant choice as well as species being conservative in their preferences. In doing this I will use examples from my own studies on geographic variation in local adaptations of host-plant utilization in response to variations in host-plant abundance. In addition, I will also use examples from other studies presented in the literature. This knowledge can be of importance for future conservation projects when decisions have to be made on which species to prioritise.

Session 03 – BIOGEOGRAPHY AND BIODIVERSITY

[0468] CICADA BIOGEOGRAPHY AND WALLACE'S LINE, DO CICADAS SING A DIFFERENT SONG?

<u>P. L. Th. Beuk¹</u>, J. P. Duffels² & A. J. de Boer³, Zool. Mus. Univ. of Amsterdam, Dept. of Entomology, Plantage Middenlaan 64, NL-1018 DH Amsterdam, Netherlands; E-mail ¹beuk@bio.uva.nl, ²duffels@bio.uva.nl, ³aboer@bio.uva.nl.

The biota of the Malay Archipelago can, simply speaking, be separated in components that appear to be related to Southeast Asian groups or to Australian groups. In the 19th century Wallace was the first to point this out. His division line between the 'Indo-Malayan' and 'Austro-Malayan' regions became known as 'Wallace's Line'. Other workers observed similar lines that could possibly serve as a division line. Wallace's Line coincides with a wide sea barrier that existed in geological times, and prevented the dispersal of organisms from West to East or vice versa. This barrier was not often crossed. However, botanical and zoological literature yield a number of instances where the barrier was taken. Most often it involves groups that have their main distribution on one side of the barrier and single species or small groups that dispersed to the other side and possibly speciated subsequently. When the wide sea barrier became much narrower in the middle of the Tertiary opportunities arose for crossing the barrier by 'island hopping'. However, considering the relatively low number of taxa occurring on both sides of Wallace's Line, crossing the barrier should be considered an exception rather than a rule. The question then arises whether taxa in the West Pacific with apparent Southeast Asian ancestry did cross the barrier. A monophyletic group of taxa of the cicada tribe Dundubiini, the subtribe Cosmopsaltriaria, does occur in the West Pacific but has a Southeast Asian ancestry. Phylogenetic analysis of the tribe revealed that the sister group of the Cosmopsaltriaria does occur on the Southeast Asian continent rather than in the Malay Archipelago. Groups of the Dundubiini found immediately west of Wallace's Line are representatives of different branches of the same monophyletic clade that includes the Cosmopsaltriaria and its sister group. From this it can be concluded that Wallace's Line was skirted on both sides rather than crossed. This alternative for crossing the barrier will be discussed in the light of biogeographic and geological evidence at hand.

Index terms: Cicadidae, Dundubiini, Cosmopsaltriaria, phylogeny, Indo-Pacific area

[0470] CONSERVATION IN ANTHROPOGENIC LANDSCAPES IN THE NEOTROPICS: RICHNESS, COMPOSITION, SIMILARITY, AND ENVIRONMENTAL CORRELATES OF BUTTERFLY FAUNULAS

K. S. Brown Jr. & A. V. L. Freitas, Dept. de Zoologia and Museu de História Natural, Inst. de Biologia, Univ. Estadual de Campinas, C.P. 6109, Cidade Universitária, Campinas, SP 13.083-970 BRAZIL, E-mail ksbrown@obelix.unicamp.br. Financial support: BIOTA-FAPESP, CNPq, PDBFF, BSP, CIFOR.

Direct comparisons at species, generic, and family levels of well-inventoried butterfly communities in a wide variety of partially anthropogenic Neotropical sites including from 250 to nearly 2000 species, by means of Sörensen's simple similarity index 2c/(a+b), Ward's minimum-variance clustering (Euclidean distances), Principal Components Analysis, and Canonical Community Ordination provides three lines of information useful for conservation evaluation and planning. First, ordination of sites by their faunulas clearly shows many distinct biogeographical regions, associated with different climate, vegetation, and disturbance types throughout the region. Second, ordination of the proportions of tribes, subfamilies and families against environmental factors shows that climate and disturbance predominate in shaping the community, with connectivity (in strongly fragmented landscapes) and soils (when very rich or very poor) also important. Third, positive or negative correlations of species richness in the various butterfly groups with environmental factors permits the identification of sensitive indicators for the variation of these factors in agricultural or urban systems. In general, non-urban anthropogenic landscapes containing as little as 10% of their area in natural fragments over 10 ha (0.01 km²) in size, with reasonably humid green connectivity (including most crops) for much of the year, can maintain highly diverse butterfly faunas similar to those of sites with complex mosaics of topography and vegetation, or with high levels of natural disturbance (like river valleys, steep areas, or bamboo forests). These communities may lack, however, certain larger or more specialized species, or those that naturally occur in highly dispersed populations (like many "hilltoppers"). The use of agrochemicals or fire, giving excessive modification of watercourses or soil biology, or intense urbanization (paving over, or planting of large structures), rapidly degrades these communities, strongly impeding their reconstitution for very long periods, even on good soils with favorable rainfall; their faunulas come to resemble those on poor lithic natural sites.

Index terms: CANOCO, PCA, Connectivity, Climate, Soils, Disturbance

[0469] BIODIVERSITY OF THE PARASITIC HYMENOPTERA IN A COASTAL MANGROVE FOREST OF BANGLADESII

B. A. Bhuiya, M. L Miah. & A. Zannat, Department of Zoology, University of Chittagong, Chittagong 4331, Bangladesh, E-mail babhuiya@ctgu.edu

A 10 month long fortnightly survey (January 1999 to October 1999) of Malaise trap collection from an aforested mangrove coastal area in the Moheshkhali Island resulted in a total of 9,309 parasitic Hymenoptera. The collection included 20 % Ichneumonoidea, 60 % Chalcidoidoidea and 20% other parasitic groups. Of the total collection of Ichneumonoidea the families Ichneumonidae and Braconidae included 25 % and 75 % respectively. The subrfamilies of the family Ichneumonidae were further studied for population. Under the family Ichneumonidae 12 subfamilies were determined. These are Anomaloninae, Banchinae Campopleginae, Cremastinae, Ichneumoninae, Labeninae, Mesochorinae. Metopiinae, Ophioninae, Phygadeuntinae, Pimplinae and Tersilochinae. Within these 12 subfamilies 31 genera were identified and their population was studied for seasonal abundance. A study of the population fluctuation throughout the period of study suggests that some members of the family Ichneumonidae are available round the year. A few of them are known to be very effective biological control agents elsewhere in investigation will help finding more specific parasitoids that may be utilized profitably against the pest insects of the mangrove forests in Bangladesh.

Index terms: Biodiversity, Parasitic Hymenoptera, Mangrove forest, Seasonal abundance, Bangladesh.

[0471] RESPONSES OF COLLEMBOLA COMMUNITIES TO LEAD SHOT DEPOSITIONS IN A HEATHLAND ENVIRONMENT

Luc De Bruyn^{1,2}, Frans Janssens², Frederik Hendrickx³ & Jean-Pierre Maelfail^{1,3}, ¹ Inst. Nature Conservation, Kliniekstr. 25, 1070 Brussel, Belgium; ² Dept. Biology, Univ. of Antwerpen, Groenenborgerlaan 171, 2020 Antwerpen, Belgium; ³ Lab. Ecology, Univ. of Gent, K.L. Ledeganckstr. 35, 9000 Gent, Belgium; E-mail : luc.de.bruyn@instnat.be.

It has been stated by several authors that the abundance, species diversity and life history characteristics of Collembola can provide information on environmental conditions. Because different collembolan species possess different sensitivities to metal pollution, an analysis of their community composition and organisation might provide an accurate tool to estimate soil pollution. In view of a project that aims to construct a multi-species test system for contaminated soils, a multitude of invertebrate taxa were collected in the heathland "Groot Schietveld" near Antwerp, Belgium. In this heathland area a elay pigeon shooting stand is situated. As a consequence, the soil in the target zone is heavily contaminated sites with comparable soil and vegetation structure as a control. Collembola were sampled with a core sampler (\Box =5cm; depti=10cm) and extracted with a modified McFayden apparatus. Soil lead content and additional soil parameters (humidity, carbon content, pH, ...) were related to differences in community structure and functionality.

Index terms: ecological indicator, heavy metal, pollution

[0472] WHICH IS AN ADEQUATE DIVERSITY INDEX FOR INSECT COLLECTIONS?

Luis Bulla & Rubén Candia, Instituto de Zoología Tropical, Facultad de Ciencias, Universidad Central de Venezuela. Apto 47058, Caracas 1041-A,m Venezuela. E-mail: rcandia@strix.ciens.ucv.ve. This work was financed by the ISC Programme of the European Commission, Project CT 94-0099 VE.

Insect collections have some peculiarities that make rather different from other biological assemblages. In the first place, they are characterized by an unusually high number of species. Collections of 100 or more species are the rule, and over 500 species are not exceptional. Secondly, They are seldom complete. Many species are not captured even in very big sample. As a consequence of this fact, most insect samples have a high abundance of species represented by only one or two individuals (singletons and doubletons, in Chao's terminology). Diversity indices are numbers that combine in a single value two attributes of the sample; its richeness or number of species present and its evenness, or the degree to which the abundances of the different species are similar. Insect samples have usually very heigh richness and comparatively low evenness values. Consequently, if a diversity index is going to be used with insect samples it would be desirable that it fullfills at least two conditions; 1) it has to be sensitive to increments in richness even if the number of species is very high; 2) it has to estimate adequately evenness even if it is very low. We will prove, throughout algebraic manipulation and the analysis of real samples that the usual diversity indices (Shannon's H', Simpson's 1-D, and Hill's N1 and specially N2=1/D) are markedly insensitive to changes of diversity when working with high richness communities, and strongly overestimate evenness if the value of this parameter is low. For this reason, we recommend the use of the "new generation" of diversity indices, that estimate diversity as the product of an evenness measure and the number of species (D=E x S were D is the diversity value, E an evenness measure and S the number of species). The difference among these indices is the type of evenness index used. Several options are available for the index E; among others Camargo's O and E'(1993), Bulla's E (1994), Smith & Wilson's E_{var} (1996) and Hill's E_{ma} (1997). The advantages of these indices over the classic ones are show using a collection of insect samples from seven different savannas that represent the changes that take place in the insect comunity trough the introduction of a pine forest on a natural savanna, its harvest and the recuperation of the system.

[0473] DIVERSITY OF TWO LOWLAND RAINFOREST BEETLE TAXA (IIISTERIDAE AND STAPHYLINIDAE: PSELAPHINAE) AT A WESTERN AMAZONIAN LOCALITY

C. E. Carlton, M. Dean & A. K. Tishechkin¹, ¹Dept. of Entomology, Louisiana State Univ., Baton Rouge, LA 70803 USA, E-mail: ccarlto@unix1.sncc.lsu.edu

To estimate beetle diversity at a single locality in Amazonian Ecuador, we analyzed collection from a two-month sampling effort at Yasuni Research Station (Napo Province). Collecting methods included Berlese sampling, flight intercept traps, light traps, and hand collecting from specific habitats (e.g., social insect nests). Histerid beetle diversity at the site was estimated to include 130 species among 2631 specimens. Pselaphine staphylinid diversity was 174 species among 898 specimens. We generated species richness and richness estimator curves to assess the thoroughness of our efforts. Using the proportion of target tax relative to total beetle diversity worldwide and at selected comparative sites, we calculated total potential beetle species richness at Yasuni. These data will be useful for continuing studies of regional insect diversity and site complementarity in the Amazon Basin.

Index terms: Coleoptera, Biodiversity, Species richness, Ecuador

[0474] THE INFLUENCE OF ORGANIC MATTER ON THE DIVERSITY OF SIMULIDAE ON THE MICROBASIN OF LAGEADO DOS FRAGOSOS IN CONCÓRDIA, SANTA CATARINA STATE, BRAZIL

L.C. Castro¹, D.P. de Paiva², M. N. Strieder³ & M. T. S. Padilha¹, ¹ Dept of Zootheenics. Federal University of Santa Catarina, Rodovia Admar Gonzaga, 1188, Itacerubi, 88034-901, Florianôpolis, Santa Catarina, Brazil, E-mail lucastro2000@ig.com.br; ² Dept. of Sanity, EMBRAPA/ CNPSA, BR 153, km 110, P.O. Box 21, 89700-000, Concôrdia, Santa Catarina, Brazil, ³ Dept. of Entomology, Unisinos, P. O. Box 275, 93022-000, São Leopoldo, Rio Grande do Sul, Brazil.

Peixe and Jacutinga rivers are responsible for the provisioning, drainage and agricultural activity in the area of the microbasin of Valley of Peixe river. In spite of having suffered a decrease of 15% from 1980 to 1991, the rural population represents 40% of the total population. Due to the socioeconomic prosperity initially reached, along the time, the inadequate use of the soil, the retreat of the vegetable covering and the intensive exploration of the agricultural activity collaborated for the environmental degradation that the area demonstrates now. The small watersources present different pollution degrees, as pouring out of animal dejections or fot the abusive use of agrotoxic in the husbandry. That fact is worse, for the uncomfortable presence of the blackflies (Simulium sp.), that are diptera, whose female is haematophagous and provokes serious damages, through its pricked, to the animals and the own producers. It was made collections in 12 points in Lageado dos Fragosos, affluent of Jacutinga river in the municipal district of Concórdia, Santa Catarina, Brazil to identification of the species. Three of those points were considered witness for they have presented not very degraded. After the removal of the immatures from the different substrata, these were placed in alcohol 90% and later on, in the laboratory, transferred for alcohol 70%, when they were quantified and identified under stereoscopic microscope; it was just used the last stadium's immatures. The found species were: Simulium (Chirostilbia) acarayense, Simulium (Inaequalium) travassosi, S. (I.) botulibranchium, S. (I.) nogueirai, S. (I.) subnigrum, S. (C.) pertinax, S. (Psaroniocompsa) incrustatum, S.(P.) anamarie(,) e S. (Thyrsopelma) orbitale with predominance in number of S. (C.) pertinax e S. (T.) orbitale. The diversity of simulidae species founded in some points, suggests an ecosystem in balance (ANDERSON & DICKE, 1960), which is a beneficial situation linclusively because of nor all the species were anthropophilic. However, five collection points showed the presence of only one specie In fact, those points were characterized, visually, as polluted, in the begginning of this research. The study of the influence of the levels of organic matter on the population of simulidae's immature should embrace, also, a larger period of time, to allow conclusions and extrapolation of the results.

Index terms: blackflies, Simulium pertinax, Simulium sp., organic matter, pollution, watersources

[0475] BEE FAUNA DIVERSITY OF BAIHA STATE, BRAZIL

M. S. de Castro¹ & B. F. Viana², ¹Exp. Unit of Bahia Enterprise of Agrie. Develop. EBDA, Salvador, Bahia and Dept. of Biology Sciense, State Univ. of Feira de Santana, Bahia. Dorival Caymi Av., 15.649 Itapuã Salvador, Bahia, Brazil 41.635-150. E-mail: marina@e-net.com.br; ²Dept. of Zoology, Biology Inst. Federal Univ. of Bahia-Salvador, Bahia, Brazil 40.170-110. E-mail: blande@ ufba.br.

Bahia is a large State located at Northeastern of Brazil ranging from latitudes 9°S to 18°S. The main biomes are Tropical Dry Forest/Woodlands – TDF ("caatinga" vegetation), Tropical Humid Forests - THF (Atlantic Rain Forest), Tropical Savanna – TS ("cerrado") and Semidecidous and Altitudinal Forests located on the Chapada Diamantina Plateau - SAF. In Brazil about 46 systematic surveys were done since they started at thirty years ago. In Bahia since thirteen years ago 9 studies were done: 4 on TDF, 2 on THF, 1 on TS and 2 on agroecosystem. Bee community diversity can be assessed for each survey by alpha diversity (number of species found in each area). Inventories in Bahia found from 31 to 150 species in single sites. The sites where fewer species were found are in "Caatinga" – plaeoquarternary sand dunes of the middle São Francisco river (42) both sites located at Northeast of Bahia latitudes 9° and 10°S. Surveys in "Caatinga" located at latitude 12°S resulted in the number of species of 80 and 94 species. The Tropical Savanna was the site where more species were found (150). In a small fragment of the Atlantic forest 70 species were found. The number of species found in surveys carried in Agroecosistems were 71 (various crops) and 95 (tropical and exotic fruits).

Index Terms: Biodiversity, Apoidea

[0476] BIODIVERSITY AND ECOLOGICAL IMPORTANCE OF WATER MITES (ACARI, HYDRACHNIDIA) IN ITALIAN SPRINGS

B. Cicolani & A.Di Sabatino, Dipartimento di Scienze Ambientali, University of L'Aquila, Via Vetoio 20, 67100 L'Aquila, Italy, E-mail: cicolani@aquila.infn.it. Research supported by grant of MURST, cluster 11

The paper summarizes the results of recent investigation on spring habitats in Italy, with particular reference given to the water mite taxocoenosis. 220 springs and spring systems were examinated over a broad geographic range (Sicily, Sardinia, Southern and Central Apennines and Alpine region). Globally, about 120 species of water mites were identified, some of which result endenic or with an interesting disjunct distribution. Our data clearly indicate water mites as one of the most characteristic groups inhabiting spring biotopes. Compared to other spring-dwelling invertebrates, water mites show a high level of species diversity and the highest proportion of crenobionts species (ranging from 40% to 60%). Further, the different assemblages of the water mite community have proved to be related to such environmental factors as: spring typology, altitude, human impacts and energetic inputs. Due to the complexity of their life cycle and the multilevel biocoenotic interactions (parasitism, predation, competition) water mites are well suited to detect any changes in natural condition of natural condition in these ecosystems are expected. Index terms: water mites, spring habitats, Italy, biodiversity.

[0478] AQUATIC INSECT BIODIVERSITY IN STREAMS OF DIFFERENT BASINS AT A REGIONAL SCALE

Corigliano M. del C.¹, E.A. Vallania², E. S. Tripole², M. A. Gil², P. A. Garclis² & A. I. Medina², ¹ Depto. de Ciencias Naturales, Univ. Nac. de Río Cuarto, X5804-BYA, Rio Cuarto, Argentina. ² Area de Zoología, FQByF, Univ. Nac. de San Luis, Chacabuco y Pedernera, 5700 San Luis, Argentina. E-mail: mcorigliano@exa.unrc.edu.ar.

The Sierras Pampeanas in Cordoba and San Luis provinces present similar characteristics at regional scale due their common orogeny. However, climatic and hydraulic conditions vary from east to west being San Luis, the western region, more arid and with streamflows lower. An inventory analysis with special emphasis in Ephemeroptera, Plecoptera and Trichoptera (EPT) was developed to assess and compare aquatic insect biodiversity in Sierras Pampeanas streams. Studied sites were localized in different altitudinal stretches of each basin. Macroinvertebrates from 28 locations were sampled with Surber net and identification and counts were performed. Environmental variables were measured. TWISPAN classification, detrented correspondence analysis ordination and cluster analysis were developed. Sites of the same altitude were ordinated and classified together independently of the hydric basin they belonged, but within each group, samples from consecutive reaches were more frequently nearest in cluster analyses. Sites and taxonomic associations were classified in higher altitudinal lower order streams, foothills and lowland reach. Baetis, Leptohyphes, Caenis and Tricorythodes were the more widespread association among Ephemeroptera and Marilia, Smicridea and Oxyethira among Trichoptera, as it has been reported in published data from rhithron conditions in Neotropical Region. Helicopsyche turbidae, Polycentropus joergenseni and Protoptila dubitans characterized higher altitudinal levels as well as Baetodes and Camelobaetidius penai among Ephemeroptera. Other species were rare and Anacroneuria was the single Plecoptera observed. EPT associations in Cordoba and San Luis have similar composition but they differ in their relative abundance. Ephemeroptera predominated in Cordoba while Diptera and Oligochaeta densities were higher in San Luis. In the most arid region the majorities of streams has lower discharge and are regulated by dams, which would determine the dominance of non-EPT groups. Considering regulations of rivers for dam constructions and other anthropic activities, EPT associations in Cordoba and San Luis streams are threatened and under risk.

Index terms: Baetis, Leptohyphes, Caenis, Trichorythodes, Marilia, Smicridea

[0477] GRASSHOPPER (ORTHOPTERA: ACRIDOIDEA) SPECIES DIVERSITY IN THE PAMPAS, ARGENTINA

<u>M. M. Cigliano¹</u>, M. L. de Wysiecki² & C. E. Lauge², ¹Depto. Entomología, Museo de La Plata, Paseo del Bosque s/n 1900 La Plata, Argentina. E-mail: lauge@mail.retina.ar, ² Centro de Estudios Parasitológicos y de Vectores (CEPAVE), Calle 2 Nro. 584, 1900 La Plata, Argentina.

A study was conducted to describe the major features of geographic and temporal variation in the diversity of grassland grasshopper species (Orthoptera: Acridoidea) in different sites of the Pampas, Argentina. Species richness and relative abundance were assessed at twelve sites in eastern La Pampa and western Buenos Aires provinces, from 1994 through 1999. Mean species richness at the regional level was ten, and thirty four grasshopper species were collected throughout of the study. Comparison with grasshopper species diversity from the Great Plains of North America is discussed. An evaluation of the proportions of species in each of the three distribution groups (broad, intermediate, and narrow) revealed that, over all sites, broadly distributed species made up 14.7 % of species composition and intermediately and narrowly distributed species made up 26.5% and 58.8%, respectively. Multivariate analyses summarized the evaluation of the top-ranked species collected on our study. The three top-ranked species in the studied sites appear to be Dichroplus elongatus, D. pratensis, and Staurorhectus longicornis. Results showed that, contrary to what it was expected, one of the widely distributed species in the region (i.e., Baeacris punctulatus) does not always constitute the most abundant species. Finally, the loss of one of the historically most common species in the Pampas, D. maculipennis, is also discussed.

Index terms: Dichroplus elongatus, Dichroplus maculipennis, Dichroplus pratensis, Baeacris punctulatus, Staurorhectus longicornis.

[0479] ADVANCES IN THE KNOWLEDGE OF HYMENOPTERA IN THE BIOSPHERE RESERVE "EL CIELO", MÉXICO

J. M. Coronado-Blanco¹ & E. Ruíz-Cancino¹, ¹UAM Agronomía y Ciencias, UAT. Cd. Victoria, Tam., 87149. México

Hymenoptera contains a great quantity of species with value as parasitoids and predators of insect pests. This is an interesting group in relation to biology, because is developed in a diversity of habitats and by the complexity of its behaviour, having some organization in some families of wasps, bees, and in ants. The Biosphere Reserve "El Cielo" is located in SW Tamaulipas, in the municipalities of Gómez Farías, Ocampo, Jaumave and Llera. Diurnal collectings (aerial and sweeping nets, Malaise traps, yellow pan traps and ligth traps) have been done in more than 25 localities with vegetation as oak forest, pine forest. cloud forest, subcaducifolious tropical forest and some crops. Few records were taken from papers of other authors (in Aphelinidae, Eulophidae and Formicidae). Most of the material is deposited in the Insects Museum of the "UAM Agronomía y Ciencias, UAT", in Cd. Victoria, Tamaulipas, México. We found 44 families of Hymenoptera, including 356 genera and 204 determined species, which had contributed to the knowledge of the Hymenoptera of this Reserve in the State of Tamaulipas. The major diversity of species have been found in the families Ichneumonidae (152 genera, 244 morphospecies and 124 determined species) and Braconidae (52 genera, 1 determined species). Moreover, other families are present in the Reserve: Formicidae (26 genera, 22 species), Encyrtidae (22 genera, 6 species), Vespidae (21 genera, 20 species), Sphecidae (17 genera, 8 species), Pompilidae (12 genera), Anthophoridae (8 genera), Apidae (6 genera), Chalcididae and Bethylidae (5 genera each), Aphelinidae, Halictidae and Megachilidae (4 genera each), Eulophidae and Chrysididae (3 genera each), Tiphidae (2 genera) and Pelecinidae, Ceraphronidae, Colletidae, Eucharitidae, Gasteruptidae, Leucospidae, Mutillidae, Mymaridae, Scoliidae and Signiphoridae (1 genera each). Also, there are undetermined specimens of other 18 families. Therefore, 23 species have been described in the last decade by authors from México (Ichneumonidae, Encyrtidae and Aphelinidae), USA (Braconidae and Aphelinidae), Russia (Encyrtidae, Ichneumonidae and Ceraphronidae), Turkmenistan (Aphelinidae) and Sweden (Eulophidae). Then, we found S6% of the families recorded for Hymenoptera in the American Continent. This situation reinforce the importance of the Biosphere Reserve System and their role in the conservation of beneficial insects

Index terms: Tamaulipas, wasps, diversity

[0480] LAKES, PONDS AND WETLANDS AS HABITAT FOR BEETLES (COLEOPTERA, ADEPHAGA AND POLYPHAGA)

D. Cuadrado & J. Garrido, Dept. of Ecology and Animal Biology, Univ. of Vigo. E-36200, Spain, E-mail jgarrido@uvigo.es.

In the following study we show the conclusions of a 4 sampling research during 1 year over 4 lakes in the NW of Spain (Galicia). Vixán, Xuño and Bodeira situated in the coast; the other one, Cospeito, in the inlands. In Vixán we found a salinity value of 27,3‰, in Xuño we didn't find salinity, and in Bodeira the value was 0,3‰. In Cospeito salinity was not found. We also measured other parameters: pH, oxygen saturation, oxygen concentration, conductivity, TDS (Total Disolved Solids) and temperature, We collected 52 species of water-beetles, using Analysis of Canonical Correspondences we found that beetles distribution was related to conductividity, we also observed the importance of water level in sampling zone and how variable was oxygen level according to the hour of the day, density in vegetation and degree of wind exposure. On the other hand we observed that this type of ecosistems was very variable, because a lake can be reduced to a pond or a welland with few centimetres of water. Index terms: water beetles, lakes, ponds, wetlands

[0482] THE ARGENTINEAN SPECIES OF THE ANT GENUS *LINEPITHEMA* (FORMICIDAE: DOLICHODERINAE)

F. Cuezzo, CONICET - Instituto Superior de Entomología "Dr. Abraham Willink" (INSUE). Facultad de Ciencias Naturales e Instituto Miguel Lillo. Miguel Lillo 205, 4000 San Miguel de Tucumán. Argentina. E-mail: institillo@infovia.com.ar.

The genus Linepithema (Formicidae: Dolichoderinae) was recently treated and re-defined at generic level by Shattuck (1992). Ants belonging to this genus are common in Argentine. One of its species, Linepithema humile, also known as the "Argentine ant", has received a lot of attention because is widely distributed around the world. It is assumed that it was probably exported from Argentine and Brazil to the rest of the world, where is considered a plague acting as a strong competitor of local ant fauna and causing damage to native plants. Although the significance of the genus, very few is known about the other species of *Linepithema*. No key for species are currently available. The genus is compound of 26 taxa (species, varieties and subspecies) with Central and South American distribution except for L. humile. Two more species are recognized from the fossil records, The material used in the present study belong to several personal field collections. Also a number nest series deposited in different Museum collections were examined. As a result of the present contribution 11 taxa are recognized, including one species new for the science. The rest of the taxa are redescribed considering the different castes (worker, male and female). A key for South American living species is provided and drawings of the main characters are made in order to help identifications. Patterns of geographical distribution and data of biology to several species inhabiting natural places in Argentine are given.

Index terms: ants, Hymenoptera, Linepithema, Taxonomy

[0481] NEOTROPICAL SPECIES OF THE ANT GENUS DORYMYRMEX (FORMICIDAE: DOLICHODERINAE), I. DORYMYRMEX FLAVESCENS COMPLEX

F. Cuezzo, CONICET - Instituto Superior de Entomología "Dr. Abraham Willink" (INSUE). Facultad de Ciencias Naturales e Instituto Miguel Lillo. Miguel Lillo 205, 4000 San Miguel de Tucumán. Argentina. E-mail : instililo@infovia.com.ar.

Dorymyrmex is an ant genus with American distribution that represents one of the most confusus cases in the systematic history of Formicidae. Several attempts to put in order the internal taxonomy of this genus were made in the past but no taxonomic review of Neotropical species were proposed. IN the past, the genus was subsequently divided into as much as 7 different subgenera by subsequent authors. These have been regarded as subgenera of *Dorymyrmex* or as genera related to it. The last attempt to reorder this genus was made by Shattuck (1992). In his paper, Shattuck considers 7 Neartics spp. and 72 in the Neotropics. He joined all species in one genus establishing characters to define Dorymyrmex at generic level. This conception is followed in the present paper. The neartic species were reviewed by Snelling (1995). The aim of this paper is to contribute to knowledge of the neotropical species of Dorymyrmex. More than 3000 exemplars belonging to several nest series were examined including types material of Museum collections and personal collections made through different areas of Argentina and Chile.As a result of a global analysis of the genus, a new arrange into nine species complexes of the neotropical species is proposed. The complexes were defined based on groups of characters. A key to separate species complexes is provided. A taxonomic review of Dorymyrmex flavescens complex is also given with redescriptions of the different castes (worker, male and female). Each description is accompanied with standard measurements and schemes of the main characters. New keys to species and data of geographical distribution to each species are provided. After this study, flavescens complex comprise 15 species distributed in Chile and Argentine. I consider D. alboniger as new synonym of D. ebeninus (new status), D. azulensis, and D. albipes were redescribed as good species (first available use); D. weiseri, D. patagon, D. mandibularis and D. jactans considered as good species were elevated to species range (new status). ectotypes and paralectotypes were designed when it was necessary. The other complexes felimited in the present contribution are currently being reviewed by the author and will be publish in the near future.

[0483] COLLEMBOLA (ARTHROPODA: HEXAPODA) BIODIVERSITY IN TROPICAL AGRICULTURAL ENVIRONMENTS OF ESPIRITO SANTO, BRAZIL

<u>M. P. Culik¹</u>, J. L. de Souza¹ & J. A. Ventura¹, ¹Empresa Capixaba de Pesquisa, Assistência Técnica e Extensão Rural, EMCAPER, Rua Afonso Sarlo, 160 - Bento Ferreira, CEP 29052-010, Vitoria, Espirito Santo, Brazil, E-mail: markculik@hotmail.com.

Collembola are among the most widespread and abundant arthropod inhabitants of terrestrial ecosystems, and by feeding on organic matter and microorganisms they have important influences on soil microbial ecology and fertility. However, despite their environmental importance, basic information on the biodiversity and ecology of Collembola is lacking. The Neotropical collembolan fauna is probably the most diverse but least known in the world and knowledge of the collembolan fauna of Espirito Santo, Brazil, which contains some of the most diverse tropical forests in the world, consists of only two records of nine species. Likewise, knowledge of the biology of Collembola in agroecosystems is also limited. The goal of this research is to increase basic knowledge of the biodiversity and ecology of Collembola in tropical agricultural environments. Specific objectives are to determine what Collembola species inhabit agricultural soils of Espirito Santo, obtain a record of the seasonal abundance of Collembola in this area, and determine effects of alternative agricultural practices on Collembola in this tropical environment. Field sites for the project are located at the EMCAPER Central Mountain Research Center, Domingos Martins (20° S latitude), and consist of three sites designated: A, Fertilizer site (the site contains two blocks (replications) with plots, $100m^2$, subjected to two fertilizer treatments, organic fertilizer (compost) and inorganic fertilizer application); B, Tillage sile (with treatments, organic fertilizer (compost) and inorganic fertilizer application); B, Tillage sile (with two blocks containing plots, 155m², subjected to two different (illage treatments, no-tillage and conventional tillage); and C, Mulch site (with two blocks containing plots, 150m², subjected to two different mulch treatments, mulch and uo mulch application). The same plots have received similar treatments annually since the sites were established in 1992 (site A) and 1991 (sites B and C, in an organic system) and a variety of vegetable crops are grown on the sites. Beginning in December 1999, two soil core samples (5cm diameter) are taken randomly from the surface 10cm of each plot each month. Collembola are extracted from the soil cores using Tullgren lunnels and identified as far as possible to species level. Fourteen taxa of Collembola have been identified from initial samples collected from site A including Hypogastrura sp., Brachystomella sp., Onychiurus sp., Tullbergia sp., Isotomodes sp., Heteromurus sp., Entomobrya sp., Pseudosinella sp., Sinella sp., and Oncopodura sp., Two genera, Isotomodes and Heteromurus, are new records for Brazil. These initial results indicate that a diverse variety of Collembola can inhabit agricultural soils in Espirito Santo. This research is continuing and additional information on collembolan diversity and effects of agricultural practices on collembolan populations will be presented. Additional studies such as this in other areas and environments in Espirito Santo are also likely to add greatly to knowledge of the biodiversity and ecology of Collembola. This research is supported in part by a grant from the National Geographic Society. hidex Terms: Neotropical, biogeography, soil biology, organic agriculture

[0484] *BIOTRACK:* CONCEPTUAL AND INFORMATION TECHNOLOGY SOLUTIONS FOR UNDERSTANDING MORE OF BIODIVERSITY

J.M. Dangerfield, <u>D.A. Briscoe</u>, A.J. Pik, I. Oliver & A.J. Beattie, Key Centre Biodiversity & Bioresources, Dept of Biological Sciences, Macquarie Univ., Sydney, NSW 2109, Australia.

Our current understanding of biodiversity is largely limited to information from vertebrates and plants. Sampling constraints, taxonomic impediments and the sheer volume of material have constrained our use of the organismal diversity in other taxa, yet invertebrates and microbes account for more than 99% of extant biodiversity. Here we describe *BioTrack*, a system that integrates para-taxonomy, sampling protocols, a powerful relational database, bar-code technology and the use of high-quality digital images into a complete solution for question driven assessment and monitoring of biodiversity. We demonstrate the use and advantages of *BioTrack* in a large-scale project to test the efficacy of land systems as surrogates for biodiversity, in which 178,000 invertebrate specimens from 1500 pitfall traps were sampled and sorted. We also briefly describe other applications. Our results show that conceptual shifts and information technology tools, such as *BioTrack*, Monitoring, Parataxonomy, Computers

[0486] SOCIEDAD MEXICANA DE ENTOMOLOGIA, A.C.

C. Delova & S. Ibáñez-Bernal, Sociedad Mexicana de Entomología & Instituto de Ecología, A.C., Apartado Postal 63, 91000 Xalapa, Veraeruz, MEXICO, E-mail: deloyac@ ecologia.edu.mx.

The Mexican Society of Entomology (Sociedad Mexicana de Entomología, A.C.) was founded on January 29, 1952 at Mexico City. This society publishes a newsletter, Boletin Informativo, and a scientific research journal, Folia Entomologica Mexicana. The latter began in 1961 and currently publishes 3 numbers per year. Through the end of 1999 there have been 34 National Congresses, and since 1975 these meetings have been an annual event. Beginning in 1984 the Memorias of the National Congress began to be published independently; before that year they were published in Folia Entomologica Mexicana. The number of papers presented at the Congress has grown from 50 in 1958 to 353 in 1991; a total of 5,513 have been presented through 1996. There are 8 session subjects: Acarology and Arachnology, Biology, Ecology and Behavior, Biological Control of Pests, Agricultural Entomology, Forest Entomology, Medical and Veterinary Entomology, Physiology and Toxicology, and Systematics and Morphology. In addition, a great many symposia have been organized on a wide variety of specific subjects, Folia Entomologica Mexicana is recognized by the Mexican National Council of Science and Technology as a journal of excellence and is well known internationaly. The Mexican Society of Entomology has at present nearly 1,000 members, not only from Mexico but from other countries of the world.

Index words: entomological societies, Latin America, Mexico.

[0485] THE INSECT PESTS OF MYRCIARIA DUBIA (MYRTACEAE) IN PERU: A REVIEW

C. Delgado¹ & <u>G. Couturier</u>², ¹Instituto de Investigaciones de la Amazonía Peruana, Progr.biodiversidad, C.P. 784, Iquitos, Peru, E-mail pbioinv@halcon.rail.org.pe ²Antenne IRD Entomologie, Mus. nat. d'Histoire naturelle, 45 rue Buffon 75005 Paris, France, E-mail couturie@mnhn.fr.

Myrciaria dubia (Myrtaceae), called camu camu in Peru, is a native shrub of the Amazon basin that grows naturally along the periodically flooded banks of rivers and lakes. Its fiuits are round shaped berries and have a very high content of ascorbic and deshydroascorbic acid (from 8.64 to 9.70 g/kg of pulp). The fruits are collected in the native stands and sold in local markets to process juice and sorbet. The fruits have been exported as frozen pulp for a few years. Due to the increasing demand of the foreign market, the plant is now cultivated in experimental and commercial plantations. The Peruvian Ministry of Agriculture promoted since 1997 a 5 years project to develop cultivated areas in agroforestry systems. In natural conditions, M. dubia is only slightly damaged by insects whereas domestication in very different ecological conditions permitted the colonization by numerous species of phytophagous insects. Since 1985 the entomological fauna of this fruit have been studied in natural conditions and cultivated orchards. In this work, 62 species are reported for Peruvian Amazonia (Iquitos, Pucallpa). The major pests in plantations are, *Ceroplastes flosculoides and Conotrachelus* dubiae, newly described species; Tuthillia cognata, only known on M. dubia; Aleurothrixus floccosus, Edessa sp.,Dysmicoccus brevipes and Xylosandrus compactus, that are common and polyphagous pests of various crops. Many other species of Coleoptera, Diptera, Hemiptera, Lepidoptera, Phasmoptera, and Thysanoptera are considered at the moment, as secondary pests. Biology and ecology of the new pests are now studied in order to develop the use of IPM strategies.

Index terms : Conotrachelus dubiae, Edessa sp., Tuthillia cognata, Xylosandrus compactus

[0487] THE VENEZUELAN SPECIES OF POEMENIINAE, LYCORININAE AND XORIDINAE (HYMENOPTERA:ICHNEUMONIDAE)

F. A. Díaz, Univ. Centroccidental Lisandro Alvarado, Decanato de Agronomía, Depto. Ciencias Biológicas, Tarabana 3023, Lara, Venezuela.

Ganodes wahli, Lycorina albomarginata and Xorides sondrae are described and illustrated. G. balteatus, L. apicalis and X. humos are recorded for the first time in Venezuela. Ganodes (Poemeninae) is a small Neotropical genus ranging from tropical Mexico to southern Brazil and comprising five rather similar species. Only two are described, G. balteatus from southern Brazil and G. matai from Costa Rica. Lycorina (Lycorininae) is a moderate sized genus that is represented in Venezuela by two species, the widespread tropical American species L. apicalis, whose known range extends from southern Mexico southward into Brazil, and the new one. Xorides (Xoridinae) is a large cosmopolitan genus that is represented in the Neotropics by fourteen described species, and ranges from Mexico to Argentina. Characteristics that allow to separate the Venezuelan species are given.

Index terms: Ganodes wahli, Lycorina, Xorides sondrae

Symposium and Poster Session

[0488] SPECIES OF OPHIONINAE (HYMENOPTERA: ICHNEUMONIDAE) FROM THE ANDEAN AND CENTRAL WESTERN REGIONS OF VENEZUELA

F. A. Díaz¹ & Y. Colmenárez¹, ¹Univ. Centroccidental Lisandro Alvarado, Decanato de Agronomía, Depto. de Ciencias Biológicas, Tarabana 3023, Lara, Venezuela. E-mail: dbfrancis@hotmail.com.

The venezuelan representatives of the ichneumonid subfamily Ophioninae present in the collection of insects at the Museo Dr. José M. Osorio (UCOB), Universidad Centroccidental Lisandro Alvarado, Tarabana, Lara state, are reviewed and a key is provided to the four genera occurring in the Andean and Central Western regions of Venezuela. One species of Alophophion, fifty species of Encospilus, four species of Ophion and one species of Thyreodon, are found. Two genera, Alophophion and Thyreodon, and twenty eight species, Enicospilus aktites, E. alvaroi, E. bima, E. brevis, E. cressoni, E. duckworthi, E. echeverri, E. forsithei, E. gallegosi, E. hallwachse, E. jesicae, E. lacsa, E. lebophagus, E. madrigalae, E. masoni, E. mexicanus, E. peigleri, E. persimilis, E, pescadori, E. simoni, E. tenuigena, E. xanthocarpus, E. xanthostigma, Ophion cacaoi, O. calliope, O. euterpe, O. flavidus and Thyreodon atriventris, are recorded for the first time in Venezuela. Alophophion is a moderately species-rich genus whose component taxa are restricted to the cooler southern part of South America, with 25° S as its previously stablished northern limit. Now, being recorded at 9° 7' N this limit spreads enormously. Alophophion gauldi is described and illustrated. Enicospilus chiriquensis, E. columbianus, E. cubensis, E. devriesi, E. dispilus, E. exoticus, E. fernaldi, E. flavoscutellatus, E. flavus, E. glabratus, E. guatemalensis, E. hemicrescellae, E. kelloggae, E. kleini, E. leoni, E. liesneri, E. maculipennis, E. major, E. marini, E. monticola, E. opleri, E. purgatus, E. randalli, E. sanchezi, E. scuintlei, E. trilineatus and E. ulfstrandi are the previously recorded species in Venezuela. Information about known distribution and hosts is briefly outlined.

Index terms: Alophophion, Enicospilus, Ophion, Thyreodon

[0489] BIODIVERSITY OF CYNIPOIDEA FROM BRAZIL (HYMENOPTERA)

N. Diaz¹, <u>F. Gallardo¹</u>, P. Ros-Farré² & J. Pujade-Villar², ¹Dept. Científico de Entomología, Museo de La Plata, Paseo del Bosque s/n, 1900 La Plata, Argentina,E-mail gallardo@museo.fcnym.unlp.edu.ar; ² Dept. de Biologia Animal, Facultat de Biologia, Universitat de Barcelona, Avda. Diagonal, 645, E-08028-Barcelona, Spain, E-mail pujade@porthos.bio.ub.es.

The fauna of microhymenoptera from the Neotropical region is poorly known biologically as well as taxonomically, and this is specially evident if we consider their high biodiversity, the great number of undescribed species housed in the different entomological collections and that many areas have been scarcely sampled or remain nearly unknown. In these aspects Brazil is not an exception, inventory works are necessary to provide information on the distribution and ecology of species, as well as specimens necessary to systematic studies. De Santis (1980), was who first listed the Hymenoptera from this country, including 91 species belonging to the superfamilia Cynipoidea. Recent studies made by several authors notably increased this number with the description of new genera and species; besides this news taxa, many new records of brazilian Cynipoidea have been found, and even Paleartic species introduced for the biological control of some pests. The main objective of the present catalogue is to update the state of the knowledge of the representatives of this taxon in Brazil and the organization of this work follows the guidelines of that published for De Santis (op.cit.). For each species, the synonymy, the geographical distribution in the country, hosts and first Brazilian references are given. It is also provided a table with the number of species for families and subfamilies, registered for each state and territories of Brazil, the used abbreviations are those adopted by the Department of Mail and Telegraphs of that country.

Index terms: Catalogue, cynipoid wasps, brazilian fauna

[0490] HISTORICAL BIOGEOGRAPHY OF THE SOUTH AMERICAN RHYTIRRHININI (COLEOPTERA; CURCULIONIDAE)

M. Donato¹, P. Posadas¹ & D. R. Miranda- Esquivel², ¹Departamento Científico de Entomología and Laboratorio de Sistemática y Biología Evolutiva (LASBE). Museo de La Plata. Paseo del Bosque S/ N, 1900 La Plata, Argentina. ²Universidad Industrial de Santander. AA 678, Bucaramanga, Colombia: E- mail: mdonato@museo.fenym.unlp.edu.ar

The weevil sutribe Listroderina belongs in the tribe Rhytirrhinini (subfamily Cyclominac), and has 25 genera and 300 species in the Americas. The historical biogeography of the subtribe was reconstructed applying dispersal- vicariance analysis (DIVA) using genera as terminals. The results at the ancestral node suggest that the subtribe has been originated within an area actually represented by the Central Chile, Paramo, Puna, Patagonia and Subantartic provinces of the Andean subregion and the Neotropic. At this time has suffered extintions and was confined in Central Chile, Paramo and Subantartic provinces. Posteriorly took place extintions and dispersions and the subtribe was restricted in the Paramo and Puna provinces, after that occurred a dispersal event to the Subantartic province from these areas. A vicariant event separates Puna and Paramo provinces in one hand, and the Subantartic province in the other. Macrostyphlus generic group was confined in Paramo and Puna provinces and from there dispersed to other areas. In the Subantartic province Antarctobius, Falklandius, Listronotus and Listroderes generic groups was diversified. This hypothesis is not coincident with that of Morrone, J. J. Glab. Ecol. Biogeog. Lett. 188- 194, 1994, who proposed an austral biota to the southern most part of the Andean subregion, meaning Central Chile and Subantartic provinces, which dispersed northward, using track compatibility analysis and parsimony analysis of endemicity. Nonetheless one of the optimal reconstruction from DIVA for the subtribe ancestral node is coincident with Morrone's hypothesis.

[0491] EVALUATION OF ECOLOGICAL NETWORK QUALITY FOR BUTTERFLY INDICATOR SPECIES BY COMPARISON OF OBSERVED POPULATION DENSITY AND PREDICTED DENSITY FROM BOTANICAL RELEVÉS

<u>M. Dufrêne^{1, 2} & J. Sawchik², 1. Centre de Recherche de la Nature, des Forêts et du Bois</u> (MRW), Avenue Maréchal Juin, 23 B-5030 Gembloux Belgium, 2. Unité d'Ecologie et de Biogéographie (UCL), Place Croix du Sud, 4 B-1348 Louvain-la-Neuve Belgium

Minimum viable site networks are crucial for many threatened species, although the design procedures for doing so are always problematic, especially for invertebrate species. The present study investigated methods to estimate the potential habitat quality of an ecological network for butterfly species of wel grassland, by measuring a small set of ecological parameters. We use this approach to evaluate fragmentation consequences, by comparing site potential and observed densities. It is expected that greater differences will be observed when sites are more isolated. Species assemblage analyses with the Indicator Value approach revealed five species (Brenthis ino, Clossiana selene, Lycaena hippothoe, Lycaena helle, Proclossiana eunomia), as indicators of the main wet grassland types. Density predictions are performed on the basis of botanical relevés as explanatory variables with classical autecological multiple regressions and a synecological approach that combines canonical correspondence analysis and multiple regressions for these five species. Models are defined with a reference site set and are evaluated with a test site set. The precision of autecological approach was better on the reference site test, however the ability to generalize with the test site set of the synecological approach was largely better. The coefficient of determination of regression models were very high for Brenthis ino (75.10%) Clossiana selene (85.82%), Lycaena helle (61.36%) and Proclossiana eunomia (66.62 %). For Lycaena hippothoe, the predictions were not reliable as a result of sampling and behavior problems. On the test site set, differences between predicted and observed abundance were largely correlated with site isolation ($r^2 = 51.10\%$, 79.96% and 79.48 % respectively for Clossiana selene, Lycaena helle and Proclossiana eunomia). The more the sites are isolated, the greater the chances that potentially good sites are empty-Reciprocally, when the sites are not isolated, observed abundance is always greater than predicted, seeming to confirm the role of metapopulation effects by the significance of interactions or true rescue effects between more closed populations. Index terms: Proclossiana eunomia, Brenthis ino, Clossiana selene

[0492] TERMITE DIVERSITY AND LAND USE CHANGES: LESSONS FOR FUTURE GENERAL BIODIVERSITY STUDIES

P. Eggleton¹, ¹Dept. of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, E-mail: pe@nhm.ac.uk.

Termites are not only the most important arthropod decomposers in tropical forests, they are also extremely sensitive to the effects of forest clearance. Complete degradation of forests will often lead to the almost total destruction of termite assemblages, with a potentially enormous concomitant loss of ecosystem services. Termites would therefore seem to be extremely good target organisms both as indicators and as direct mediators of ecological processes. In this talk I will critically evaluate the problems of using termites as indicators of land use change, especially those due to variation in sampling technique, analytical procedures and biogeographical history. Generalising to studies with a wider remit I conclude that many of the studies that assume simple disturbance responses in species richness are flawed, often by an overemphasis on catch-all parameters, especially species richness and diversity indices. Compositional (multivariate) approaches are likely to be much more informative and far more sensitive to the complex but subtle changes increasingly being observed in disturbed biotas.

Index terms: Isoptera, land use changes, species richness, analyses of assemblage composition

[0494] LATITUDINAL AND ALTITUDINAL VARIATION OF THE RICHNESS, DIVERSITY AND COMPOSITION OF THE BUTTERFLY COMMUNITY IN THE "CORDILLERA ORIENTAL" (COLOMBIA)

<u>G. Fagua</u>¹, ¹Laboratory of Entomology, Dept. of Biology, Pontificia Univ. Javeriana, Carrera 7 No. 43 – 82. (Edificio 52 – Piso 5). Santafé de Bogotá, D.C., COLOMBIA, Email fagua@javercol.javeriana.edu.co.

The altitudinal and latitudinal variation in richness, estimated richness, diversity, frequency and structure of butterfly communities along four altitudinal gradients on the eastern slope of the Cordillera Oriental were studied. The study gradients were located in the mountains along the following rivers: Margua (7º 45' N, 72º 28' W, Toledo, None de Santander), Gazaunta (4º 36' N, 73º 25' W; Medina, Cundinamarca), Pato (2º 43' N, 74º W, San Vicente, Caquetá) and Sibundoy-Rumiyacu (0° 25' N, 77° 16' W - 1° 5' N, 76" 42' W, Nariño and Putumayo). Samples were collected at 14 sites between 600 m and 2200 m elevation. The samples were made during the rainy season. I collected 565 butterfly species of the 780-850 possible species for the study area. I observed an inverse correlation between altitude and: richness, richness estimated, abundance and diversity, and a positive correlation between altitude and dominance. I also observed an inverse correlation between richness and latitude. The altitudinal variation patterns for each subfamily were variable, but richness generally declined with altitude. Only Satyrinae, Lycaenidae and Pieridae were independent of altitude, but not of latitude, and declined with the latitude. I propose priority areas for conservation and emphasize the importance of the region for the protecting Colombian biodiversity. The region has 30% of the butterfly species of the country in only the 8% of the total area.

[0493] WHITE FLIES FAUNA OF WILD PLANTS AND THEIR ABUNDANCE IN EGYPT

<u>S. Elnagar</u>¹, G. Sewify¹, S. Abd-Rabou² & N. Ahmed², ¹Department of Economic Entomology and Pesticides, Faculty of Agriculture, Cairo University, Egypt; ²Plant protection Research Institute, Agriculture Research Center, Cairo

Two years survey at different locations in Egypt revealed eleven species of white flies associated with 39 wild plant species. Most of the wild plant species are first recorded as hosts for the whiteflies *i.e.* 9 new host species for (*Bemesia tabaci*).6 Species for (*Trialeuroodes vaporariorum*) and 5 Species for (*Parabemisia myricae*). The seasonal abundance of five most prevalent whitefly species on both wild and economic host plants is discussed.

[0495] DIVERSITY OF DIURNAL INSECTS SPECIES IN PLANTS OF AN AGROFORESTRY SYSTEM IN ACRE

M. Fazolin¹ & J.L.V. Estrela², ¹Embrapa Acre, Caixa Postal, 392-CEP 69901-180, Rio Branco Acre, Brazil; E-mail murilo@cpafac.embrapa.br.; ² Dept. of Entomology, Universidade Federal de Viçosa Caixa Postal, 392-CEP 69901-180, Viçosa Minas Gerais, Brazil.

The agroforestry systems established in the Acre region are composed mainly of perennial plants such as peach palm (Bactris gasipaes), cupuaçu (Theobroma grandiflorum), coffee (Coffea arabica cv. Catuai), acai (Euterpe oleracea) and Brazil-nut (Bertholletia excelsa). In the first years of establishment of these systems, annual crops such as beans, rice and corn are intercropped between the lines of the perennial crops. This procedure increases the diversity of plant species in this agroescosystem, makes it possible to expect that an integration of some stable properties of natural communities takes place, particularly an increased diversity of insect species, resulting in a decrease of the level of infestation of pests. The experiment was conducted from January,1995 to December, 1998 in an area of 0.5 ha, consisting of 70 plants of peach palm, 53 of cupuacu, 36 of coffee, 20 of acai and 10 of Brazil-nut, all in the spacing of 6 x 6 m. The evaluations were done at weekly intervals using an entomological net to capture all insects present in a sample of 30% of the plants. In this agroecosistem, starting in 1995, growing values of the index of diversity of the insect species were observed, probably due to the increase in the leaf biomass of the perennial plant species, culminating in 1997 with the maximum value in the period (80.0). In 1998, there was a decrease in this value (55.1). Analyzing the average of all years jointly an index of 90.1 was obtained, value considered high and expected for diversified agroecossistems. The individual indexes obtained for each plant species were: Brazil-nut, 17.9; coffee, 25.7; acai, 37.6; cupuacu, 40.1 and peach palm, 41.0. Besides these diversity indexes, it was also verified that high populations of important pests of annual crops such as Cerotoma tingomarianus and Mormidea maculata were still present in the environment surrounding the plants of peach palm and acai, even two years the bean and rice crops were harvested. It can be concluded that these plants species, although important components for the diversification of the agroecosystem, are shelters or refuges for these pests. Therefore this fact should be taken in consideration when establishing new areas that have these plant species as initial components, especially because larger populations and larger levels of damages caused by the same pests were verified during this period. The study of the mechanism of association of these insects with these palm species may lead to the identification of the causes that make them possible give it origin, once it was not verified that these insects feed of these shelter plant species.

Index terms: Cerotoma tingomarianus, Mormidea maculata, insects diversity, plants diversity.

[0496] STRUCTURE AND DIVERSITY OF STREAM INSECT ASSEMBLAGES APPLIED TO ASSESSMENT: THE LULES RIVER (TUCUMAN, ARGENTINA)

H. R. Fernandez¹, V. F. Romero², E. Domínguez¹, S. A. Cohen¹ & <u>V. Manzo¹</u>, ¹Fac. Cs. Nat. Univ. Nac. Tucumán, Miguel Lillo 205, 4,000, Tucumán, Argentina. E-mail: Mayfly@unt.edu.ar; ²Fund. Miguel Lillo, Miguel Lillo 251, 4,000 Tucumán, Argentina.

The use of stream Insect Assemblages for water quality and anthropogenic impact assessment is becoming more and more important. Based on the previous knowledge of insect assessment as bioindicators established for the rivers of Tucumán Province, we started a study on a mountain river that is going to be dammed. These data obtained before the dam construction will be very valuable for the evaluation of the dam impact. Lules river and its affluents drain approximately 4,200 Km², with an annual flow of 6.07 m³/s. The studied segment of the river runs through rain mountain forest (Yungas province). The sampling was carried out in 4 stations, located from 490 to 880 m, using Suber sampler, with 3 replications in each station. The results of this study, obtained in the Lules drainage, showed that the water quality, using as biotic index a score-system and confirmed by physic-chemical analysis was good in all stations and seasons. Forty-five insect taxa were collected, but for the multivariate analysis only 27 were used (scarce and infrequent taxa were not included). Using the Canonical Correspondence Analysis (λ_1 =0.52; λ_2 =0.35), all the stations grouped together except the summer and fall samples of the first station (880 m). The taxa responsible for the separation of this station were Parargyractis sp. (Pyralidae) in summer and Thinobius sp. (Staphylinidae) in Fall. The results of this study show that the summer spates have a stronger impact on station 1, which persist through most of the fall season. For the damage on the riversides, the relation spate/normal flow is also bigger in station 1. These results are also important at the moment of water quality assessment through biotic index.

[0498] COMPOSITION AND RELATIVE ABUNDANCE OF DIPTERAN FAMILIES (EXCLUDING NEMATOCERA AND ACALYPTRATAE) COLLECTED BY MALAISE TRAPS, WITHIN AND OUTSIDE FOREST FRAGMENTS IN TWO DIFFERENT AREAS

J. C. R. Fontenelle¹, F. S. de Castro¹, E. L. Paschoalini¹, J. C. Almeida¹ & R. P. Martins¹, ¹Laboratório de Ecologia e Comportamento de Insetos. Dept. de Biologia Geral. Univ. Federal de Minas Gerais, Cx Postal 486 CEP: 31140-390 Belo Horizonte, M.G. Brasil. E-mail: juliocrf@mono.icb.ufmg.br.

The importance of study of forest fragmentation is growing, owing to the increase in the process itself, principally in urbanized regions. Flies occupy a large variety of niches, both created and modified by human activity. Two areas with fragments of forest, within the metropolitan region of Belo Horizonte, Minas Gerais, Brasil (one, the Ecological Station of the Universidade Federal de Minas Gerais, and the other an area preserved by the Zoobotanical Foundation of Belo Horizonte) were used for the present study. A total of 8 Malaise traps were placed, 2 within the forest fragment and 2 outside, in each of these areas. 8210 Diptera from 17 families were collected in two non-consecutive weeks of sampling, and the total number of flies was significantly greater in the second week of collection, 6078 versus 2132. There was also a greater number of flics collected in traps just outside of the forest versus within, 2164 and 1352, respectively, in the UFMG Ecological Station, and 2749 and 1945 in the preserve. The family with the greatest number of individuals collected was Phoridae, comprising roughly 28% of the total, with Stratiomyidae, Syrphidae, Tachinidae, and Sarcophagidae together making roughly 48%, and Dolichopodidae, Muscidae, Pipunculidae, and Calliphoridae accounting for another 21%. Several families were found in significantly greater numbers outside the fragments than inside, such as Syrphidae, Tachinidae, Sarcophagidae, Dolichopodidae. Phoridae, Stratiomyidae, and Conopidae, but no families were significantly more abundant within the fragments. Analysing the distributions of abundances in the different habitats, we note that within the fragments there was a tendency suggestive of a greater dominance of specific families in this habitat-

Index terms: Fly, Brachycera, Cyclorrhapha, Forest fragment, Community

[0497] GEOGRAPHIC RANGES AND PATTERNS OF DIVERSITY FOR PSEUDACTEON FLIES, PARASITOIDS OF SOLENOPSIS ANTS, FROM ARGENTINA AND BRAZIL

P. J. Folgarnit¹, O. A. Bruzzone¹, S. D. Porter², M. A. Pesquero & L. E. Gilbert³, ¹Centro de Estudios e Investigaciones, Universidad Nacional de Quilmes, Roque Saenz Peña 180, 1876 Bernal, Bs As, Argentina, E-mail: pfolgarait@unq.edu.ar; ²USDA-ARS, CMAVE, Gainsville, FL 32604, USA; ³Department of Zoology, University of Texas, Austin, TX 78712, USA.

More than 40 species have been described within the cosmopolitan genus Pseudacteon, which specializes in attacking Solenopsis ants and is being considered to be used as a biological control tool in USA. Information on Pseudacteon records and distribution is currently dispersed and hardly published. However, this type of data is very important as a source of information on phorids localities for future captures and to infer phorids climatic tolerances to rear and release them at proper places in the States. Using bibliographic information, data from brazilian nuseums, and collections made by the authors, we compiled a data base on Pseudacteon throughout the distribution range of the two exotic fire ant pests, Solenopsis invicta (red) and Solenopsis richteri (black). The whole area included the region between 10-40°S and 35-65"W encompassing Argentina and Brazil. We used the grid method to estimate richness per cell and per phytogeographical regions and calculated equiprobabilistic curves following Rapoport (1982). We also estimated geographical ranges and climatic correlates for each species and classify them as broadly or narrowly distributed species. Equiprobabilistic curves were calculated for each cell using as central points of observations four cells that span a latitudinal gradient. These cells were: Goiania-Brasilia (GB), Belo Horizonte-Sao Paulo (BHSP), Corrientes (CO), and Capital-Buenos Aires (CBA); the first two in Brazil and the latter two in Argentina. There was no clear latitudinal pattern in species richness but phytogeographical regions in Brazil had greater diversity. However, the pattern of species that were lost from the centers of observations towards other cells changed consistently if the center was calculated at lower latitudes or at higher ones. This means that most of the species found at CO and CBA represented assemblages of species found in GB and BHSP, and represented species with broad geographic ranges and climatic tolerances. These data suggest that the introduction of broadly distributed Pseudacteon species will be more successful because these species have been able to spread across different climatic and phytogeographical regions and may have greater physiological tolerances to abiotic variables. In fact, broadly distributed Pseudacteon flies represent species that currently find red and black fire ants throughout their geographic range of distribution. Index terms: biogeography, biological control, fire ants, Phorids, richness

[0499] COMPOSITION AND RELATIVE ABUNDANCE OF HYMENOPTERA FAMILIES IN TWO URBAN AREAS OF BELO HORIZONTE, MINAS GERAIS, BRAZIL

J. C. R. Fontenelle¹, **D. A.Yanega ²& L. R. S. Zanetle ³**, ^{1,3} Lab. of Insect Behaviour and Ecology, Biological Science Inst., Fed. Univ. of Minas Gerais, P. O. Box: 486, Belo Horizonte, Minas Gerais, Brazil, E-mail: ¹Julioerf@mono.icb.ufmg.br; ² Dep. Entomology, Univ. of California, Riverside, CA 92521, USA, E-mail: dyanega@pop.uer.edu.

Two areas in the UFMG's Campus, with forest fragments, (Prefeitura = 20 ha / 6 of forest and Estação = 68 ha / 16 of forest), within the metropolitan area of Belo Horizonte, Minas Gerais, Brazil, were sampled with Malaise traps during two different seasons (between May 1996 and May 1997). A total of 6 traps (3 per area) were set, only during the day (9 a.m. to 4 p.m.), in the forest fragment's borders. 4556 Hymenoptera from 45 families were collected. In both areas, a greatest number of individuals was collected during the wet season. In the "Prefeitura" area, during the dry season, 521 insects from 29 families (H'= 2,68) were collected, in the wet season 1488 insects from 42 families (H'= 2,68) were collected, in the wet season 1488 insects from 42 families (H'= 2,68) were collected in the wet season 1488 insects from 42 families (H'= 2,69) were collected in the wet season 1488 insects from 42 families (H'= 2,69) were collected during the dry season, 521 insects from 29 families (H'= 2,68) were collected, in the wet season 1488 insects from 42 families (H'= 2,69) were collected during the dry season and 1840 insects from 41 families (H'=2,91) in the wet season. The most abundant families (in decreasing order) were: Ichneumonidae, Formicidae, Scelionidae, Braconidae, Eulophidae and Chalcididae, together they represent almost 60% of all the collected individuals. In the two areas, in both seasons, Ichneumonidae. Formicidae, Scelionidae and Braconidae were among the most abundant families. Index terms: Malaise traps, community ecology, Hymenoptera parasitica

(0500) LANDSCAPE DIVERSITY AND THE DISTRIBUTION OF THE [0. BUTTERFLIES OF THE GENUS ACTINOTE (LEPIDOPTERA: NYMPHALIDAE) THE IN SERVICE ACTINITY AND THE DISTRIBUTION OF THE [0.]

<u>R.B.Francini</u>, Museu de História Natural, FAFIS, Univ. Católica de Santos, Rua Euclides da Cunha, 247, 11065-902, Santos, SP, Brasil, E-Mail francini@unisantos.com.br. Financial support: BIOTA-SP (FAPESP)

A study was undertaken of 21 species of butterflies of the genus Actinote (Lepidoptera: Nymphalidae) (Actinote alalia, A. brylla, A. canutia, A. carycina, A. conspicua, A. discrepans, A. genitrix, A. melanisans, A. mamita mitama, A. morio, A. parapheles, A. pellenea pellenea, A. quadra, A. rhodope, A. surima surima, A. thalia pyrrha, A. zikani, A. bonita, A. dalmeidai, Actinote ca, terpsinoe, Actinote sp.4), and 47 species of larval food plants in Asteraceae genera: Mikania, Eupatorium, Trichogonia, Symphyopappus, Erigeron, Senecio and Vernonia, in the region between 21°40'-24°00'S and 44°30'-47°00'W, about 65.000 km². Four species A. carycina, A. thalia pyrrha, A. parapheles, and A. melanisans had an wide distribution in the whole area, while five: A. quadra, Actinote ca. terpsinoe, A. morio, and Actinote sp. 4 occupied a very restricted area The Activitie ca. terpsinoe, A. morio, and Activities 5, 4.0ccupied a very contacted and the geographical distribution of each species of Activities was related with various environmental characteristics (geological terrain, altitude, relief, soils, mean yearly rainfall, hydric excess, vegetation types and anthropic influence). The richest areas were located between 500-1500 m. A PCA on the whole coincidence matrix showed that the variation in anthropic impacts accounted for 76% of the species distribution. In spite of this, the PCA on separate matrices showed that this distribution was 86% explained by influence of remnant environments of dense forests among vegetation types. The association between the species of Actinote of the area (coefficient of Jaccard) showed that 28 pairs are mutually exclusive. The species with largest association indices were A. carycina, A. thalia pyrrha, A. melanisans, and A. surima. The distribution of the 21 species of Actinote by squares of 5' showed that the richest areas were along a central diagonal, oriented SW-NE, in the highest points of the Serra da Mantiqueira. A. brylla is present on the coastal plain and lower Serra do Mar slopes, and Actinote ca. terpsinoe only in the NW of the study area. Grouping the data by squares of 30' showed that the richest area (17 spp.) is situated in the NE, corresponding to the Itatiaia mountains followed by Serra do Mar, near Paranapiacaba (Santo André, SP), with 14 species. The correlation between Actinote species richness and the environmental factors by squares of 30' showed a strongly association with rain forests and rainfall between 2000-4000 mm. Index terms: environmental analysis, Serra do Mar, Serra da Mantiqueira

[0501] MANAGING THE DIVERSITY OF CARABIDAE IN AGRICULTURAL LANDSCAPES

<u>B. W. French¹ & N. C. Elliott²</u>, ¹USDA, ARS, NGIRL 2923 Medary Ave., Brookings, SD 57006, E-mail wfrench@ngirl.ars.usda.gov; ²USDA, ARS, PSWCRL 1301 N. Western Road, Stillwater, OK 74075.

The family Carabidae is a highly diverse group of Coleoptera with approximately 40,000 species worldwide. These beetles occupy a variety of habitats including grasslands, forests, riparian zones, and agricultural fields. Their ecological role as polyphagous predators in these habitats makes them important participants in community dynamics. What once was a vast area of grasslands, the North American Great Plains is now a mosaic of highly fragmented landscapes. Dominating the landscapes are agricultural fields intermingled with grass pastures and riparian zones. We used pitfall traps to collect carabid beetles in several winter wheat fields adjacent to grasslands and riparian zones in north central Oklahoma. We placed traps in the edges and interiors of the wheat fields and adjacent natural habitats. We classified edges and interiors as distinct habitats, and focus this analysis on differences in species richness (S), Shannon diversity indices (H), and Shannon evenness indices (J) among the habitats throughout the winter wheat growing season (autumn through spring). Species richness measures the number of species present. Species richness was higher in the natural habitats than in the wheat habitats during autumn. During winter S was least in the wheat interiors adjacent to riparian zones, and showed no differences among the grassland-wheat habitats. Compared to autumn and winter, we captured more species during spring, and significant proportions were captured within the habitat edges. Species diversity accounts for both S and relative abundance. Species diversity was higher in the natural habitats than in the wheat habitats during autumn. During winter H showed no differences among the riparian-wheat habitats or the grassland-wheat habitats. During winter H was least in the wheat interiors adjacent to riparian zones and grasslands. Species evenness indicates the variation in relative abundances among species with values ranging from 0 to 1. Low values indicate that a few species dominate in total abundance in that particular location. During autumn and winter J showed no differences among the riparian-wheat habitats or during autumn for the grassland-wheat habitats. However, J was significantly less in the wheat interiors adjacent to grasslands during winter and in the wheat interiors adjacent to riparian zones during spring. We discuss the differences in S, H, and J among habitats in terms of managing agricultural landscapes to enhance carabid diversity and abundance.

Index terms: ground beetles, insect communities, predators, agroecosystems, biological control.

[0502] SYSTEMATICS AND BIOGEOGRAPHY OF THE CYCLOTELINE THEREVINAE (DIPTERA: THEREVIDAE)

S. D. Gaimari^{1, 2} & M. E. Irwin¹, ¹134 EASB, 1101 W Peabody Dr., Univ. Illinois, Urbana, IL 61801, USA; ² current address: Dept. Entomology, National Museum of Natural History, Smithsonian Inst., Washington, DC 20560-0169, USA.

The cyclotelines represent a Laurasian group of Therevinae (Diptera: Therevidae), members of which are compared using 65 adult morphological characters. Cladistic analysis using parsimony reveals several convincing synapomorphic characteristics in support of the monophyly of this group, which is currently an assemblage of 10 genera spanning the Americas and into Middle, Far East, and Southeast Asia. Methods of cladistic biogeography were used to compare patterns of cycloteline cladogenesis and vicariant events in geological history. Using the taxon-area cladogram, a resolved area cladogram was derived using component analysis. In assessing the probable ancestral area inhabited by early cyclotelines, several additional quantitative methods were employed. All of the latter analyses suggest Asia as their ancestral area, with subsequent movement into the New World. Two major vicariant events account for their current distribution. The first relates to the Beringian land bridge connecting western North America and eastern Asia in the Cretaceous. Second, New World cyclotelines were affected by the Early Eocene breakup of the bridge between North and South America, and their distributions support hypotheses favoring continental origins of the Greater Antilles. By the Late Cretaceous, 65-90 million years before present (Myr), high sea levels resulted in extensive epicontinental seas. Potentially important to cycloteline cladogenesis was the Mid-Continental Sea separating Euramerica (i.e., eastern North America + western Europe) from Westamerica which formed a single continent with eastern Asia via the Beringian land bridge. In the late Cretaceous and early Paleogene, these northern latitudes were characterized by subtropical climates. From the middle to late Paleogene (Eocene into Oligocene), the northern latitudes encountered a steady increase in humidity and precipitation, and a drop in temperatures, all of which could have acted as vicariant barriers separating the North American and Asian cycloteline fauna. Further south, North and South America were connected through the Cretaceous-Paleogene boundary. This proto-Antillean link was on the eastern edge of the Caribbean plate which migrated eastward in the early Eocene, to eventually become the present-day Greater Antilles. A second land mass followed on the western edge of the plate, becoming attached to southern North America. This Central American isthmus only reattached North and South America as recently as the Pliocene, less than 5 Myr. Index terms: Asiloidea, Cretaceous, Laurasia, Beringia, Proto-Antilles.

[0503] A RELATIONAL DATABASE MODEL TO INTEGRATE DISTRIBUTION DATA IN GEOGRAPHICAL INFORMATION SYSTEMS (G.I.S.)

A. Gayoso¹ & <u>]. Garrido²</u>, ¹Dept. of Animal Biology, Univ. of Santiago de Compostela. E-15701, Spain., E-mail bagayoso@usc.es; ²Dept. of Ecology and Animal Biology, Univ. of Vigo. E-36200, Spain, E-mail jgarrido@uvigo.es.

Relational databases are normally used to manage the distribution data of biological populations. They help us to make simple inventories of specific areas, but also to make complex ecological analyses, such as resource selection functions, to characterize the distribution of organisms. Their field of application in Ecology and Faunistics can be made wider if it in used in combination with Geographical Information Systems (GLS.) to generate quality distribution maps or to carry out detailed spatial analyses which aimed to identify any hidden patterns and to identify the environmental variables affecting of the organisms' distribution. In this work, we propose a design for relational databases oriented to record the results of field studies on freshwater arthropods (mainly Coleoptera) that makes possible integrate these results in a GLS. This integration enables the user to make quick and powerful spatial searches and analyses of the information contained in the database.

Index terms: database, G.I.S., Faunistics, distribution

[0504] ACOUSTIC METHODS IN BIODIVERSITY INVESTIGATIONS OF CICADAS IN TROPICAL RAIN FORESTS

<u>M. Gogala</u>, Prirodoslovni muzej Slovenije, (Slovenian Museum of Natural History) Presernova 20, SI-1001 Ljubljana, Slovenia, E-mail: matija.gogala@uni-ij.si.

One of the difficulties in the investigation of insect biodiversity in the tropical rain forests is the limited possibility for location and collection of animals, the high number of morphologically similar species, and in many cases a high number of undescribed taxa. In such insect groups as Cicadoidea that emit loud and species specific sound signals, the use of acoustic methods can be of great help. During our field work in Malaysia we had the chance of comparing our acoustic sound patterns ("acoustic species") with the results of other colleagues working in the same localities or even at the same time with classical collection methods. In many cases we were able to point out the possible existence of different species by differences in song patterns and in some cases we also confirmed the identity or the presence of certain species in the investigated region which could not be proven by other means. On the other hand, we were not able to detect in certain localities the same or a higher number of distinct species than our colleagues who used light trapping. This can be explained by different daily time windows or seasons in which single species are acoustically active, in unrecognized differential sound characteristics, or in unsuitable equipment for a detection and recording of sounds with unusual frequency ranges or propagation substrates (e.g. ultrasonic sounds and vibrational signals). Index terms: Homoptera, Cicadoidea, song, sound

[0506] COMPARISON OF CARYOCAR BRASILIENSE CATERPILLAR FAUNA IN TWO CERRADO AREAS OF THE DISTRITO FEDERAL, BRAZIL

E. G. S. Gondim'; <u>H. C. Morais</u>¹ & I. R. Diniz², 1. Department of Ecology; 2. Department of Zoology, University of Brasília, 770910 900 Brasília, DF, Brazil, morais@unb.br

Caryocar brasiliense (Caryocaceae) is a typical cerrado tree, having economic importance due to its fruits and wood. The objective of this study was to compare the caterpillar faunas, which utilize this tree as a host, in two cerrado areas of the Distrito Federal, Brazil. One of the areas belongs to EMBRAPA-Cerrado Research Center (CPAC) (15° 35' S 47° 42' W), and the other area, "Fazenda Água Limpa" (FAL), belongs to the University of Brasília. The two study areas are about 60 km apart. Collection were made between October, 1997 and December, 1998 at CPAC, and from May to December, 1999 at the FAL. Fifteen C. brasiliense individuals were visited weekly at each study area and all caterpillars were collected. Caterpillars were numbered as morphospecies and raised in the laboratory, in order to obtain adults, which were then identified and deposited into the Entomological Collection of the Department of Zoology of the University of Brasília. Twenty-nine species from 14 families of Lepidoptera (previous collections and this study) were recorded. A total of 810 visits were made at CPAC, and in 9.6% of these, caterpillars were found, totaling 147 specimens from 20 morphospecies. The most abundant were Rhodoneura intermedia (Thyrididae) and Inga sp. (Occophoridae). At the FAL, 395 visits were made, with 9.9% of the trees presenting caterpillars, registering 106 specimens from 15 morphospecies, with Phidotricha sp. (Pyralidade) and one Noctuiidae species being the most abundant. At both areas, most of the caterpillars were found in May and June, on old leaves, where at least 75% of them built some kind of shelter. Significant differences were not found for the frequency of plants with larvae ($\chi^2 = 0.018$ df = 1 p>0.05), and the caterpillar faunas of the two areas were highly similar (Sorensen index = 0.514). In spite of the difference between the most abundant species, the overall features of the caterpillars are extremely similar in relation to diet (old leaves), defense mechanisms (crypt coloration and shelters) and months of greater abundance. The low frequency of plants presenting caterpillars throughout the year, and a peak of abundance occuring at the beginning of the dry season (May-June) corroborate previous surveys made for other host plants of the cerrado in the Distrito Federal. Despite the paucity of caterpillars, C. brasiliense presents a rich fauna of Lepidoptera larvae, showing similar features in both areas here studied. Index terms: Inga, Phidotricha, Rhodoneura, Noctuidae, Lepidoptera.

[0505] BIODIVERSITY OF GALLING INSECTS: HISTORICAL, COMMUNITY AND HABITAT EFFECTS IN THE NEOTROPICAL SAVANNAS

S. J. Goncalves-Alvim & G. W. Fernandes, Lab. Ecologia Evolutiva de Herbívoros Tropicais, Univ. Federal de Minas Gerais/ICB, CP 486, 30161-970, Belo Horizonte, MG, Brazil, E-mail: silmary@icb.ufmg.br.

Five hypotheses were tested to explain the pattern of galling insect species richness in four neotropical savanna physiognomies, "canga", "campo sujo", "cerrado", and "cerradāo", that occur in Minas Gerais, southeastern Brazil. i) *The plant species richness hypothesis*: predicts that galling insect richness is positively correlated with plant species richness. The increase of plant species richness explained 35% of the variation in galling insect richness (r² = 0.35, p < 0.05). Galling insect richness also showed a positive relationship with species of herbs and trees (p < 0.05), corroborating the plant species richness hypothesis. ii) The plant structural complexity hypothesis: predicts a positive relationship between galling insect richness and structural complexity of plants. Most of the galling insect species occurred on trees, followed by shrubs and herbs. However, the difference in mean number of galls was only significant between herbs and trees (p < 0.05). Therefore, these results corroborate only partially the plant structural complexity hypothesis. iii) The resource concentration hypothesis: predicts a positive relationship between galling insect richness and density of plants. A significant relationship was observed between the number of galling insects and density of herbs ($r^2 = 0.38$, p < 0.05), and shrubs ($r^2 = 0.39$, p < 0.05), but not on trees, therefore corroborating partially the resource concentration hypothesis. iv) The harsh environment hypothesis: predicts that galling insect richness is positively correlated with nutrient stress in the soil. The number of galling insect species showed a negative correlation with content of magnesium, potassium and zinc, corroborating the harsh environment hypothesis. There was also an increase galling insect richness with increasing iron content. In addition, galling insect richness showed a negative relationship with the organic matter content, and total capacity of cation change [CTC(T)]. The content of magnesium, potassium, iron and CTC (T) explained 72% of the variation in galling insect richness in the four vegetation types. v) The plant family size hypothesis: predicts a positive relationship between galling insect richness and host plant family size. Galling insect richness was positively influenced by plant family size ($r^2 = 0.42$, p < 0.05), corroborating the plant family size hypothesis. Overall, the results corroborate the hypothesis that predicts that habitat nutritional stress might be the main factor generating the patterns of galling insect richness in Brazilian savannas. Other variables, such as the composition, density and species richness of plants (local factors), and family size of host plants (historical factor) also influenced the richness of galling insects in the studied neotropical savanna physiognomies.

Index terms: environmental stress; galling insect richness; insect-plant interactions

[0507] FUNCTIONAL BIODIVERSITY AMONGST DIFFERENT MICROSITES IN A PATAGONIAN STEPPE, SOUTHERN ARGENTINA

<u>Guerrieri F.I.</u>¹, Folgarait P.J.² & Sala O.E.³, UIIB-CEI Universidad Nacional de Quilmes, R. Sáenz Peña 180, 1876 Bernal, Buenos Aires, Argentina. E-mail: ¹mordi@bg.fcen.uba.ar; ²pfolgarait@unq.edu.ar; ³sala@ifeva.edu.ar;

Soil organisms are important for maintaining soil structure and function. Despite there being little information on soil biodiversity, soil-related processes seem to differ according to the soil fauna assemblage. Nothing is known about the composition of the soil fauna of the Western District Patagonian steppe (Southern Argentina; 45°41'S, 70°16'W). Nevertheless, the region's flora and its climate have been properly described. The vegetation comprises bushes and grasses, grouped in patches within a bare soil matrix which covers the 52% of the surface. This distribution defines 5 microsites differing in their contents of water and organic matter: amongst bushes, the main are Adesmia campestris and Mulinum spinosum, grasses can be found either as a ring around M. spinosum or as scattered tussocks, and, finally, bare soil. We analysed the nematodes and the mesofauna distribution and diversity amongst the mentioned microsites. 10 soil samples were taken from each microsite. Nematodes were extracted using Baermann's funnels and their abundance was quantified. Litter and soil mesofauna organisms were extracted using Berlese's funnels. Abundance and richness were compared across microsites and amongst zoological groups with non-parametric tests (Kruskall-Wallis test, Mann-Whitney test and \square^2 -test). The greatest nematodes abundance was observed at bushes. Litter mesofauna richness and abundance were greatest at M. spinosum (p<0.032) and A. campestris (p<0.005), respectively. Mites were the richest and the most abundant zoological group in the litter. Soil mesofauna richness was greatest at A. cumpestris (p<0.05) whereas the greatest abundance was found at tussocks (p<0.03). Amongst zoological groups, mites and dipterans were the richest and mites were also the most abundant. Using bibliographic information on diets, we assigned the organisms found to trophic groups. According to their relative abundance within each microsite, we inferred different interactions among trophic groups. We observed that soil foodwebs were more complex than litter ones. Soil foodwebs involve phytophagous organisms and organic matter was supplied both by living roots and decomposing litter; except at bare soil, where no litter was found. Amongst microsites, most complex foodwebs were found at bushes and the least complex occurred at the bare soil. These results show that different vegetation modules corresponded to different soil invertebrates assemblages. Index terms: soil fauna, diversity, Patagonia, nematodes, mesofauna, foodweb

[0508] EXPLORATION AND DIVERSITY OF INDIAN MITE FAUNA(ACARI) AND INDICATIONS OF UNEXPLORED AREAS FOR FUTURE STUDY

S.K. Gupta, 1C/10, Anandam Housing Complex, 7 K.B. Sarani, Calcutta- 700080, India.

Commensurating with the rich biodiversity of India due to I to luxuriant vegetation , varied climatic conditions and diverse ecological niches, the mite fauna of India is also varied and rich as appears from the fact that while little over 40% of the Indian geographical areas have been properly surveyed, the mite fauna known so far indicates adequate richness as uptil now 2350 species represented by 725 genera, 190 families and 4 orders are recorded from India, of which, over 70% shows endemism. The number of species / general families known under each order is :- Astigmata- 155 /75/35, Mesostigmata 475/ 125 /35, Prostigmata 1275 /340 /60 / and Cryptostigmata 435/190/60. This paper provides all these details and documents number of species known from different environs like :water vertebrate and invertebrate associates plant , nests,stored preducts, dusts, mushroom, aquatic weeds , lichens and soil dwelling prosignatid mesostigmatid and cryptostigmatid mites. Besides, a brief discussion is made regarding unexplored areas in India needing surveys, emphasizes the taxa needing intensive/revisionary studies, focuses the economically important groups needing priorities and indicates the groups where more work or very little has been done. All these will provide guidelines to the future workers in formulating research stratagies on Indian mites.

Index terms : Indian mite diversity, mite environs, Indian mite review, future strategies,

[0509] ENTOMOLOGICAL SOCIETIES IN LATIN AMERICA

<u>G. J. Hallman¹</u> & A. R. Panizzi², ¹United States Dept. Agriculture, Agric. Research Service, 2301 S. International Blvd., Weslaco, TX 78596. E-mail ghallman@weslaco.ars.usda.gov. ²Centro Nacional de Pesquisa de Soja, EMBRAPA, Caixa Postai 231, Londrina, PR 86001-970, Brasil, E-mail panizzi@enpso.embrapa.br.

The theme of the XXI International Congress of Entomology is "entomologists preserving biodiversity". The theme of this symposium concerns the role of entomological societies in Latin American in preserving biodiversity. Latin American entomological societies are ideally situated to the task of preserving biodiversity. Three of the four so-called "megabiodiversity" countries are in the region: Brazil, Colombia, and Peru. The Amazon basin and adjacent regions contain levels of biodiversity that can only be imagined. This poster unites information from existing entomological societies in the region, especially those that are not represented in other posters or talks of this symposium. Unfortunately, several societies can be considered in a state of prolonged "diapause", in that they have been inactive for years. It is a challenge for the entomologists of those countries to revive these sleeping societies and put them to work solving the entomological problems of the region, including the preservation of biodiversity.

[0510] BLACK FLIES (DIPTERA: SIMULIDAE) FROM THE GRAND SAVANNA REGION OF VENEZUELA

N. Hamada⁴ & M. E. Grillet², ¹Inst. Nacional de Pesquisas da Amazônia-INPA/CPEN; Caixa Postal 478; 69011-970 Manaus, AM, Brazil; E-mail ahamada@inpa.gov.br. ²Inst. de Zoología Tropical (IZT), Univ. Central de Venezuela (UCV); Ap. 47058, Caracas 1041-A,Venezuela.

Little work has been done on black flies from the Grand Savanna region (Bolivar state) of Venezuela. This region includes Canaima National Park, which is known for its endemic species. Seventeen species of Simuliidae have been previously reported for the Grand Savanna region. The present study provides distribution data on black fly species collected during our sampling period in the Grand Savanna region, Venezuela, providing information needed for ecological studies of aquatic insect communities in the region. The study was done in streams accessible by roads in Canaima National Park, Grand Savanna region, Venezuela. Since the Pacaraima mountain region (Roraima, Brazil) has a long border with this area we decided to include the black fly species collected there, since both regions can share species. The samples were collected in October 1996, February and October 1998. Voucher specimens of all species examined are deposited in the Invertebrate Collectiion of UCV, Caracas, Venezuela and at the Invertebrate Collection of INPA, Manaus, AM, Brazil. Twenty-one species of Simulium were collected in the study area. In Canaima National Park the following species were collected: S. iracouboense, S. spinibranchium, S. subpallidum, S. metallicum species complex, S. guianense, S. inaequale, S. incrustatum, S. quadrifidum, S. cauchense, S. goeldii, S. kabanayense, S. suarezi, S. maroniense, S. perflavum, S. ignacioi and S. lutzianum. In the Pacaraima mountains the following species were collected S covagarciai, S. metallicum species complex, S. lutzianum, S. rorotaense, S. maroniense, S. trombetense, S. perflavum, S. bipunctatum, S. rubrithorax and S. cauchense. This is the first record of S. covagarciai in Brazil, this species had previously only been reported from the Parima mountains, Venezuela, its type locality. This is also the first record of the S. metallicum species complex in Brazil and southern Venezuela; this species complex has been reported only in the northern portion of the Orinoco Basin. The S. mletallicum species complex has at least 12 cytotypes distributed in Central America and northern South America, in Venezuela, only cytotype E is associated with the onchocerciasis transmission. Cytological studies will be necessary to define the cytotype present in the study area, and collection of females in this area will be necessary to determine if they are anthropophilic, Index terms: aquatic insects, Simulium, species distribution, species richness

[0511] BLACK FLIES (DIPTERA: SIMULIIDAE) OF FRENCH GUIANA: A PRELIMINARY LIST OVER 50 YEARS AFTER FLOCH AND ABONNENC

N. Hamada¹ & F. Fouque², ¹Inst. Nacional de Pesquisas da Amazônia-INPA/CPEN; Caixa Postal 478; 69011-970 Manaus, AM, Brazil, E-mail nhamada@inpa.gov.br; ²Institute Pasteur, Cayenne, French Guiana, ffouque@pasteur.cayenne.fr.

The last black fly paper published from French Guiana was by Floch & Abonnenc in the 1940s. Until that time, six species were reported for this region: Simulium cauchense. Simulium rorotaense, Simulium maroniense, Simulium, iracoubocnse, Simulium oyapockense and Simulium guianense. The objective of the present study was to widen the black fly list for this region and to determine the geographical distribution of the species. The samples were collected in June 1999 around Cayenne, Saül, Vovony community (L'Approuage River), Maroni River (on the border with Suriname) and along the highway that connects Cayenne to Iracoubo. With only 16 samples, we double the number of species known in French Guiana; we add to the list presented above the following species: Simulium quadrifidum!1033, Simulium goeldit, Simulium trombetense, Simulium near incrustatum, Simulium metallicum species complex 1 and S. metallicum species complex 2. In the two large rivers sampled (Maroni and L'Approuage) the most abundant species was S. iracouboense; S. guianense also was collected in these places, but in lower abundance. Although S. guianense is involved with transmission of onchocerciasis in Brazil and Venezuela, in French Guiana this species appears not to be anthropophilic, since the indigenous people that live along these water courses did not complain about their biling, as in some places in Brazil and Venezuela where they can be very annoying. *Simulium oyapockense* is involved with onchocerciasis transmission in lowland areas in Brazil, but in French Guiana this species was collected in very low abundance in the large rivers; it also appears not be anthropophilic. Simulium cytotype E is involved with onchocerciasis transmission in metallicumng1033 mountainous areas of Venezuela, near the Atlantic Ocean. The two species in the S. metallicum species complex collected in French Guiana were collected in small mountain streams also, but they appear not to be anthropophilic, since the riverine population does not complain about biting females. It is clear that once we increase sample size in French Guyana we are going to find more black fly species, since this country has many types of geographical landscape and black flies are poorly studied

Index terms: aquatic insects, Simulium, species distribution, species richness, taxonomy
[0512] SPATIAL MAPPING OF TWO PEST POPULATIONS IN NEW JERSEY SWEET CORN

<u>G. C. Hamilton</u>¹, M. Hughes², K. Holmstrom¹ & S. Walker¹, ¹Dept. of Entomology, Rutgers – The State Univ. of New Jersey, 93 Lipman Drive, New Brunswick, NJ, 08901, USA, E-mail hamilton@aesop.rutgers.edu; ²Grant F. Walton Center for Remote Sensing and Spatial Analysis, Rutgers – The State Univ. of New Jersey, 14 College Farm Road, New Brunswick, NJ, 08901, USA.

In 1999 and 2000 the Rutgers Cooperative Extension Vegetable IPM Program operated a network of approximately 80 blacklight insect survey traps in New Jersey to monitor adult populations of corn earworm (*Helicoverpa zea*) and European corn borer (*Ostrinia nubilalis*). All trap sites were mapped using a Trimble GeoExplorer II Global Positioning System unit. Data collected from these sites were used by the Grant F. Walton Center for Remote Sensing and Spatial Analysis to map the spatial distribution of each species. Average daily population data were imported into ArcView software and linked to corresponding mapped locations throughout New Jersey. Weekly, throughout the growing season, statewide spatial distributions of both pests were produced and distributed to growers via extension newsletters and websites to augment the current IPM outreach program in pest management.

Index Terms: Helicoverpa zea, Ostrinia nubilalis, GPS mapping, information delivery

Symposium and Poster Session

[0514] THE INSECTS COLLECTED BY THE COMISIÓN CIENTÍFICA DEL PACÍFICO: STUDYING BIODIVERSITY THROUGH HISTORICAL COLLECTIONS

<u>I. Izquierdo</u>¹, C. Martín¹ & C. M. Santos¹, ¹Departamento de Colecciones y Documentación. Colección de Entomología, Museo Nacional de Ciencias Naturales, c/ José Gutiérrez Abascal, 2. 28006 Madrid, Spain. E-mail izquierdo@mncn.csic.es.

The Comisión Científica del Pacífico is one of the most representatives Spanish scientific expeditions. This expedition travelled across different countries of South America between 1862 and 1866, with the aim of studying its Fauna and Flora diversity, as well as multiple ethnological and social aspects of the visited places. The zoological collections gathered by this expedition, which have been the object of several research projects, are kept in the Museo Nacional de Ciencias Naturales of Madrid since then. They constitute one of the most esteemed funds of the Museum due to their historical relevance and their high interest as an inestimable resource for biodiversity studies. This paper exposes an analysis of the results of this expedition from the entomological point of view, considering the value of this material as representative of sites and ecosystems that could be nowadays very altered by the human influence. The current situation of the insect material that has reached us is evaluated by giving data of the localities, specimens and species of each group, as well as type specimens, etc. The objective is to attract toward these collections the attention of taxonomists and specialists on Neotropical fauna whom could be interested on its study, especially on the unpublished material. Information on the access to this material through an ongoing project Servidor World Wide Web de las colecciones documentales y científicas de la Comisión Científica del Pacífico (1862-1866) is also given. The project takes advantage of the new communication, information and multimedia technologies for the diffusion of the Comisión travel and its results, using an interactive information server where catalogs of the funds (zoological, textual and iconographic) will be offered, and a virtual trip with pictures and situations of the expedition itinerary will be recreated.

Index terms: biodiversity, Neotropical Fauna, scientific expedition, entomological collections, World Wide Web server

[0513] MANAGING THE BIODIVESITY OF NORTHERN AUSTRALIA'S SEMI-ARID RANGELANDS: CHANGES IN ANT SPECIES COMPOSITION AND COMMUNITY ORGANISATION TO GRAZING GRADIENTS AND FIRE REGIMES

B. D. Hoffmann, CSIRO Wildlife & Ecology, TERC, PMB 44 Winnellie NT 0822 Australia, and N. T. Univ. Casuarina NT 0909.

Northern Australia's savannas are used primarily for cattle production. Unlike most southern Australian rangelands, the native vegetation is still relatively intact and there is a great potential to conserve biodiversity whilst managing the region for cattle production. But while much is understood about the effects of stocking rates and fire on cattle production, little is known about how these management decisions affect biodiversity. In particular, ants play pivotal roles in ecosystem function within Australia's rangelands. Here I report the changes in ant species composition and community organization to grazing gradients and fire regimes within the semi-arid ranglands of the Victoria River District (VRD) of Australia's Northern Territory. Two grazing gradients were sampled ranging from beside a point water source to 10km from water. 5 fire regimes of varying burning frequency and seasonality were managed in 1 ha plots for 5 years and sampled in the latter two years. Species richness and total abundance did not change significantly with grazing intensity, however, multivariate analysis showed that species composition changed markedly. Despite large changes in species composition, only six of the 24 most common species correlated significantly with grazing intensity. Likewise, limited ant responses were found to fire regimes of different frequency, intensity, and seasonality. The greatest factor influencing ants was weather, particularly rain just prior to sampling. No species were found only in a grazing and fire exclosure. The conservation of ant diversity within the VRD appears achievable with current cattle management pracitices.

[0515] PHYLOGENY AND BIOGEOGRAPHY OF THE GENUS PROCALUS (COLEOPTERA: CHRYSOMELIDAE)

<u>V. Jerez</u>, Departamento de Zoología, Facultad de Ciencias Naturales y Oceanográficas, Universidad de Concepción, Casilla 160-C.Concepción, CHILE, e-mail: <u>vijerez@udec.el</u>. Grant: 96.113.036-1.2

The genus Procalus is a small genus of flea beetles represented by nine species: P. mutans , P. viridis, P. lenzi, P. reduplicatus, P. malaisei, P. silvai, P. artigasi, P. ortizi and P. vilosensis. This genus is endemic to Austral South America associated to the genera of Anacardiaceae, Lithrea and Schinus. The area of distribution of Procalus and its host plants, is included in the ecoregion named Mediterranean zone or Central Chile. This area is characterized by a high percentage of endemic fauna and flora. The objectives of this article, are to test the monophyly of Procalus, to identify characters shared by two or more species within the genus and to discuss biogeographic distribution. In this work, a phylogenetic analysis of *Procalus* was done by Hennig 86 (Farris,1988) using morphological and biological characters of adults, eggs and larvae stage of all species. The cladistic analysis resulted in a parsimonious tree of 114 steps. (CI: 0.56, RI: 0.42). This allows to establish the monophylly of Procalus, supported by eight synapomorphies: (1) association with Anacardiaceae, (2) mandibles of males with a tuberculate mola, (3) sternite VIII of males with a fosete, (4) metafemoral spring simplified, (5) egg shell constituted by a simple extrachorion (6) mycropyle indistinct, (7) larvae with the anterior margin of labrum emarginate and (8) egg bursters present in mesothorax. By means of PAE (Parsimonious analysis of endemicity), it was determined that some species present large distribution ranges, comprising all the Mesomorphic zone of Chile; on the other hand, other species have more restricted distribution areas constituting endemic areas. It is hypothesized that the diversification of Procalus, could be due to speciation mechanisms generated in the last glacial period and that the current distribution of the genus could reflect in part their evolutionary history.

[0516] MÜLLERIAN MIMICRY: CAN POLYMORPHISM BE STABLE ?

<u>M. Joron, Génétique et Environnement</u>, cc065, Univ. de Montpellier 2, Place E. Bataillon, 34095 Montpellier cedex 5, France, E-mail joron@isem.univ-montp2.fr, and The Galton Laboratory, University College London, 4 Stephenson way, London NW1 2HE, U.K.

Positive frequency dependence in warningly coloured insects imposes a potentially strong selection against new/rare variants, hence theoretically precluding the existence of stable polymorphism in such insects. Most aposematic insects and their Müllerian mimics are indeed monomorphic, but there are a few exceptions. The Amazonian butterfly Heliconius numata (Nymphalidae, Heliconiinae) is polymorphic over most of its range, some populations bearing an amazing 10 different forms, each of which is an accurate mimic of a separate species in the genus Melinaea (Nymphalidae, Ithomiinae). We studied how such polymorphism could be maintained in the face of purifying selection, both empirically and theoretically. Crosses between the 8 different sympatric and parapatric forms of H. numata from a small area of eastern Peru confirmed the existence of very tight linkage between different colour-pattern genes (previously suggested from Brazilian forms), and showed that the different super-alleles formed an almost linear polymorphic series. However, crosses and progeny from wild-caught females revealed 1) that some mimetic forms are stable heterozygotes, and 2) that dominance is more complete between sympatric forms than between parapatric forms, indicating that selection for accurate mimicry is indeed acting. Tight linkage of colour genes is not expected in Müllerian mimics, and the evolution of supergenes is discussed. Field collections of H. numata and Melinaca spp. over three years suggested that the mimetic environment (the locally most common aposematic pattern) is very variable spatially, but apparently not temporally. Variability in selection pressure is therefore a likely cause of polymorphism in H. numata. Data are confronted to previous studies in H. numata and other systems. Although this study and data from the literature suggest that the selection against non-mimetic forms is indeed strong (ca. 10% in Heliconius erato in the same area of Peru), we propose that selection acts on numbers and not frequencies, and the analysis of a number-based selection model reveals that selection is rather small once a particular threshold is passed; this implies that polymorphism once evolved could be slow to remove.

Index terms: Heliconius numata, Melinaea spp., warning colour, supergene, spatiotemporal variability. [0518] AN APPROACH TO THE KNOWLEDGE OF THE BIOGEOGRAPHICAL HISTORY OF THE BEE GENUS *CALLONYCHIUM* (HYMENOPTERA: ANDRENIDAE) IN SOUTH AMERICA

L. Ruz ¹, ¹Laboratorio de Zoología, Sección Entomología, Universidad Católica de Valparaíso, Av. Brasil 2950, Valparaíso, CHILE, E- mail: lruz@ucv.cl.

Callonychium, a monophyletic group of solitary bees includes, up to now, 21 species. The range of distribution of this Neotropical genus goes from Ecuador to the Patagonia (Andean-Patagonian Domain), spreading out west to the Andes through desert areas of the northern regions and central Chile; east to the Andes into the whole Chaco (mostly Argentina) and in the Amazonian Domain (Paranense and Cerrado Provinces in Brazil. Distributional data has been obtained from collections of South and North American museums, which were recorded, mapped and analized, although information for several species is parcial and scarce. A previous cladistic analysis performed for the genus showed the relationships among the species and the diferenciation of two main clades. Relevant vicariant events such as the formation and uplift of the Andes, as well as geological factors and glaciations have apparently had an important effect on the biogeographic history of these organisms, among which some distributional patterns and endemisms have been recognized. It is interesting to notice that the greater species diversity of Callonychium is found in the xeric area of the Chaco Domain; only species of the subgenus *Paranychium* are present toward the west slope of the Andes occupying endemic areas, although several species of this subgenus also extend into the Chaco. On the other hand, the species of the sub genus Callonychium s, str. are distributed toward the east of the Andes ; only two Brazilian species have been recorded separately for the Paranense-Pampeana and Cerrado-Caatinga Provinces. Biogeographical studies on South American insects performed in the past have never considered bees in particular, except for some local studies in Brazil. Besides, most of the current biogeographical investigations on insects have been carried out in relation to Patagonian species, in cold places where most of bees are not present. This is the first attempt to study the distributional pattern of a group of Apoidea for a better understanding of its biogeographical history. Vicariant analysis, still in process, however, have not been conclusive yet, due to some polytomous relationships showed in the phylogenetic tree.

Index terms: Vicariance, distributional patterns, Neotropic, Apoidea

[0517] GEOGRAPHICAL VARIATIONS IN DELTOCEPHALINE LEAFHOPPERS (HOMOPTERA, CICADELLIDAE) IN EAST ASIA

<u>S. Kamitaui</u>, Entomological Laboratory, Faculty of Agriculture, Kyushu University, Fukuoka 812-8581, Japan, E-mail kamitani@agr.kyushu-u.ac.jp.

Geographical variations in two deltocephaline species complexes, Deltocephalus ogumae complex and Recilia heuksandoensis complex, were studied. These are very similar to each other in appearance, and both are distributed in East Asia including Southeast Asia. The host plants of both complexes are small undergrowth, Oplismenus undulatifolius and O. compositus (Poaceae), which are very common in East Asia. The semi-brachypterous wing form of deltocephaline species seems to indicate their less dispersal ability, hence susceptible to the influence of geographical isolation. The purpose of this study is to clarify the geographical variations in the deltocephaline species complexes in East Asia, especially in the Ryukyu Islands, and to analyze the evolutionary process with phylogeny. Materials were collected from the mainland of Japan, the Ryukyus, Taiwan, Java and Sulawesi. In D. ogumae complex, three morphological character states on aedeagus were observed, and two states on male subgenital plate were observed. The distributional pattern of these characters was not well consistent. In R. heuksandonensis, four states on aedeagus were observed, although this species complex was collected only from four restricted localities. Thus, these species complexes have unique geographical variations influenced by the global warming after the Wurm great ice-age. Index terms: geographical variation, Cicadellidae, East Asia

[0519] POPULATIONAL FLUCTUATION OF THE CITRUS LEAFMINER PHYLLOCNISTIS CITRELLA (LEPIDOPTERA: GRACILLARIDAE) IN THE PIEDMONT OF THE DEPARTMENT OF META

<u>G. A. León M.</u> & J. C. Campos P., Centro de Investigación La Lebertad, CORPOICA, A.A. 3129 Villavicencio, Colombia. E-mail: gleon@corpoica.org.co

From october 1996 to october 1998, it was carried out a study to determine the populational levels and the incidence times of the citrus leaf miner *Phyllocnistis citrella*, in two citric producers regions, belonging to Acacias and Restrepo municipalities, which are representatives of the Piedemonte of the Meta Department. Results shows a slightly bigger incidence of the pest in the locality of Acacias without statistical significal difference, then is concluded that a similar tendency in populational behavior at the two localities was founded. During july, august and november it was detected the biggest populational levels of the pest at the two localities. The smaller levels of population are presented during the months of january, february and march period that coincides with the time of smaller precipitation in the two areas. It was detected a direct relationship between populational levels and the percentages of natural parasitism of the pest only in Restrepo, but not in Acacias.

Index terms: Populational dynamics; citrus pest; pest-natural enemies relationship.

[0520] LEAF LITTER ANT AND TERMITE DIVERSITY IN IGUASSU AND RIO PILCOMAYO NATIONAL PARKS, ARGENTINA

<u>M. Leponce</u>¹, L. Theunis^{1,2} & Y. Roisin², ¹Royal Belgian Institute of Natural Sciences, Conservation Biology Section, rue Vautier 29, B-1000 Brussels, Belgium, E-mail Leponce@kbinirsnb.be, LTheunis@kbinirsnb.be; ²Université Libre de Bruxelles, CP 160/12, Dept. Animal Biology, 50 av. F.D. Roosevelt, B-1050 Brussels, Belgium, yroisin@ulb.ac.be.

Standardized methods of data collection are essential for large-scale comparisons of biodiversity distribution. We combined standardized protocols for collecting ground living ants and termites. Along 200m long transects, 3 samples were systematically taken every 10m: 1 leaf litter sample (1m² of leaf litter sifted and placed in a mini-Winkler extractor), I pitfall sample, and I soil sample (Agosti 1997). Additional termites and ants were collected in 20 contiguous 5 m x 2 m sections along the transects where every stump, log, or twig was investigated (wood samples) and where hand collection was performed (Eggleton et al. 1995). Our aim was to evaluate the efficacy of this inventory technique and the effect of habitat dryness on faunal organization in subtropical forests of Argentina. We collected in two contrasted habitats separated by 400 km along the 25th degree of latitude South : the semi-evergreen rainforest of Iguassu National Park and the xerophilous forest of Rio Pilcomayo National Park. Three transects separated by 2 - 10 kms were conducted at each site. Leaf litter samples yielded most of the ant species : 68 and 74 species were identified in Iguassu and Pilcomayo, respectively (23 species shared). Termites were also more abundant in Pilcomayo (16 species) than in Iguassu (8 species) (no species shared). The former site was especially richer in wood feeding species (9 vs. 2 species). The ant faunal similarity (Jaccard index) between transects and between samples within a transect suggests a greater heterogeneity of the ant fauna in Pilcomayo than in Iguassu. For termites, the faunal similarity between transects in both sites was generally I dow (average laccard index = 0.25). A good concordance was found between transects in the ranking of ant species according to their occurrences in the samples. These results indicate that the species richness patterns are markedly different between termite and ants. If the species accumulation curves (best fitted by the equilibrium model of island biogeography) show that 3 transects per habitat are unsufficient for reliably estimating the total species richness of both taxa in both sites, it appears however that one transect already gives a fair idea of the relative ranking of ant species.

Index terms: Formicidae, Isoptera, standard protocols, semi-evergreen forest, dry forest.

[0522] OCCURENCE OF LEAF-CUTTING ANTS IN DIFFERENT REGIONS OF RIO GRANDE DO SUL STATE

A. E. Locck¹, D. D. Grützmacher¹, A. H. Medeiros¹ & R. da S. Borba¹, ¹ Dept. of Fitossanidade, Univ. Federal of Pelotas, C.P. 354, Pelotas, RS CEP: 96.010-900, Brasil, E-mail alcienim@ufpel.tche.br

A survey in 282 counties among seven different regions in Rio Grande do Sul State was done to identify the occurrence of the leaf-cutting ants, to know the predominant species in each region and to verify their geographical distribution. Ants from 10,744 samples were identified, being observed 11 species: Atta sexdens piriventris Santschi, 1919; Acromyrmex laticeps (Emery, 1905); Acromyrmex crassispinus (Forel, 1909); Acromyrmex heyeri (Forel, 1899); Acromyrmex lundi (Guerin, 1838); Acromyrmex ambiguus (Emery, 1887); Acromyrmex striatus (Roger., 1863); Acromyrmex lobicornis (Emery, 1887); Acromytmex coronatus (Fabricius, 1804); Acromytmex landolti balzani Emery, 1890 and Acromyrmex aspersus (F. Smith, 1858). The most frequent species were Atta sexdens piriventris and A. laticeps, representing 62 % of the studied samples, and found in all regions. However, according to the region their distribution varied from very abundant to rare like Atta sexdens piriventris that occurred in almost every county in Planalto, Alto Uruguai, and Noroeste regions. In Sul and Campanha regions A. sexdens piriventris was found only in a few counties in a low frequency, while A. ambiguus, A. heyeri and A. lundi were found in a high frequency. A. crassispinus occurred in all studied regions, with frequency higher in the Serra region, while A. laticeps, predominated in Serra, Alto Uruguai, Planalto and Noroeste regions. The species, A. aspersus, A. coronatus and A. landolti balzani occurred rarely in isolated points. In Depressão Central region, considered as a transitional one for delimiting with east, south and north regions, the highest number of species was found, with various predominance. The variation in percentage of species found in different regions may be explained by soil type, crop system and existing vegetation, being necessary a more detailed regional study. In general, leaf-cutting ants are controlled in a similar way. However, considering the differences among the species in habit, nest, specificity of leaves cutting and geographic delimitation, some factors should be considered and they justify specific control techniques. This work cooperates in identification, regionalism and quantification of the important leaf-cutting ants species that occur in Rio Grande do Sul State. Index terms: Leaf-cutting ants, Acromyrmex, Atta, geographical distribution.

[0521] MONITORING REGIONAL AND GLOBAL CHANGES IN BIODIVERSITY: CHALLENGES FOR ENTOMOLOGISTS IN THE 21ST. CENTURY

T. M. Lewinsohu^{1,2}, ¹Lab. Interações Insetos-Plantas, Depto. Zoologia, Inst. Biologia, UNICAMP, C.P. 6109, CEP 13081-970, Campinas, SP, Brasil. E-mail: thomasl@unicamp.br; ²Conservation International do Brasil, Belo Horizonte, MG.

The last decade has seen a major shift in focus of conservation initiatives from the concern over the fate of a select group of endangered taxa or emblematic species, to an awareness of the necessity of conserving and managing entire communities within their regions and preserving ecosystem functions and services. Surprisingly - to politicians but certainly not to scientists - there are as yet no established procedures to assess unequivocally the current status or ongoing changes in the world's biodiversity. Following on the Rio-92 Convention on Biological Diversity, several initiatives are attempting to deal with this necessity. Here I will outline a recent enterprise spearheaded by the Center for Applied Biodiversity Science of Conservation International. After a brief presentation of the general goals and strategy of the project, I will concentrate on issues that are especially relevant to entomologists. The CABS/CI undertaking focuses on areas of high biodiversity value (species richness, endemism, at high risk), hence on recognized hotspots; primary targets are a set of tropical forests on different continents which should expand ultimately to a worldwide network. The main goal is to enable the assessment of quantitative, structural and functional changes in biodiversity and to ascribe these changes to major impact agents. Reliable measures of biodiversity change and dependable assignment to actual causes are necessary both as monitoring tools and as arguments to provoke political and economic action. Towards this end, it is necessary to make use of existing data, infrastructure and analytical tools, as well as choosing an efficient set of biological indicators for ongoing measurement. This entails the integration of intensive, site-specific monitoring and research with regional surveys and remote sensing, Entomologists have a particularly challenging task in this program and in other enterprises with similar purposes. In areas of high diversity, even the basic surveying and taxonomy is yet to be done; thus, fundamental work has to be carried out almost in parallel with its application. Since all encompossing taxonomic coverage is unfeasible, focal groups and field methods have to be selected carefully, based on issues of expediency such as ease of collecting, current state of the taxonomy, capacity etc; but also on the information content of the resulting data. Alternatives to taxonomic groups as standard units for surveying have to be appraised; for instance, assemblages with clear functional assignments (e.g. soil organisms) or readily identified links to particular resources or habitats (such as animal or plant hosts) may prove more informative than much larger but mass-collected sets of organisms.

[0523] DISTRIBUTION OF THE GENUS ADELPHA (LEPIDOPTERA: NYMPHALIDAE: LIMENITINAE) IN THE AMERICAN CONTINENT

R. A. Di Mare^{1,2}, J. A. Teston^{1,3} & E. Corseuil^{3,4}, ¹ PPG-Biociências PUCRS, Av-Ipiranga, 6681, Caixa Postal 1429, CEP 90619-900, Porto Alegre, RS, Brasil; ² Depto. Biologia, CCNE, UFSM, Camobi, Santa Maria, RS, Brasil, E-mail: ram13@zaz.combr, ⁴ E-mail: jateston@pucrs.br,⁴ E-mail: corseuil@pucrs.br

The Adelpha genus is distributed from USA to Uruguay and 50% of the species can be found in Brazil. So far few studies were performed with this group, although these butterflies are common. One reason is the difficulty of working with their small and sparse natural populations. The populations dynamic is not very well known either. It can be also related to the difficulty of settling down a phylogenetic pattern of these species. Coloration and venation patterns of wings, genitalia, or combination of these, were already tested, but the result were always conflicting and chaotic. In spite of the difficulties, they are suitable to studies with evolutionary interests, because of the conservatism of the pattern of coloration of the wings, similarity among species of distant distribution, and absence of this pattern among sympatric species. Mimetic relationships among species of this genus and others, like Doxocopa, are until now ignored, as well as studies related with the palatability. The species are opportunistic and polyphagous, since its use 5 orders, 16 families and about 56 plants species, registered until now, with a preference for Rubiaceae Some species like as A. cocala and A. iphiclus can use up to eight different host plants This work makes a revision of the host plants used and distribution by the species of the genus. The work is based in the following Adelpha species: abia, alala, anfidia, arete, aricia, attica, barnesia, basileia, basiloides, bocotia, boreas, bredowi, caliphiclea, calliphane, caphira, celerio, cestrus, cocala, collina, corcyra, coryneta, cytherea, deborah, delenita, delphicola, demialba, diocles, donysa, epione, epizygis, erotia, erymanthis, escalantei, ethelda, euboea, falcipennis, felderi, fessonia, gavina, gilletella. goyama, heraclea, herbita, hyas, incomposita, iphiclus, irma, irmina, isis, ixia. jacquelinae, jordani, justina, lapitha, lara, lerna, leuceria, leucerioides, leucophthalma. makkeda, massilia, melanthe, melona, mesentina, milleri, mincia, mythra, naxia, nea olynthia, paraëna, phliassa, phylaca, pithys, plesaure, poltius, pseudococala, rothschildi, salmoneus, saundersii, seriphia, serpa, sichaeus, stilesiana, syma, thesprotia, thessalia, thoasa, tracta, valentina, velia, ximena, zalmona, zea, zina and zunilaces. Index terms: Biogeography, Checklist, Host plants, Systematic.

Index terms: surveys; indicators; global change; biodiversity loss.

[0524] PREDICTING SPECIES RICHNESS BY ASSESSING THE SAMPLING EFFORT: THE CASE OF THE IBERIAN DUNG BEETLES (COLEOPTERA SCARABAEINAE)

<u>F. Martín-Piera</u>^{1*} & J. M. Lobo^{1**}, ¹Dept. Biodiversidad y Biología Evolutiva (Entomología), Museo Nacional de Ciencias Naturales (C.S.I.C.), c/ José Gutiéπez Abascal, 2; 28006-MADRID (SPAIN), e-mail: ^{1*}fermin@mncn.csic.es; ^{1**}mcnj117@mncn.csic.es.

Recommendations for conservation of areas, based on predictions from species richness 'hot-spots', can be seriously biased if the effect of sampling effort is overlooked. Samplingeffort skewing can be reduced by using a defined sampling-effort unit, and, as proposed herein, by taking the number of database records per spatial unit as a measure of such effort. The geographic distribution of Iberian dung beetle species richness is predicted using several environmental variables as surrogates of biodiversity. Before elaborating a function to predict Iberian species richness, spatial variability of the sampling effort was assessed on a scale of 50 km UTM grid squares. For which firstly, physiographic subregions were defined by climatic variables (annual mean temperature, annual temperature variation, annual days of sun, total annual precipitation, total summer precipitation and annual precipitation variation) as well as mean elevation and altitudinal range. Secondly, to search for the well-prospected areas the asymptotic relationship between the added number of species at different levels of sampling effort were investigated. Then, the pool of well-surveyed UTM squares in each subregion was established by means of a ranking of the recording effort required for an arbitrary rate species increment. Eighty two squares (32.2%) were thus recognised as adequately sampled. Twenty four variables (two spatial, two geographic, four topographic, three geologic, eight climatic, and five land use) along with interaction terms, for this 82 squares, were used to generate the species richness geographic distribution model. Final model account for more than 65% of the species richness variability. Species richness 'hotspots' are concentrated mainly in Mountainous subregion, particularly in the Pyrenees and Iberian Central System, and in a few grid squares in the North and South Plateau of Central Spain.

[0525] FLIES AS A BIOINDICATOR FOR BIODIVERSITY LOSS IN AGRICULTURAL LANDING USE SYSTEMS

<u>M. Martins</u>, ¹, M. C. Esposito² & R. Santos², ¹Museu Paraense Emílio Goeldi, Dept. of Zoology, P. O. Box 399, Belém, Pará, Brazil 66040-170, E-mail marlucia@museugoeldi.br ²Univ. Federal do Pará, Box 479, Belém, Pará, Brazil 66075-900, BR, E-mail esposito@amazon.com/br rcos@ufpa.br.

The recent literature has been discussing about the validation to use bioindicator species in order to predict the biodiversity changes related to replacement of primary forest for landing use. Lawton et al (1998) show that no one groups serve as a good bioindicator taxon for changes in the species richness of other groups. In this project, we study some saprofagous flies families to understand the effect of substitution of primary forest liabitats by subsistence agricultural systems over this guild. We are looking for the changes in richness, composition and relative abundance of species. In terms of composition there are two kinds of changes expected: First, the disappearance of very sensitive species, characteristics of primary forest, and, second, the increasing number of invasor species, correlated to anthropic disturbation. Our collections were carried on Igarapé-Açú city, in secondary forests patches around small plantations. We used attractive traps, disposed in sorted points along sites with regrow ages from 2 to about 50 years old. The present data pointed to a fauna impoverishment of about 50 per cent for blow flies and 80% for fruit flies, when compared to inventories realized on the other studies areas, in primary forest habitats. Chrysomya putoria, C. albiceps, and Drosophila. malerkotliana were the invasor species observed in the area. All these species invaded the Amazon region in the 70's coming from Africa and the Malaysian region. The fly's species remnants of primary forestry were D. willistoni and D. sturtevanti (Drosephilidae), and Eumesembrinella quadrilineata and Mesembrinella bicolor (Calliphoridae). These species represented 32% of all individuals collected in the area. The other hand, the invasor species summed 59% of this collection. The rest of individuals belong to more generalist's native species, commonly present in forest and open areas. The similar responses observed for species of different genus and families, and the general diversity patterns and abundance distribution in these flies, indicate that the guild approach, like this saprofagous flies, could be useful in the biodiversity studies. However, the validation of these focused groups as a bioindicator needs more detailed investigation and depends on the consolidation of efficient evaluation protocols, which also has been tested in this project. Index terms: Drosophilidae, Calliphoridae, saprofagous guilds, invasor species

[0526] FACTORS AFFECTING TERMITE DISTRIBUTION AND DIVERSITY IN NATURAL AND MANAGED CENTRAL AMAZONIAN FOREST ECOSYSTEMS

C. Martius¹, ¹ Center for Development Research (ZEF Bonn), Walter-Flex-Strasse 3, D-53175 Bonn, Germany, E-mail: c.martius@uni-bonn.de

Termites are the most dominant group of decomposers organisms in soil arthropod assemblages in tropical rainforests. Litter and soil termites were collected in a primary forest site, a secondary forest site and two sites of a polyculture plantation system in central Amazonia. Termite genus diversity, abundance and biomass all were highest in the primary forest. The values in the secondary forest were half those of the primary forest, and they were lowest in the plantation systems, indicating that the latter sites may suffer from functional constraints concerning the process of organic residue decomposition. The average termite biomass of the sites was positively correlated to dead wood volume on the forest floor, but the termite biomass of the individual samples was not related to the wood in the litter layer of the sample. The possible correlation to other factors is discussed. In a second study, nest-building termite density was recorded in undisturbed primary forest site, and compared to the density in forest sites subject to selective logging. Only one genus, Nasutitermes, showed a (positive) correlation to increased logging impact, indicating that it is a group of species that follow forest disturbance. The implications of these findings for monitoring programs and for ecosystem management are discussed. Index terms: Isoptera, distribution, diversity, agroforestry, land use systems

[0527] A COMPARISON BETWEEN RECONCILIATED TREES, DISPERSE-VICARIANCE AND PARALOGY FREE BIOGEOGRAPHIC SCHEMES

D. R. Miranda-Esquivel¹, **M. Donato² & P. Posadas**², ¹ Escuela de Biología. Universidad Industrial de Santander. AA 678, Bucaramanga, Colombia. E-mail: dimiranda@uis.edu.co.² Laboratorio de Sistemática y Biología Evolutiva (LASBE), Museo de La Plata, Paseo del Bosque, 1900 La Plata, Argentina.

Proliferation of methodological schemes is a common place in present day biogeography. Many of those approaches have not been tested against the other approaches. The last comparison was conducted in 1994 by Carpenter & Morrone but new approaches as Disperse - Vicariance Analysis and Paralogy free sub- trees has been developed during the last 10 years. Our goal is to compare those approaches against reconcilied trees analysis, a common biogegraphic technique, using 12 biogeographic units of southern South America applying on 12 supraspecific taxa of arthropods and vascular plants for which phylogenetic analysis were available. The analyses show that dispersal could be a very common event, even more frecuent than vicariance. Dispersal could interfere with those reconstructions based on the premise that vicariance is the only or the more frecuent process. Paralogy free sub- tree analysis could be a solution to reconciliated trees but dispersal could also obscure this technique. To tackle the dispersal problem we propose to evaluate the dispersion events as depicted by the cladogram and to eliminate those event from the reconcilied trees analysis.

Index terms: Biogeography, Phylogeny, Southern South America

[0528] A CLADISTIC ANALYSIS OF NEOTROPICAL, ETHIOPIC AND AUSTRALIAN SUBGENERA OF THE GENUS SIMULIUM (DIPTERA:SIMULIIDAE)

D. R. Miranda-Esquivel¹ & S. Coscarón², ¹ Escuela de Biología. Universidad Industrial de Santander. AA 678, Bucaramanga, Colombia. E-mail: dmiranda@uis.edu.co. ² Museo de La Plata, Paseo del Bosque, 1900 La Plata, Argentina.

A phylogenetic analysis of Neotropical, Ethiopic and Australian subgenera of the genus *Simulium* was undertaken using 46 terminal taxa (ingroup = 42 taxa and 4 outgroups used simulitaneously) and 201 characters from larval, pupal and imago morphology, along with one ecological character. Multistate characters were coded as unordered. Two analyses were conducted: equal weights and implicit weights. To select the optimal concavity value we used the PC value. For the final cladogram the relative Bremer support was calculated. The cladogram shows that neotropical taxa are not a monophyletic taxon. There a monophyletic unit groping together *Xenosimulium*, *Freemaniellum*, *Anasolen*, *Hearlea*, *Hemicnetha*, *Thyrsopelma* and *Thrichodagmia*, this monophyletic unit is closed related to the other Neotropical taxa. The other Etiopic/Australian taxa form the other monophyletic unit.

Index terms: Phylogeny, Implicit weights, Monophyly

[0530] CICADA DIVERSITY IN BRASÍLIA, BRAZIL

P. C. Motta, Dept. of Zoology, Univ. of Brasília, 70910-900, Brasília, DF, Brazil. E-mail mottape@unb.br.

The annual appearance of cicadas (Hemiptera: Homoptera: Cicadidae), with their exuviae shed on tree trunks and their characteristic acoustic signals, from the middle of September until December, is so intense in Brasilia that it even becomes an obligatory subject in the local media. Despite their abundance and eloquence, there are no studies over them. Diversity and population dynamics studies of cicadas may be made by using their exuviae. The objectives of this study were to verify the differential emergence periods, abundance and the sex ratio of cicadas which occur in an urban area of Brasília. In all, 33 samplings were made, from September 10th, 1999, until January 5th, 2000, within a transect of 3.5 km by 16 m in an urban area of Brasilia (Asa Norte), where 292 trees were visited, and the exuviae were collected up to a height of 2.5 m on the trunk. A dichotomous key was prepared to identify species from their exuviae. The secure identification of species awaits confirmation. The exuviae began to emerge from the soil during mid-August, at the peak of the dry season. The number of individuals increased a great deal at the end of September and the beginning of October, coinciding with the first rains. In this period the intense and simultaneous vocalizations also begin. October is the month with the greatest number of exuviae. A total of 11800 exuviae were collected, representing 9 cicada species, the most abundant being Dorisiana viridis (57%), Quesada sp. (20%) and Quesada gigas (14%). The remaining species (9%), were Fidicina mannifera, Fidicina pronoe, Fidicina sp., Dorisiana drewseni, Dorisiana sp. 1 and Dorisiana sp. 2. Quesada gigas is most frequent from September until the middle of October, while all others being so in October. The proportion of males in the sex ratio is greater for *Dorisiana viridis*, while females are more abundant for Quesada gigas and Quesada sp. The number of exuviae on trees with rough bark is greater than on trees with smooth bark. It is estimated that eight hundred thousand to one million cicada individuals occur per year, between the months of September and November, in Brasília.

Index terms: Quesada, Dorisiana, Fidicinna, Cicadidae, exuviac

[0529] NEOTROPIC BIOGEOGRAPHY: A PERSPECTIVE FROM SIMULIIDAE TAXA

D. R. Miranda-Esquivel, Escuela de Biología. Universidad Industrial de Santander. AA 678, Bucaramanga, Colombia. E-mail: dmiranda@uis.edu.co.

Neotropic is a complex biogeographic area. Most of the biogeographic reconstructions are based in terrestrial organisms and the fresh water organisms have been not used extensively to test the relationship between the endemism areas. In This analysis a biogeographic study of the Neotropical Simuliidae endemism areas was conducted using nine phylogenies and 16 biogeographical units. The analysis was done in two steps, first a taxon biogeography approach to evaluate the ancestral area and the dispersal events for each supraspecific taxon using the dispersal-vicariance scheme. Second a cladistic biogeographic approach using reconciliated trees but eliminating those dispersal events evaluated during the first step. The results show a high level of dispersal between SE Brazil and Cerrado and between the Mountains of Mesoamerica and the Pacific region. Those dispersal events could interfere with previous reconstructions. The reconciliated tree shows the sequence (Neartic (Mountains of Mesoamerica (Pacific Caribean (Yunga, North Andes (Desert (Puna (Patagonia (Monte (Subantartic, Central Chile) (SE Brazil, Cerrado) (Guyana, Amazonia). This sequence is congruent with previous proposals using terrestrial organisms.

Index terms: Dispersion-vicariance, Reconciliated trees, Ancestral Area, Phylogeny.

[0531] THE ALL TAXA BIODIVERSITY INVENTORY IN GREAT SMOKY MOUNTAINS NATIONAL PARK

B. Nichols, United States Department of the Interior, National Park Service, Great Smoky Mountains National Park, 1314 Cherokee Orchard Road, Gatlinburg, Tennessee 37738, USA. becky_nichols@nps.gov

Great Smoky Mountains National Park, in Tennessee and North Carolina, USA, comprises more than half a million acres and contains some of the richest and most diverse floral and faunal communities in the temperate world. Past inventories of these communities have not been comprehensive, and fewer than 10,000 (10%) of an estimated 100,000 species in the Park are known. Existing and impending threats to this area include invasion by exotic species, air pollution, and forest diseases. Protection of natural resources from these threats requires management methods that could be enhanced by information on the identity and status of resident species. The need for such information led to the inception of an All Taxa Biodiversity Inventory (ATBI) in the Smokies. This comprehensive inventory will involve all life forms and is expected to take 10-15 years. The project will be funded through Discover Life in America (DLIA), a non-profit, volunteer, science and education organization which will direct the operation and secure funding." The Park and DLIA will form a cooperative agreement to conduct the inventory. The first pilot field season (1999) has been successful, and it inspired considerable public interest and press exposure, both regional and national. Among the taxonomic groups that were studied are flies, ants, fungi, crustaceans, diatoms, slime-molds, and small mammals. Additional funding has been acquired for work to begin on other groups, including worms, spiders, crayfish, ectoparasites, moths, plants, and remaining vertebrates. The project already has discovered previously unidentified species and many new distributional records. This type of scientific survey has never been undertaken on such a scale anywhere in the world, and it will serve as a model for future projects in other national parks and protected areas. Gaining a better understanding of natural communities, species distributions, and interactions will allow for better management and provide a critical knowledge base for responding to threats.

Key words: diversity, taxonomy, education

[0532] INSECT INDUCED GALL DIVERSITY IN COIBA NATIONAL PARK (PANAMA)

J. L. <u>Nieves-Aldrey</u> ¹& A. Ibañez², ¹Museo Nacional de Ciencias Naturales (CSIC), Dpto Biodiversidad. C/José Gutiérrez Abascal 2, 28006 Madrid (España), E-mail aldrey@mncn.csic.es; ²Real Jardín Botánico (CSIC), Plaza de Murillo,2. 28014 Madrid (España), E-mail alicia@mundivia.es.

The Coiba National Park, in the Pacific Ocean, is located in Veraguas province at the SW of Panama Republic. The terrestrial habitats of the National Park, mostly mangrove and rainforest ecosystems, are well preserved because of the existence since 1920 of a Penal Colony in Coiba, the park largest island. Since 1993 scientists from Panama and Spain are carrying out a Flora and Fauna inventory research project, and preliminary results have been compiled in a book published in 1997. Here we present the results of the inventory of the galls induced by insects and acari on flower plants in the National Park. Field data come from irregular sampling between August 1997 and September 1999 with three (twoweeks long) more intensive samplings in August 1997, July 1998 and August 1999. Seventeen sites, representing the main terrestrial habitats of the National Park were surveyed with intensive sampling in 7 localities. The preliminary list of galls from Coiba comprises 59 different galls from 43 plant genera and 29 botanical families. Bignoniaceae demostrated to be the most galled plant family with seven galls, accounting for about 12 per cent of total. In decreasing order others most galled plant families were: Myrtaceae, Euphorbiaceae, Guttiferae, Fabaceae, Melastomataceae and Moraceae. Leaf galls accounted for about 90% of the collected galls. Most leaf galls were pit/blister galls followed by covering and pouch galls. The identification of the gall-inducing taxa found mite galls (Acari: Eriophyidae) and among insect galls, gall midges (Diptera: Cecidomyiidae) and Psylloidea and Coccoidea galls (Homoptera). A first identification indicates that an important number of the Coiba gallicolous species can be undescribed. The gall richness per collecting site was between 3 and 12 species, showing, at the richest places, to be higher than predicted for such mesic-tropical-island habitats. Coiba gall diversity is discussed related to available data from other tropical and temperate sites. Index terms: Galls, Cecidomyiidae, Psyllidae, Eriophyidae, richness

[0533] HYMENOPTERA FROM "EL VENTORRILLO" (CENTRAL SPAIN): AN EXAMPLE OF HIGH ABUNDANCE AND RICHNESS AT THE LOCAL GEOGRAPHIC SCALE

J. L. <u>Nieves-Aldrey</u>, Museo Nacional de Ciencias Naturales (CSIC), Dpto Biodiversidad. C/José Gutiérrez Abascal 2, 28006 Madrid (España), E-mail aldrey@mnen.csic.es.

The Biological Research Station of "El Ventorrillo" is located at an altitude of 1500 m, on the south slope of the Sierra de Guadarrama (central Spain), about 60 km far from Madrid. Between 1988 and 1991 an insect biodiversity inventory was carried out using Malaise and yellow pan traps. Out of the near 1,000,000 insects trapped, the Hymenoptera represented more than 70,000 individuals. The abundance of Hymenoptera, as measured by Malaise trap catches, was very high, reaching a peak of 916 individuals per trap day at the most productive trap and sampling period. Until now eighteen hymenopteran families have been identified to species level accounting for 1071 species. Among the identified families, the more speciose at the study area were in decreasing order: Pteromalidae, Ichneumonidae, Eulophidae and Tenthredinidae, all of them surpassing 100 species. The richness of the 29 remaining families at the area of study was estimated extrapolating regional richness data from some countries in Europe. The global Hymenoptera richness at El Ventorrillo is estimated in 1700 species, representing 18% of the overall Iberian Hymenoptera richness, expected to be near 10,000 species. The hymenopteran numbers at the study area are compared with other local richness data from Spain and other sites in Europe and America. The comparatively high abundance and richness figures at El Ventorrillo, from an area less than 0.5 square kilometres, could be explained by its central geographic position in Iberia, the relative high altitude, favourable orientation and its rich floristic composition.

Index terms: Biodiversity, Malaise traps, local richness, inventory

[0534] DISTRIBUTION PATTERNS OF ANTS IN EAST ASIA (HYMENOPTERA: FORMICIDAE)

K. Ogata, Institute of Tropical Agriculture, Kyushu University, Fukuoka 812-8581 JAPAN

Recent taxonomic studies of ants in East Asia have clarified the biodiversity and suggested the utilization them as bioindicators. The purpose of the present study is to review a biogeographical attribute of ants in East Asia and to give basic information in comparing and assessing the local ant communities. There are about 200 species distributed in Japan excluding the Ryukyus and Korean Peninsula. The present study analyzes their distributions and classifies the patterns based on 2 factors: geographical range and temperature. According to the geographical, the ants are grouped into 3 major categories: 1) endemic to Japan and/or Korea (N: narrow); 2) East Asia (I: intermediate); 3) over the range of East Asia (W: wide). To see the aspect of temperature factor affecting the distribution, Warmth Index (WI) is used representing a kind of accumulative temperature calculated by a sum of average temperature of months over 5 °C. According to WI, the distributed area of ants is divided into 3 categories: 1) WI less than 85 °C (c: cold); 2) WI between 85 °C and 110 °C (t: temperate); 3) WI more than 110 °C (w: warm). Thus the distribution patterns can be presented in a 3 x 3 matrix table (N/I/W x c/l/w). In terms of thermal range of distribution, 6 patterns can be distinguished: 1) c zone; 2) t zone; 3) w zone; 4) cooler zone (n: c + t zones); 5) warmer zone (s: w + t zones) and 6) all zones (a). Based on this classification, the distributions of ants are divided into 18 patterns. Among them, the species having narrow distribution range are most abundant occupying about 40 %. The number of species in WI categorization shows temperature gradient (c zone=12 spp., t zone=16 spp., w zone =47 spp.). It should be noted that the species having wide range of geographical distribution tend to introduce new environment easily. The local study on ants in old and new urban parks shows that the species of the categories Ws and Ww will enlarge their distribution.

Index terms: Ants, Japan, Korea, temperature

[0535] BUTTERFLY DIVERSITY IN SERRA DO CIPÓ, BRAZIL: A RELIMINARY SURVEY

<u>E. G. Oliveira</u>¹ & G. W. Fernandes¹, ¹Departamento de Biologia Geral, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, 30161-970, Belo Horizonte, MG, Brazil, E-mail evandro@mono.icb.ufmg.br.

Serra do Cipó is located in the southernmost portion of the Espinhaço Mountains, a high altitude mountain range in southeastern Brazil. It harbors one of the most diverse ecosystems in the world with high degree of floral endemism and morphological convergence. Low soil fertility, prolonged dry season, strong winds, and other harsh environmental conditions, which strongly influence its flora and fauna, characterize the region. In this scenario, we would expect to find a relatively poor butterfly fauna. On the other hand, due to its speciose flora and because the region has never been properly surveyed, we would also expect to find rare and new species. In an attempt to address these questions, for the first time we have sampled the butterflies in the region by (i) direct netting and (ii) trapping using rotting fruits as bait. During the first three months of this study, we have collected butterflies belonging to all common subfamilies, and the preliminary list of species suggests that its diversity may be higher than previously postulated. We have also recorded migration (i.e., unidirectional flight) events, which had not been previously studied in the region. Migration of Pieridae was observed in several occasions indicating that this is a common phenomenon in the region.

Index terms: Lepidoptera, species composition, mountain habitat, migration

Symposium and Poster Session

[0536] SAFETY OF PROTECTIVE CLOTHING AND SEMI-CABIN FOR TRACTOR DRIVER APPLYING INSECTICIDES AND ACARICIDES BY TRACTOR-TRAILED AIR-CARRIED SPRAYER IN CITRUS (CITRUS SINENSIS)

M. L. Oliveira¹ & J. G. Machado Neto¹, ¹Dept. de Fitossanidade, FCAV/UNESP – Câmpus de Jaboticabal, 14.870-000, Jaboticabal, SP, Brazil, E-mails: oliveiraml@hotmail.com; joaquim@fcav.unesp.br.

Safety of the tractor driver applying pesticides to citrus by tractor-trailed air-carried sprayer was evaluated calculating the margin of safety (MOS) from data of NOEL of pesticides and the occupational exposure in a 6 hours workday. Working condition of tractor driver was classified as safe (if MOS \geq 1), or unsafe (if MOS <1). Demoal exposure of tractor driver (DE) was evaluated using or not protective clothing and semi-cabin. Protective clothing was composed by AZR clothing (hood, long sleeved jacket, pants and acetate face visor) completed by nitrila gloves, rubber boots and charcoal treated disposable respirator. Evaluations on tractor driver were carried out in applications using Arbus 2000 Valência tractor-trailed air-carried sprayer in citrus orchard of the Cambuhy Agricola Farm, Matão-SP, Brazil during february/99. Cu⁺² of a cupric fungicide was used as tracer of spray. DE of tractor driver was quantified directly on white overall with long sleeve and hood and on cotton gloves. Exposure of face was evaluated on female sanitary pads attached on disposable face masks and exposure of feet was on same type of pads attached on upper part of rubber boots. DE of tractor driver in three working conditions were evaluated in ten replications for each activity during 30 to 40 minutes. After the exposure overalls were divided into parts and were immersed in solution of HCl (0.1 N) for extraction of the tracer. Same procedure was carried out on pads. Quantification of Cu⁺² was by atomic absorption spectrophotometer. The values of Cu⁺² recovered in spray collectors and concentration of the tracer in the spray solution were used to estimate the DE. Dermal exposure to 135 recommended pesticides were estimated using DE to spray and the dose of pesticides. These data were used to calculate MOS with the following equation: MOS = [NOEL x 70] / [1.1 DE]. The DE to spray driving the tractor without semi-cabin and clothing was of 217.3 mL/day. Wearing protective clothing it was 7.2 mL/day and with semi-cabin, 145.1 mL/day with 96.7% and 33.2% efficiencies respectively. Among 135 insecticides and acaricides recommended for citrus 56.4% were classified as safe (MOS \geq 1) for the tractor driver working without protective clothing and semi-cabin, 91.1% when the tractor driver used the protective clothing and 57.4% when the semi-cabin was used.

Index terms: citrus, pesticides, protective clothing, semi-cabin

[0537] GEOGRAPHIC DISTRIBUTION AND PHENOLOGY OF FIEL PLANTS AS PARAMETERS OF TROPHIC RESOURCES IN NEOTROPICAL ENTOMOTAXOCENOSES

<u>S. G. Oliveira</u>¹, A. Caldas² & J. R. Almeida³, ¹ Univ. do Est. Rio de Janeiro, Departamento de Biologia Animal e Vegetal, Setor de Ecologia, Rua São Francisco Xavier, 524, Maracanã – 20559-900, E-mail: sigomes@uerj.br; ² Univ. Fed. do Rio de Janeiro, Escola de Engenharia, Departamento de Hidráulica e Saneamento, CT – COPPE, bloco C, sala 211 Ilha do Fundão, 21941-590, E-mails: claudio@pcc.coppe.ulfj.br;

If a population for a certain hostplant species becomes abundant and concentrated along a certain part of the habitat, the phytophagous community tends to respond with a specielized diet strategy(monopaghy). If, on the other hand, a variety of food resources are present in low frequency, and if some factors such as predation and competition affect negatively the chance of these phytophagous organisms find and actually exploit the host plants, the resulting strategy is usually a generalized diet. The adaptation of a specialist insect to the foodplant it uses goes further beyond simple tolerance to the plant's defense substances. There are behavioral barriers that prevent specialized insects from using other plant species. The ecological advantage of specialization allows, for instance, a specialized insect to develop a synchronism with the phenology of its hostplant. In this work, we studied the geographic distribution and the phenology of field plants as parameters for trophic resources in neotroppical entomotaxocenoses. Large-scale collect areas throughout Brazil were previously selected based on the protential dispersion and the diestribuion of the plants. These areas were established random transects that covered six of the Braziulian morphoclimatic and phytogeographic domains: Tropical Atlantic, Cerrado, Caatinga, Tropical Amazonian, Pantanal and Araucaria Pine Forest. Most hostplants were herbaceous with relatively low biomass concentration in the reproductive structures. Another point to be considered is the dynamic of the availability of the resouces. These characteristics together suggest that, at least quantitatively, the availability of some specific food resources in some of the plants is low when compared with the consumption volume. Field observations confirm the use of other resources. In geographic distribution na abundance of the hostplants the fields did not present a uniform aspect troughout the year, varying according to the composition and structure of the soil, precipitation, and especially agrazing schedule. Depending on the degree of variation of these factors, some especies might be more or less conspicuous. The phenology of the hostplants and exploitation of available resources by the entomotaxocenoses were the vast majority of field plants was herbaceous. The relative amount of nutrients and minerals in these plants displayed some variation.

[0538] THE DIVERSITY OF COCCINELLIDAE IN SOUTHEN CHINA

II. Pang, State Key Laboratory for Biocontrol, Zhongshan University, Guangzhou 510275, P.R. China; E-mail: 1s40@zsu.edu.cn.

The present paper summarized developmental history of systematic of Coccinellidae over 200 years, discussed effect of development of integrated insect taxonomy and molecular systematic to Coccinellids. It deals with the analysis of diversity of Coccinellidae in Southern China, based on the land formation and climate condition on the evolution of plants, as well as the coevolution of insects and plants. A list of Coccinellidae in Southern China with 9 subfamilies, 76 genera and 547 species is constructed. We referred to document from abroad, improved methods of DNA extract in the present condition. The genomic DNA was extracted separately from fresh samples, alcohol steep samples, dry samples. Fragment of about 500 bp of the mitochondria 16S ribosomal RNA gene was amplified by polymerize chain reaction (PCR) from the DNA using primers CPE264-01: 5'-GCCTGTTTATCAAAAACAT-3', CPD264-02: 5'-CCGGTCTGAACTCAGATCA-3' and primers CPE418-01:5'-CGCCTGTTTATCAAAAACAT-3', CPE418-02:5'-CCGGTCTGAACTCAGATCACGT-3', Fragment of about 2000 bp of the 18S ribosomat RNA gene was amplified by PCR from the DNA using primers 18N1: 5'-TCTATCTGGTTGATCCTGCCAG-3', 18N11R: 5'-TCGATCCTTCCGCAGGTTCACC3'. The study results can be proved new data for phylogenetic reconstruction of the family relatiouships within coccinellids based on DNA sequences of rDNAgene.

[0539] DEVELOPMENT OF PHYTOPHAGOUS HETEROPTERANS ON DRY ARTIFICIAL DIETS

A.R. Panizzi¹, J.R.P. Parra² & <u>D.R. Carvalho</u>², ¹Centro Nacional de Pesquisa de Soja (CNPSo), Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA), Caixa Postal 231, Londrina, PR, 86001-970, Brasil. E-mail: panizzi@cnpso.embrapa br. ²Departamento de Entomologia, Escola Superior de Agricultura Luis de Queiróz (ESALQ), Caixa Postal 9, Piracicaba, SP, 13418-900, Brasil. E-mail: jrpparra@carpa.ciagri.usp.br, deccarvalho@hotmail.com.

Laboratory studies were conducted in Londrina and Piracicaba to develop an artificial dry diet for phytophagous heteropterans. The diet components were: soybean protein (15g); potato starch (7.5g); dextrose (7.5g); sacarose (2.5g); cellulosc (12.5g); vitamin solution (5.0ml); soybean oil (20.0ml); wheat germ (17.9 gr); and water (30.0ml). Six different diets with slight variations in their components were rested: 1) Basic diet with rough texture cellulose: 2) Basic diet with rough texture cellulose plus anticontaminant (nipagin) (0.44g); 3) Basic diet with fine texture cellulose plus anticontaminant (nipagin) (0.44g); 4) Basic diet, with half soybean oil and half olive oil, with rough texture cellulose; 5) Basic diet, with haif soybean oil and half clive oil, with rough texture cellulose plus anticontaminant (nipagin) (0.44g); and 6) Basic diet, with half soybean oil and half olive oil, with fine texture cellulose plus anticontaminant (nipagin) (0.44g). All diets were oven dried for 4 hours at 75 °C. Diets were wrapped in aluminum foil and kept in the refrigerator. Small cubs of 5x5x5mm were offered to 2nd instars (n = 30) of Nezara viridula (L.), Piezodorus guildinii (Westwood), and Dichelops melacanthus (Dallas) (Pentatomidae) at 25 °C, RH 60 ± 10% and 14hL:10hD photoperiod. Diets 1,2 and 3 allowed N. viridula nymph survivorship of ca. 70%. With diet 1 all adults obtained were normal. Survivorship of P. guildinii and D. melacanthus were smaller (range of 12.5 to 50.0%, and 20.0 to 30.0%, respectively, fed on diets 1 to 3). Additional studies with N. viridula using the basic dict with soybean protein (7.5g) plus lyophilized soybean pods immature (7.5g), yielded the best results, with > 80% nymph survivorship and adult reproduction.

Index terms: Pentatomidae, stink bugs, rearing, artificial media.

[0540] SOCIEDAD ENTOMOLÓGICA DE PUERTO RICO

A. Pantoja & E. Abreu, University of Puerto Rico-Mayaguez Campus, Department of Crop Protection, P.O. Box 9030, Mayaguez, Puerto Rico 00681, E-mail Pantoja: a_pantoja@rumac.upr.clu.edu; Abreu: eabreu@prtc.net.

The first Puerto Rican Entomological Conference was on May 25, 1912. The organization of this first Conference was largely due to the enthusiastic support of D. L. Van Dine, at that time in charge of the Sugar Producers Experiment Station of Puerto Rico. The first publications of the Society were published in summary in the Journal of Economic Entomology, February 1931. The Society ceased activities until March 1932 when the third meeting of the Society was held in conjunction with the Fourth Congress of the International Society of Sugar Cane Technologists at San Juan, Puerto Rico. Papers presented at that meetings were printed in the House of Representatives of Puerto Rico, and reports of the meetings were printed in the Journal of Economic Entomology and in Entomological News. Additional activities by Society members were held in April and July 1933. A more formal organization Sociedad Entomológica de Puerto Rico (SEPR) or Entomological Society of Puerto Rico, was founded December 4, 1976 at the Puerto Rico Agricultural Experiment Station in Rio Piedras. The SEPR defined its constitution and by laws by April 25, 1981. The SEPR published a bulletin Contribuciones de la Sociedad Entomológica de Puerto Rico starting in 1981, but it was published sporadically. The last volume was published in 1985. The Society was inactive for many years and was reactivated in early 1999. Currently the society has 40 members. The SEPR is the only current entomological society in Puerto Rico. During 1999, the SEPR held a joint meeting with the Florida Entomological Society in Puerto Rico. The SEPR is concerned with critical issues of economic entomology, biodiversity, and insect ecology. Index terms: entomological societies, Latin America

[0541] REVISION AND PHYLOGENY OF THE GENERA OF LITHININI OF AUSTRAL SOUTH AMERICA (LEPIDOPTERA: GEOMETRIDAE)

E. Parra, Departamento de Zoología, Facultad de Ciencias Naturales y Oceanográficas, Universidad de Concepción, Casilla 160-C, Concepción, CHILE. e-mail luparra@udec.cl; http://www.udec.cl/entomologia/

The tribe Lithinini (Forbes, 1948) is amply distributed throughout the world. Its diagnosis is supported by the combination of various characters, although the deciding character seems to be the presence of a long, thin anellus processes. Rindge (1986) separates the American genera into two sections, a Holartic and South American, with a distribution restricted to the austral zone. The genera of this region are characterized by having high levels of endemism. This revision contains numerous taxonomic changes, the proposition of a new genus and species, and a systematic list of the valid taxa. The phylogenetic analyzis was done with Hennig86 (Farris, 1988), where all groups, except Catophoenissa, formed a monophyletic group supported by the following synapomorphies: (1) absence of metathorasic tuft; (2) absence of abdominal tuft; (3) cristae present; and (4) anellus processes not spiniform. The 20 austral South American genera show the following hypothesized relationships: (Franciscoia (gen. nov. (Proteopharmacis (Maendragonaria (Odontothera ((Martindoelloia (Callemo, Guara))) (Calta (Laneco (Psilaspilates (Lacaria, Nucara) (Euclidiodes (Acauro (Siopla, Duraglia) (Yapoma (Incalvertia, Rinoligia))))))))). Aspects of the Natural History and distribution, which are found to be associated to the temperate and sclerophyllous forest of austral America, are discussed.

(0542) THE SOCIEDADCHILENA DE ENTOMOLOGIA

L. E. Parra, V. Jerez, T. Zaviezo, A. Cammouseight & D. Lanfranco, Casilla 21132, Santiago 2, Chile Fono: +56 2 6814095; Fax: +56 2 6817182; e-mail luparra@udec.cl; http://abulafia.ciencias.uchile.cl/sche.

The Sociedad Chilena de Entomología (SChE) was founded on June 4, 1922 in Santiago with the name Sociedad Entomológica de Chile; in March 30, 1933 it was changed to its current name. There are currently 100 members who are mostly university researchers and teachers with some members from public institutions and graduate students. The SChE meets for its annual congress in different institutions and universities in Chile. The SchE traditionally unites investigators from different countries, such as Argentina, Brasil, and Perú, and stimulates undergraduate and graduate student participation. The Revista Chilena de Entomología is published periodically once a year since 1951. Volumes 1-9 were financed by the University of Chile. It contains mostly papers on taxonomy and biology, with special reference to Chile or the Neotropics. Approximately 10 articles are published each year in Spanish or English. The publication of the journal is possible thanks to a donation by the late United States dipterologist Charles P. Alexander. The members of this society work principally in systematics, ecology, biogeography, veterinary medicine, economic entomology (agricultural and forest) and arachnology. The SChE organizes monthly meetings with oral presentations of advanced research of the members and incorporates new investigators and students with presentations of their regults

[0543] THYSANOPTERA DIVERSITY AT PARQUE ESTADUAL DE ITAPUÃ, VIAMÃO, RS, BRAZIL

S. M. J. Pinent¹, H. P. Romanowski¹ & L. R. Redaelli², ¹Dept. of Zoology, Inst. de S. M. J. Filterit, R. F. Kolminowski & L. Miv, Federal do Rio Grande do Sul, Ave. Biociências, Pós-Graduação Biologia Animal, Univ. Federal do Rio Grande do Sul, Ave. Paulo Gama P. 12.105, CEP 90040-060, Porto Alegre, Brazil, E-mail silviapi@portoweb.com.br; ²Dept. de Fitossanidade, Fac. de Agronomia, Univ. Federal do Rio Grande do Sul, Ave. Bento Gonçalves 7712, CEP 91540-000, Porto Alegre, Brazil.

There are huge gaps on our knowledge about the biology and diversity of wild thysanopterans of neotropical regions. This work aims to help filling this lacuna, by surveying these insects at Parque Estadual de Itapuã, RS, Brazil (30°22'S and 51º02'WGr), throughout the year. Four 500 m long transections, embracing different vegetation types, were established, in which a survey of thysanoptera species is being carried out and information on their natural history is recorded. In each transection, five points, 100 m apart from one another, were marked, and at each of these points two stations were set: one by the transection and another 1,5 m away from it. At these stations, flowers, branches, grasses and litter are sampled. Up to now, a total of 4,289 thrips was recorded; amongst those specimens identified so far, 49 belong to the Phlacothripidae family, 93 to the Thripidae and 3 to the Heterothripidae. The microhabitat with the highest thrip abundance was flowers (n=2689), followed by branches (n=765), litter (n=654) and grasses (n=181). Species richness, diversity and similarity will be estimated, for the different habitats, to evaluate the occurrence and distribution of thysanopterans in the area. Index terms: Thysanoptera, diversity, wild thysanopterans, neotropical fauna.

[0544] LITTER MICROARTHROPOD COMMUNITY IN AN URBAN FOREST STAND OF SÃO JOSÉ DO RIO PRETO, STATE OF SÃO PAULO, BRAZIL

D. Prieto¹, A. R. Oliveira² & <u>I.C. Bonfanti-Almeida³</u>, ¹Depto. de Biología Animal y Humana, Facultad de Biología, Universidad de La Habana, CP 10400 La Habana, Cuba. E-mail dania@fbio.oc.uh.cu, ²Setor de Zoologia, ESALQ/USP, CP 9, CEP 13418-900, Piracicaba, SP, Brasil, E-mail arolivei@carpa.ciagri.usp.br, ³Depto. de Biologia, UNIRP, CP 593, CEP 15025-400, São José do Rio Preto, SP, Brasil, E-mail bonfanti@unirpnet.com.br.

Despite the obvious importance of the microarthropods inhabiting the litter, relatively little is known about their community structure and dynamics in forest stands of urban areas subject to human interference. On this basis, a research was conducted in a seasonal semideciduous forest located at Bosque Municipal from São José do Rio Preto, State of São Paulo, Brazil. Litter samples were taken on 10 occasions with approximately 2-week intervals between late November 1998 and late April 1999. Microarthropods were extracted by means of Berlese-Tullgren funnels. The community appears to be dominated by Acari (55.0%), followed closely by Collembola (43.0%). Polyxenida, Pscoptera and Protura comprised only 2.0% of the total fauna. The mean density of all taxa for the whole period was 9,801±832 individuals m². Acari and Collembola resembled each other in the pattern of temporal fluctuation, but the variations in density were particularly significant for Collembola. Oribatida comprised 67.0% of total Acari collected. Oribatids were classified into 41 species belonging to 30 genera and 25 families. Among these, 4 species and 12 genera are new records for the State and 4 species and 2 genera for the country. Dominant and frequent oribatid species included Rostrozetes foveolatus, Scheloribates praeincisus and Galumna glabra. The aggregated pattern of horizontal distribution and abundance of the microarthropod community is related to the presence of a mosaic of microsites of varying amounts of litter and to the moisture content. Tha degree of environmental disturbance on the community structure is examined. Index terms: Acari, Collembola, mesofauna, Oribatida.

[0546] TRADITIONAL AND MOLECULAR APPROACHES TO GLOBAL HYMENOPTERA TAXONOMY

D.L.J. Quicke¹, ¹Center for Population Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, UK; Unit of Parasitoid Systematics, CABI Bioscience UK Centre (Ascot), Department of Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, and Department of Entomology, The Natural History Museum, London SW7 SBD, UK, E-mail d.quicke@ic.ac.uk.

Without doubt one of the three largest orders of insects and proportionately one of the least studied taxonomically, the Hymenoptera pose a major challenge for future taxonomists. While new species are being discovered every year in the United Kingdom (an unusual occurrence for many insect orders), it is possible to catch undescribed hymenopterans with ease. But kowing for sure that they are undescribed is a different matter. Thus using conventional taxonomy might not be the best way forward, as there is an undeniable shortage of morphotaxonomists relative to the task in hand. I propose that the way forward is to collect and process specimens with the intention that the material should be accessible equally both to DNA sequence analysis and to morphological investigation. Indeed, given the simple way that computers can now compare DNA sequences means that this methodology could largely replace morphological investigation in the first instance. Knowledge of the hierarchical way in which genes typically vary means that it ought to be easy to identify gene fragments that not only will uniquely place each sampled / sequenced entity in a putative species, but also in its more or less correct systematic position - surely no worse than the present situation. As it is unlikely that we will fully describe and illustrate all Hymenoptera within the next century using traditional processes, using new molecular techniques offers many advantages that will be discussed Index terms: Wasps, biodiversity, systematics, taxonomy, description, cryptic species, DNA.

[0545] MEASURING DIVERSITY OF CLOUD FOREST BUTTERFLIES ALONG ELEVATIONAL TRANSECTS - THE NEOTROPICAL TRIBE PRONOPHILINI (LEPIDOPTERA, NYMPHALIDAE, SATYRINAE)

T. W. Pyrczł, ¹Zoological Museum, Inst. of Zoology, Jagiellonian Univ., R. Ingardena 6, 30-060 Kraków, Poland. E-mail: pyrcz@zuk.iz.uj.edu.pl.

When evaluating diversity of montane butterfly faunas one may encounter difficulties which arise during estimation of an area related index (alpha or gamma). These indices are especially easy to distort. Therefore, a method combining within-area and betweenarea beta indices is proposed and termed the Potential Vertical Transect (PVT). PVT is the measure of the total number of species of an indicator group along an ecological gradient, where altitude is an exponent of habitat change. PVT data are extrapolated from samplings taken by the author in most discussed localities, mainly from 1500 to 3500 m by means of altitudinal transects based on a series of baited traps set every 25 -50 m. Additional data are obtained from literature and from museum specimens. In the cloud forests of the Neotropical realm, the tribe Pronophilini with over 500 species, is the best model group for measuring diversity. Butterflies of this group occur in well defined and usually narrow altitudinal bands with a noticeable percentage of endemic taxa. Adults show little vertical or horizontal vagility, they are numerous and show little variation. The results show invariant proportions of each genus or group of Pronophilini in each PVT especially in the group of "large Pronophilini" composed of 12 genera and in the genus Pedaliodes (sensu stricto). When a correlation analysis betwen latitude and 10 east Andean PVTs is applied, a strong correlation is obtained. Peripheral PVTs as those for Tucuman and for some northern areas where low species richness is a clear-cut effect of narrower altitudinal extension, are not included. The local diversity hotspot in southern Ecuador at 4° South can be explained as an effect of local topographic conditions leading to the overlapping of the west and east Andean faunal pools in that area. The gradient obtained in this study culminates at latitudes 13°-16° which is closer to the Tropic of Capricorn than to the Equator, and is obviously related to climatic factors nor to the habitat area which for long were thought to be responsible for geographic differenciation of species richness,

Index terms: distribution patterns, biodiversity gradients, vertical transects

[0547] HABITAT CONSTRAINTS AND PATTERNS OF DIVERSITY

<u>I. Ribera</u>¹, G. N. Foster² & A. P. Vogler¹, ¹Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, and Department of Biology. Imperial College at Silwood Park, Ascot SL5 7B, UK, E-mail ignr@nhm.ac.uk: ²Environmental Division, The Scottish Agricultural College, Auchineruive, Ayr KA6 SHW, Scotland, UK.

Certain large-scale patterns in species richness (e.g. latitudinal gradients, species-area relationships) are well known and robust ecological regularities. Most of the many explanations that have been proposed depend on geographical variables correlated, ultimately, with area and latitude. However, these explanations typically fail to identify underlying causal mechanisms and, equally, to demonstrate a connection between the scale at which diversity is varying with the scale at which the supposed processes affecting the diversity operate. In Europe, two contrasting types of freshwater habitat can be identified, with markedly different persistence values. Rivers and streams persist over relatively long periods, and are semi-permanent features of the landscape. In contrast, small to medium-sized stagnant water bodies are short-lived, and discontinuous in time and space. Most water beetles inhabit only one of these two habitat types, with a minority able to live in both (in western Europe the overall proportions are: 43% of species in running water, 38% in stagnant, and 19% in both). Running water species have smaller range sizes than stagnant water specialists, and this is explicable on habitat persistence as a constraint on the evolution and ecology of these insects. A model for water beetles in 15 areas in western Europe, based solely on total area, minimum latitude and a measure of mainland "connectivity", predicts with great accuracy the total number of species per area. However, when this beetle pool is divided into running water and stagnant water specialists, the results are very different. For running water species within each area, minimum latitude (seen as a surrogate for proximity to glacial refugia) is the variable with the highest correlation. For stagnant water species, the main explanatory variable is connectivity. These differences remain essentially the same when the data are divided amongst the four main phylogenetic groups represented (Hydradephaga, Hydrophiloidea, Hydraenidae, Dryopoidea). Thus, when species are separated according to a biologically significant variable (e.g. habitat persistence), their differing requirements and responses can be inferred to be the very processes that generate the observed overall patterns of diversity. An improved ability to understand these underlying causal mechanisms will enable us to make much better predictions about the extent and distribution of diversity, especially in poorly known or under-worked areas.

[0548] THE SPIDER FAUNA FROM SUGAR CANE CROP, SÃO PAULO STATE, BRAZIL

<u>I.M. P. Rinaldi</u>¹ & B. P. Mendes¹, ¹Depto. de Zoologia, Instituto de Biociências, Universidade Estadual Paulista,18618-000, Botucatu, SP, Brasil, E mail rinaldi@ibb.unesp.br.

The spider fauna (Araneae) from sugar cane crop was monthly surveyed by handling and beating in an extensive crop area of Botucatu, State of São Paulo, Brazil. Composition and richness (families and species), microhabitats preferences, diversity and eveness indexes of their fauna were analysed. A total number of 1,295 spiders belonging to 83 species and 20 families were collected. The most diverse families were Theridiidae, Salticidae, and Araneidae, and the most abundant ones were Theridiidae, Salticidae, Anyphaenidae and Titanoecidae. Seven species represented 58.6% of the total fauna, whereas *Crysso pulcherrima* weaver, alone, made up to 28.2%. About 56.6% of the spiders occupied the stratum 20 cm from the soil. Spiders were always present throughout the development of the crop. Along with the supression of the previous burning of the sugar cane crop, the importance of knowing these natural enemies increases.

Index terms: Araneae, sugar cane crop, spider diversity, natural enemies

[0550] AN UNEXPLORED STORE OF THE EQUATOGUINEAN BIODIVERSITY IN THE MUSEO NACIONAL DE CIENCIAS NATURALES

A. Sánchez¹, C. M. Santos¹ & <u>I. Izquierdo</u>¹, ¹Departamento de Colecciones y Documentación. Colección de Entomología, Museo Nacional de Ciencias Naturales, c/ José Gutiérrez Abascal, 2. 28006 Madrid, Spain. E-mail izquierdo@mnen.csic.es.

The Museo Nacional de Ciencias Naturales houses a great amount of specimens from Equatorial Guinea, which were collected during the first half of the 20th Century, when this country was a Spanish colony. The information on this material is being retrieved by the ongoing project *Inventario y Catálogo de las colecciones de fauna de Guinea Ecuatorial en el Museo Nacional de Ciencias Naturales.* The highest percentage of specimens are insects. In this paper, the information related to four superfamilies of Coleoptera -Chrysomeloidea, Elateroidea, Scarabacoidea and Tenebrionoidea-of this material is provided. Information regarding collecting data (more significative localities and collectors), as well as taxonomic data (type specimens, percentage of identified material, which can be very useful for the specialists on Afrotropical Coleoptera interested in the study of the biodiversity of this area. The way to access to this biodiversity resource through the Museo Nacional de Ciencias Naturales web site and by loan request to the Entomology Curators of the Collections Department is included.

Index terms: Coleoptera biodiversity, Afrotropical fauna, entomological collections, web site

[0549] ZOOGEOGRAPHICAL ANALYSIS OF THE FAUNA OF TERRESTRIAL HETEROPTERA FROM ROMANIA

I. Rosca¹ & <u>C. Popoy²</u>, ¹ Univ. Agricultural Sciences and Veterinary Medicine, Ave. Marasti 59, Bucharest, Romania; ² Research Inst. for Cereals and Industrial Crops, 8264 Fundulea, N. Titulescu Str., 1, Calarasi District, Romania, Email:fundulea@cons.incerc.ro

Romania is situated in Europe, at the crossroads towards Asia, and Africa, and its fauna including terrestrial heteroptera fauna, has faunistical elements proceed from these three continents, showing a large diversity which has to be knowed and preserved. Methodology. On the basis of literature and personal researches it was done world areal (spreading in the whole world) of each heteroptera species and they were enframed like zoogeogrphical elements. The whole fauna of terrestrial Heteroptera of Romania was zoogeographical compared to that from Egypt, Israel, Turkey and Central Asia (Tien Shan). It was calculated, on the species, differentiation and correlation index. Results. The 693 species of terrestrial Heteroptera recorded till the present time in Romania, which belong to 25 families, were from 9 zoogeographical elements (Cosmopolitan, Holarctic, Palearctic, Euro-Siberian, European, Mediterranean, Ponto-Mediterranean, Turanic and Endemic) which are unanimously agreed on by the various authors interested in this subject. Among the 693 species of terrestrial Heteroptera recorded in Romania, 6 are Cosmopolitan, 53 Holarctic, 61 Palearctic, 12 Euro-Siberian, 169 European, 191 Mediterranean, 53 Ponto-Mediterranean, 23 Turanian and 9 are endemic species. It can be seen that fauna of terrestrial Heteroptera of Romania contains less endenuic species than the other areas surveyed (i.e. 1.3%), this being due to the fact that Romania is not separated from the surrounding countries by effective geographic barriers, and that similar environmental conditions occur in a wide area. Taking into account relationship of terrestrial *Heteroptera* from 9 geographical zones of Europe, Asia and Africa, accordingly differentiation and correlation indexes, differentiation don't exceed value of +0.53 between Germany and North-East Africa, and correlation is highest between Romania and Ukraine (-0.61). There is not any strong differentiation or correlation between lower and higher zones of Romania, from point of faunistical species index (+0.024). Conclusions. Terrestrial Heteropteran fauna is well represented in Romania, having a large diversity. The comparison and mathematical analysis of the data on the Heteroptera fauna of Romania to that of Egypt, Israel, Turkey and Central Asia shows that the similitudes and differences are related particularly to the geographic position and the climate conditions. Key words. Heteroptera, differentiation, correlation, faunistical species index.

[0551] PATTERNS OF ANIMAL DISPERSAL, VICARIANCE AND DIVERSIFICATON IN THE HOLARCTIC

<u>I. Saumartín</u>¹, F. Ronquist¹ & H. Enghoff², ¹Dept. of Systematic Zoology, Evolutionary Biology Center, Univ. of Uppsala, Norbyvägen 18D, SE-75236, Uppsala, Sweden. E-mail: isa@mnen.csic.es; ²Universitetets Zoologisk Museum, Universitetsparken 15, DK-2100 Copenhagen, Denmark.

We analysed patterns of animal dispersal, vicariance and diversification in the Holarctic based on phylogenies of 57 nonmarine taxa, comprising 770 extant species connected by 713 speciation events. The selected phylogenies included a complete or almost complete sample of the species in each group. Age estimates suggest that the biogeographic events documented by the phylogenies span from the Late Mesozoic to the present. Four major areas were used in the analyses: eastern Nearctic (EN), western Nearctic (WN), eastern Palaearctic (EP) and western Palaearctic (WP); each area corresponding to a historically persistent land mass according to palaeogeological reconstructions. Parsimony-based tree litting shows that there is no hierarchical vicariance pattern, that is, there is no general area cladogram that can adequately describe the historical biogeography of the Holarctic. Yet, distributions are strongly phylogenetically conserved, as revealed by dispersal-vicariance analysis (DIVA). Permutation tests were used in conjunction with DIVA to pinpoint phylogenetically determined dispersal patterns. Continental dispersals (EP \leftrightarrow WP and EN \leftrightarrow WN) are significantly more common than palaeocontinental dispersals (EP \leftrightarrow WN and WP \leftrightarrow EN), which in turn are more common than disjunct dispersals (EP \leftrightarrow EN and WN \leftrightarrow WP). Within the Nearctic, (WN \rightarrow EN) dispersals are significantly more common than (EN \rightarrow WN) dispersals; within the Palaearctic, (EP \rightarrow WP) dispersals are more common than (WP \rightarrow EP) dispersals. Cross-Beringian faunal connections have traditionally been emphasized but they are not more important than cross-Atlantic connections in our data set. To analyse biogeographic patterns in more detail, we dated all nodes in each cladogram and then sorted the frequency of biogeographic events into time-intervals. Independent evidence (e.g., fossil record) or Holarctic biogeographic events were used to date the oldest and some interior nodes in each cladogram, and then the age of all other nodes was determined using a "branching clock". Trans-Atlantic distributions (WP-EN) were most common in the Early-Mid Tertiary time-class (70-20 mya), whereas trans-Beringian distributions (EP-WN) were least frequent in that period. The disjunct distribution EP-EN was most frequent in the Early Tertiary (70-50 mya). Diversification patterns differed among areas: the species richness of WN and WP increased during the Quaternary (< 3 mya), whereas the species richness of EP and EN increased during the Tertiary (70-20 mya).

Index terms: Historical biogeography, trans-Atlantic, trans-Beringian, disjunct distributions.

[0552] CHANGE OF INSECT DIVERSITY AS A GREAT MYTH

V. B. Sapunov, Scientific Res Center of Ecol Safety, Korpusnaya, 18, St. Petersburg, 197110, Russia, E-mail sapunov@VF4493, spb.edu

The important task of global ecology is essay of species diversity within taxon, ecological system and biosphere. This task has relation to a big number of international programs of variability and diversity safety. Theoretical basis of such a programs is not sufficient firm because the following questions are unclear: 1. How much species exists? 2. What is biological variability of main classes of animals andplants? 3. What is tempo of extinction? 4. What is temp of new species appearance (and does this process take place)? The first scientist who proposed approach for this problem was V.Vernadsky, which theory of biosphere is needful for deciding of the question. The present work is synthesis of this theory with empirical data gotten at field insect population. Modern ecology has no methods appropriate for general check of biological diversity of the biosphere. The real approach toward resolve of this question is use of insects as numerical well studied and representative group and any representative region of the Earth. This local data may become base for works toward study of general diversity and pattern of distribution of the species within taxons and ecological niches. The present work consider insects of natural landscape "Veppsky les"(North-West of Russia) as material for modeling of general species diversity. Insect species may be distributed into three groups - dominant, rare and hidden. Quantitative relations between them may be described by mathematical model. Majority of species are hidden, that is undetectable by methods of field ecology. The number of them may be between 30 000 000 and 1 billion, and the last mean is more real. During evolution of ecological systems pattern of distribution of insects within three groups may change. Sometimes extinction of insects is not real but means that population got state of hidden. Decrease of insect population doesn't make any ecological niche free They occupied by other species of animals. Because of great resistance of ecological systems, artificial control of insects has no sense. The number of insect species, biological mass of them and distribution within ecological niches are fundamental constants of biosphere.

Index terms: biosphere, insects, species diversity

[0554] BIO-DIVERSITY OF MOSQUITOES IN THE RIVER CAUVERY BASIN, KARNATAKA STATE INDIA

N. J. Shetty, Centre for Applied Genetics, Bangalore Univ., J. B. Campus, Bangalore 560056, Karnataka, India. E-mail: bnguni@kar.nic.in

The river Cauvery originates in the Western Ghats in the Coorg district and lies in Karnataka India to an extent of 42.2% of its total area of 81,155 sq km and flows for a length of 320 km out of its total length of 804 km in the state. Its major tributaries in the state are Hemavathi, Lakshmantheertha, Harangi, Kabini, Suvarnavathi, Lokapavani, Shimsha and Arkavathi. The area of basin in Karnataka comprises seven districts namely Coorg, Hassan, Mysore, Mandya, Chikamagalur, Tumkur and Bangalore rural totaling 34,273 sq km and an average annual flow of 11,000 M Cum, finally flowing into the Bay of Bengal in Tamil Nadu. This paper summarizes the diverse mosquito fauna at 27 different sites of river Cauvery basin (from Thalakaveri to Makedatu) for one calendar year in different seasons i.e., summer, autumn and winter. Mosquitoes were collected in the form of larvae, pupae and adults and were identified and classified. These included primary malarial vectors such as Anopheles stephensi, An. fluviatilis, An. subpictus, An. culicifacies and An. maculatus; secondary vectors like An. aconitus, An. annularis, An.varuna and other species like An. jamesi, An. karwari, An. majidi, An. vagus, An. splendidus. An. hyrcanus, An. barbirostris, An. tessellatus, An. pallidus, An. leucosphyrus, An. ramsi, An. gigas and An. jeyporiensis. An. dthali recorded in the present study is a very rare species and for the first time the said species is being reported from South India. Different species of culicine mosquitoes were also collected. These included primary vectors such as Culex quinquefasciatus, Mansonia uniformis (filarial vectors), and Cx. tritaeniorhynchus (vector for Japanese Encephalitis). In addition to this, other species like Cx. gelidus, Cx. vishnui, Cx. mimmulus, Cx. armigeres, and Cx. bitaeniorhyncus were also collected. Insecticide susceptibility tests were carried out on different species of mosquitoes of the basin area by using larvicides and adulticides supplied by W.H.O. These included organochlorines (DDT and Dieldrin) organophosphates (Parathion, Fenthion and Malathion), synthetic pyrethroids (Permithrin) and carbamate (Propoxur), Vector incrimination studies for malaria and filaria parasites have also been carried out from the field collected adult females.

Index terms: Anopheles, Culex, malaria, filaria, vector incrimination.

[0553] MUSEUM COLLECTIONS FOR ASSESSING INSECT BIODIVERSITY IN THE 21ST CENTURY: NEW METHODS AND TRADITIONAL ANALYSIS

M.J. Scoble¹, ¹Dept. of Entomology, The Natural History Museum, Cromwell Road, London SW7 SBD, UK, E-mail m.scoble@nhm.ac.uk.

The millennium coincides with a major social change, with the explosive development of information technology creating the potential to bring about the democratization of information. But while the "information age" is expected to have an impact on society similar in magnitude to the Industrial Revolution, it is still in its infancy: its patterns of behaviour are semi-chaotic and as yet largely unstructured. Even so, electronic access to data opens up whole new possibilities and ways of working. Especially notable is the potential for access to images, not only just to see what an organism looks like, but also as a means to key into information held in databases. Indeed, through digitization, civilization seems to be rediscovering the value of images, which have provided the dominant, non-oral form of communication for most of its history. For insects, not only do the world's museums held collectively the best sample of the known biodiversity, but also specimens and associated art-work are also excellent sources of digital images. However, the value of access to all this information depends on the quality of the data, including a deep knowledge of what those individual specimens and the images derived from them actually mean. We still need analysis, or what in descriptive taxonomy is often called revision. Taxonomists need to emphasize the highly analytical component in revisionary work: it tends to be overlooked, and is not helped by a parochial (noncontextual) approach still to be seen in too many descriptive papers. But new approaches are also required in the form of a sharper focus on key taxa and special geographical areas-albeit with revisionary work placed in a global context. The new technology has eased global networking for taxonomists, notably by means of e-mail. Moreover, interoperability across databases and interworking across different domains are likely to provide a greatly increased capacity for us to broaden the scope and social impact of our work. Although this means much more than just adopting new techniques of electronic communication, the potential for synergy within digital space will provide us with the means to reach a much wider, if diffuse, user community than has been possible hitherto. Index terms: taxonomic data, revisionary taxonomy, information technology.

[0555] DIVERSITY OF HYMENOPTERA IN AREAS OF PRIMARY FOREST FRAGMENT, REGENERATION FOREST AND PASTURE AT THE SOUTHEAST OF ACRE, BRAZIL

M. A. Silva¹, <u>A. P. B. W. Thomazini</u>¹, M. J. Thomazini¹ & E. S. Albuquerque¹, ¹Embrapa Acre, P. O. Box 392, Rio Branco, AC 69901-180, Brazil, E-mail ariane@epafac.embrapa.br

Insects of the Hymenoptera order carry out ecological functions of prominence, because, many of them are important for the pollination processes and dispersion of plant species, besides they act as predators and parasits of several agricultural and forest pests. The objective of this work was to evaluate the diversity of the hymenoptera fauna in a large forest fragment (800 ha) and adjacent areas, through surveys at fragmented primary forest, secondary forest (regeneration) and pasture. Eight samples (april to november/99) were taken in each area, using light traps of "Luiz de Queiroz" model, wich remained turned on during one night, monthly. The captured insects were taken to the Entomology Laboratory of Embrapa Acre, where specimens were separated, mounted and identified at the level of families and morphospecies. After that, a faunistic analysis was made, calculating the diversity index (α) of each area and the similarity quotient (QS) among areas. The indexes of abundance, frequency, constancy and dominance were also calculated for each morphospecies. It was obtained a total of 1943 individuals, of 486 morphospecies. Hymenoptera diversity was higher inside the fragment (a=33.1), that in adjacent areas of regeneration (α =26.9) and pasture (α =15.2). According to the obtained abundance indexes, most of the species collected in the fragmented forest (66.2%), regeneration forest (64.9%) and pasture (46.1%) were considered rare. In the pasture, occured the greatest proportion (79.4%) of not very frequent species. There were not constant species in the sampled areas and, in all of them, more than 74% were considered as of accidental occurrence. Three morphospecies in the fragmented forest (two of Vespidae and one of Halictidae), two in the secondary forest (one of Formicidae and one of Halictidae) and three in the pasture (two of Formicidae and one of Vespidae) stood out as predominant. There was a higher similarity between the areas of primary forest and regeneration (20.8%) than between regeneration and pasture (15.2%), being 13.5% the similarity between primary forest and pasture, and just 7.4% the similarity among the three sampled areas. It was concluded that deforestation and forest fragmentation processes on the southeast of Acre cause changes in the Hymenoptera community, besides they contribute to the reduction of richness and diversity of the local species.

Index terms: Faunistic analysis, tropical rainforest, Occidental Amazonia.

[0556] PRELIMINARY CHECK LIST OF ISOPODA (ARTHROPODA: CRUSTACEA) IN RÍA DE VIGO (NO ESPAÑA)

S. Soto, J. Garrido & F. Ramil, Departamento de Ecología y Biología Animal, Facultad de Ciencias, Universidad de Vigo, 36200 Vigo, Spain, E-mail: soto@uvigo.es.

The monographic studies about isopods in the NW of Spain come down to one only work refered to "Ría de Ferrol", while there are only internitent mentions of some species in the rest of the coast, and they are always included in general studies of the marine benthos. This study of rocky shores isopods in "Ría de Vigo" covers eight areas distributed along the ría. The samples were taken in UTL, MTL and LTL till 30 meters deep. These samples were carried out following a perpendicular transect to the coast line and with quarterly interval. In MTL the material was collected during spring tide every month. In LTL the samples were take diving, at different barometric levels according to the different communities or "facies" found in the area of study. In this communication are presented the results obtained for the samples which were carried out during the first quarterly in 1998. Up to now 2699 samples have been studied, which belong to 24 species in 18 genus, 8 families and 5 suborders.

Index terms: isopods, crustaceans, marine benthos

[0558] WHY DOES SPECIES RICHNESS INCREASE WITH FRAGMENT SIZE? PASSIVE SAMPLING IN ATLANTIC FOREST CRICKETS

C. F. Sperber¹ & A. Mesa², ¹ Unid, de Estud, em Ecol. de Comunid., Dep. Biologia Geral, Univ. Fed. Viçosa, CEP 36571-000, Viçosa, BRAZIL / Graduate program, Dep. Biologia, Inst. Biociências, UNESP, E-mail sperber@mail.ufv.br² Dep. Biologia, Inst. Biociências, UNESP, Av. 24A, nº 1515, CEP 13506-900, Rio Claro, SP

One of the few ecological "laws" is that species richness increases with habitat area. The explanations for this pattern range from island biogeography theory to sampling artefact. In this study I tested this "law" and two alternative explanations for it: (1) larger forest fragments presented greater habitat diversity for the crickets, and (2) larger forest fragments represented larger samples of the regional species pool, with no other effect on species composition but sample size. I sampled litter crickets in 18 forest fragments of semi-deciduous forest (Viçosa, MG, Brazil, 20°45'S, 42°50'W), ranging from three to 300 ha. Sampling was done with pitfall traps, located in 36 randomly located sites, in the rainy season of three consecutive years. 3765 adult crickets were sampled, belonging to 22 species, most of them new to Science. Cricket species richness increased linearly with the logarithm of forest fragment area. Data were analysed with generalised linear models, with fragments as replicates. If habitat diversity explained this relation, species similarity within fragments should decrease with increasing area. This was evaluated in two hierarchically nested spatial scales, within each fragment. If passive sampling explained the species-area relationship, (1) similarity should be independent of fragment size, (2) species richness and composition per sample should be independent of area, (3) observed species richness in the fragments should not differ from that expected by passive sampling simulation, and (4) distribution of cricket species between fragments should conform nested subsets. Similarity was independent of area in both spatial scales. Species richness and composition per sample were independent of area. Species richness in the fragments did not differ from that expected for the passive sampling simulation in 83% of the fragments. Species distribution was more nested than expected for random allocation simulation. I concluded that the species-area relation was due to passive sampling. Forest fragment size did not affect cricket species composition nor local richness. Cricket species location was homogenous throughout the forest habitat, and was independent of area. Where the cricket species not affected by forest fragmentation? I infer that either habitat loss in the studied region was still small for these insects, or cricket species that are sensitive to forest fragmentation were already extinct.

Index terms: species-area, Orthoptera, Grylloidea, diversity, habitat fragmentation

[0557] OWLET MOTH DIVERSITY (LEPIDOPTERA: NOCTUIDAE) COLLECTED WITH BLACK-LIGHT TRAP, IN SALVADOR DO SUL, RS, BRAZIL

A. Specht^{1,2} & E. Corseuil², ¹ Curso de Agronomia, UNISUL, Av. José Acácio Moreira, 787, CEP 88704-900, Tubarão, SC, Brasil, E-mail spechta@pucrs.br; ² PPG Biociências, PUCRS Av. Ipiranga, 6681, C. Postal 1429, CEP 90619-900, Porto Alegre, RS, Brasil, Email corseuil@pucrs.br.

The lepidoptera group forms one of the largest orders of insects and is referred as particularly appropriate for biodiversity studies and detection of environmental changes. The moths are relatively easy to sample because most species can be collected by using simple light traps in great number of species and individuals. This makes them particularly adapted for biodiversity approaches. The Noctuidae constitutes the largest macrolepidopteran family, large represented in Neotropical Region. The objective of this work is to evaluate the abundance and diversity of species, esteemed through the more frequently used indexes. The experiment was carried out in Salvador do Sul, RS; placed on 29°27' S, 51°30' O, altitude 610 meters, presenting subtropical climate. Fifty weekly collections were made, beginning on August 07, 1994, using two Pennsylvania black-light traps with lamps F15 T8 LN. The estimates of abundance of species and diversity indexes were generated though the EstimateS Richness Estimator Program version 5.0.1. One hundred randomization's and 10 abundance classes were used in the analyses. Of the total 3,974 noctuids belonging to 108 species and distributed in 14 subfamilys was captured. It was verified the richness of species per month of capture and observed that spring months (October to December) had the highest values. In these months 88,9% of all registered species were captured, although they were not the main months for abundance. Whatever richness 19 species are singletons 9 doubletons which could be considered rare or infrequent. The diversity indexes obtained with respective standard deviations in parentheses are Fisher Alpha 20.48 (0.88), Shannon-Wiener 3.37 (>=0.01) and Simpson 15.4 (0.46). The prediction of the total richness was 215 species for 1st-order Jackknife's method, 320 species for the 2nd-order Jackknife's and 148 for the Bootstrap's. Index terms: Ecology, Biodiversity, Inventory.

[0559] A VIEWPOINT ON PATAGONIAN BIOGEOGRAPHY FROM THE CERATOPOGONIDAE CASE (DIPTERA: NEMATOCERA)

G. R. Spinelli¹ & J. Muzón¹, ¹Departamento Científico de Entomología, Museo de La Plata, Paseo del Bosque s/n. 1900 La Plata, Argentina, E-mail spinelli@museo.fcnym.unlp.edu.ar

One of the most conspicuous areas of the austral landmasses is Patagonia, which is as well one of the largest areas located in the southern cone of South America. It is composed by two main biomas, strongly influenced by rainfall patterns: temperate forest ans steppe. Forest, located at both slopes of the Andes, are dominated by about ten species of southern beeches of the genus Nothofagus, being the biota characterized by a high degree of endemicity, showing a close relationship with fauna and flora of Australia, New Zealand and neighboring islands. On the other hand, the steppe, a large zone located east of the forest, is dominated by scattered low shrubs and bunch grasses, and its biota is currently accepted to be composed by depauperate guyano-brazilic components. Despite the different names, ranges and/or categories given to the Patagonian biomas within the published biogeographical schemes, it is widely accepted that their biotas are represented by taxa with remarkably distinct biogreographical significance, and therefore from a different origin. In this comunication, some of the currently accepted ideas about the origin and settlement of the taxa inhabiting the patagonian steppe are discussed from data on recent collections of small-sized migdes of the family Ceratopogonidae. The findings in the Valcheta stream basin (40° 59' S, 66° 40' W, altitude 630 m, in the northern slope of the Somuncurá plateau), Sierra Cuadrada plateau (44º 37' S, 67º 59' W, altitude 520 m) and valley of the river Pinturas (47º 09'S, 70° 39' W, altitude 520 m) of species belonging to genera of indubitable transantarctic origin (Paradasyhelea and Macrurohelea) suggest that current biogeographic schemes highly simplify the Natural History of Patagonia, postulating a clear distinction between the two main biomas. As it is known, during Pliocene and Pleistocene periods climate and vegetation drastically changed in Paragonia, becoming the area progressively cooler and drier. The steppe localities where species of Macrurohelea and Paradasyhelea were found during our field work, could represent areas with persistent favourable environmental conditions due to the permanent water supplies mainly by small springs. Thus, the manteinance of healthy vicariant populations of species belonging to ancestral genera could have been possible, being the desertification the herein postulated vicariant event. Finally a closer relationship between the above mentioned biomas is suggested considering records gathered from taxa inhabiting aquatic ecosystems in the steppe, which were scarcely considered previously. Index terms: Paradasyhelea, Macrurohelea, Patagonia, forest, steppe

[0560] SPECIES DIVERSITY AND FUNCTIONAL DIVERSITY OF TERMITES IN EASTERN ASIA

<u>Y. Takematsu¹</u>, **T. Abe²**, **F. Hyodo²**, **A. Sugimoto² & N. Kirtiburt³**, 1 Lab. of Chemical Ecology, Kyoto Institute of Technology, Kyoto, Japan, E-mail: takematu@ipc.kit.ac.jp, 2 Center for Ecological Research, Kyoto University, Kyoto, Japan, 3 Faculty of Agriculture, Kasetsart University, Bangkok, Thailand

Termites are widely distributed over temperate zones to the tropics, and play a crucial role in forest ecosystems as a decomposition agent. The purpose of this study is to examine how the species diversity of termites and their decomposition ability vary in the different types of forests. Eastern Asia is particularly an ideal model for this study because along its coasts there lay various types of forests from temperate forest to tropical rain forests. In this study we present the species diversity as well as functional diversity of termites in the following types of forests along the Eastern Asia coasts: tropical rain forest, dry evergreen and dry deciduous forests, and subtropical rain forest. In each type of forest, species richness of termites was assessed using the standard sampling method described by Eggleton et al. (1997). Decomposition ability was evaluated by a "comparative biomass" defined by (encounter frequency of each species)(its wet weight) instead of actual biomass, which is very difficult to measure. Then, termites were classified into the following three functional groups according to their decomposition activities: Non fungusgrowing wood feeder: Termites feeding on cellulose materials Fungus-growing wood feeder: Termites growing fungus, feeding on cellulose and lignin Soil feeder: Termites distributed in the soil, not feeding on cellulose and lignin. It was found that the species composition and functional group composition are different among forest types. The Macrotermitinae, which belongs to the fungus-growing wood feeder, was a dominant group in dry evergreen and dry deciduous forests. Soil feeding termites showed the highest diversity in tropical rain forest and decrease the species richness with increase in latitude. Non fungus-growing wood feeder was dominant in subtropical rain forest and tropical rain forest. Wood-feeder fauna of subtropical rain forest comprised Kalotermitidae and Rhinotermitidae (the lower termites), while that of tropical rainforest mainly comprised Termitidae. "Comparative biomass" was an effective index to define the tendencies of functional group diversity. It makes remarkable the dominance of fungus-feeding termites in dry areas and wood-feeding termites in subtropical rain forest. The results were related to the differences in climates and vegetations of forest.

Key words: Isoptera, species diversity, functional group, comparative biomass

[0561] DIVERSITY OF COLEOPTERA IN A FOREST FRAGMENT, SECONDARY FOREST AND PASTURE IN THE SOUTHEAST OF ACRE, BRAZIL

A. P. B. W. Thomazini¹, M. J. Thomazini¹, M. A. Silva¹ & E. S. Albuquerque¹, ¹Embrapa Acre, P.O.Box 392, 69908-970. Rio Branco, AC., Brazil, E-mail ariane@cpafac.embrapa.br

Agricultural activities involving deforestation, in the State of Acre, Brazil, were responsible for the formation of different types of ecosystems such as pastures in several degradation levels and fallows with different regeneration ages. This research had the objective to evaluate the effect of ecological succession on the diversity of Coleoptera. Samples were collected, monthly, by light traps ("Luiz de Queiroz" model) in a fragment of primary forest with 800ha and adjacent areas of secondary forest (12 years) and pasture. from April to November of 1999. The coleopterous collected were identified at family level and separated into morphospecies. Data were analyzed using the faunistic indices of abundance, frequency, constancy, dominance, diversity and similarity quotient. Species richness was greater in the area of primary forest (502), followed by the secondary forest (429) and at last by the pasture (256). However, more individuals were collected in pasture (4126) than in the areas of secondary (1750) and primary (1734) forests. Consequently, a higher diversity index was found for the primary forest (67.16) than for the secondary forest (57.30), and for the pasture (30.61). In the three areas, most of the species was classified as rare and of accidental occurance. Five species of the primary forest were considered predominant (higher values of constancy, dominance, frequency and abundance), belonging to Lycidae (2) to Scolytidae (2) and Platypodidae (1). Only three predominant species were found in the secondary forest, belonging to Byrridae, Scarabaeidae and Scolytidae. The greatest number of predominant species was observed in the pasture (8) belonging to Scarabaeidae (Ataenius sp1, sp2, Aphodius sp., Digitonthophagus gazella and Onthophagus sp.) Chrysomelidae (Maecolaspis sp.), Scolytidae and Staphylinidae. A similarity quotient of 19.5% was recorded comparing primary and secondary forest areas. Comparing secondary forest with pasture the similarity quotient was only 9.3%. The lowest similarity was obtained by comparing primary forest and pasture (6.6%). Just thirteen species, belonging to Scarabaeidae (4), Scolytidae (4), Staphylinidae (3) and Curculionidae (2) were common to the three sampled areas. It was concluded that the community of Coleoptera is different at each stage of ecological succession, with observed alterations in its composition and reduction in its diversity, mainly in the pasture area.

Index terms: faunistic analysis, tropical forest, Occidental Amazonia

[0562] RHOPALOCEROS FROM IGUAZU NATIONAL PARK (MISIONES, ARGENTINA)

A.E. Tricio¹, H.A. Chaves² & C.I. Fernandez Diaz¹, ¹ Misiones Entomological Survey Project (PREM). Fac. of Exact, Chemical and Life Sciences. Universidad Nacional de Misiones. Félix de Azara 1552. (3300) Posadas - Misiones. Tel: 0054-3752-422186. Fax: 0054-3752-425414. E-mail: atricio@rector.unam.edu.ar. ² Delegación Técnica Regional Nordeste Argentino. Iguazu National Park E-mail: hugux@latinmail.com

This report presents a Rhopalocero's list including 13 months work, from october 1995 to november 1996. The observing and capture notes were taken at Iguazu Falls area, San Martin island, Palo Rosa's jungle, including some footpaths, paths inside the vegetation and occasionally any transects between the forest. Once a month, the work was made from 3 to 5 days depending on climate conditions. The butterflies were captured using net, with fruit traps, over flowers by hand, over excrement or near water's pond. During field work species were identified by direct observation. The identification in laboratory was made by comparing chromatic patterns with identified specimens from "Misiones Entomological Survey Project - PREM"'s collection and the identifications and taxonomic statements of Dr. Mielke (Parana Federal University, Brazil). This research is the result of a great effort from the participant team and the engagement between both institutions. The pictures and list can be found at Iguazú National Park. The list includes 11 families (Pieridae, Lycaenidae, Papilionidae, Nymbphalidae, Heliconiidae, Morphidae, Ithomiidae. Riodinidae, Brassolidae, Hesperidae and Satyridae), 70 genera and 130 species. The butterflies can be found at PREM collection. Index term: Rophalocera, butterflies, Iguazú.

[0563] DISTRIBUTION OF SOME SWALLOWTAIL BUTTERFLIES OF POSADAS, MISIONES, ARGENTINA

A. Tricio, S. Najle, C. I. Fernández Díaz & P. Morawicki, Misiones Entomological Survey Project (PREM). Fac. of Exact, Chemical and Life Sciences. Universidad Nacional de Misiones. Félix de Azara 1552. (3300) Posadas - Misiones. Tel: 0054-3752-422186, Fax: 0054-3752-425414. E-mail: atricio@rector.unam.edu.ar.

The study of the wealth of species of a certain area have a great importance, not only for its historical knowledge, but also for the global comprehension of its biodiversity. Among the animals, the butterflies and the birds constitute groups of easy visualization and identification, consequently they are good indicators. The intense human activity in Posadas city, given by the urban growth and the location of Yacyretá Dam, made a deep modification to the Fluvial and Fields District of vegetation. A great part of vegetation was lost by the increassing in the amount of water in the dam iake; the new flooded land would take place, reestablishing its dynamics allowing the reappearance of the different vegetable covering in the bank of the Paraná river, where the past expression was the jungle in gallery and the grassland. Therefore, the changes in the dispersion and reproduction of the plants will be able to affect the populational structure of the butterflies. In this instance, we want to show which are the species of Papilionidae Family present in the area that will be modified. The resulting data came from the sampling methods using net and recognition during flight of the well known species during a period of time including 14 months, from August of 1997 to October of 1998. The capture places have been: Arroyo Apepú, Barrio El Laurel, Toma de Agua, Jardín Botánico and Center of the city. The Swallowtail butterflies found were Mimoides Lysithous ssp. (Graphiini); Heraclides anchisiades capys, H. astyalus astyalus, H. hectorides hectorides, H. thous brasiliensis (Papilionini); Battus polydamas polydamas, Parides agavus, P. anchises nephalion (Troidini). The greatest diversity observed was at Barrio el Laurel through the months of April, September, and December. At Center and Toma de Agua points there was no record of this family. The fragile balance among plants and animals which inhabited the Earth has survived several episodes of massive extinction after millions of years of evolution. Now once again, but this time by the human influence with destruction of their habitats, the introduction of exotic species and the intensive and not sustained use of the biological resources. In the scientific forums and of political deliberation, the process of erosion of the natural resources comes being boasted as one from the most serious problems to be faced by the human population at the end of this century Index Term: Lepidoptera, Papilinionidae, Argentina

[0564] PRESENCE OF *DIURAPHIS NOXIA* (*HOMOPTERA: APHIDIDAE*) COLONIZING BARLEY CROPS IN THE CENTRAL AREA OF THE PROVINCE OF CÓRDOBA (ARGENTINA)

<u>G. A. Truol</u>¹; P. S. Herrera² & J. D. Arneodo³, 1. INTA; 2. CONICOR; 3. CONICET, IFFIVE - Instituto Nacional de Tecnología Agropecuaria (INTA). Camino a 60 cuadras km. 5½ (5119) Córdoba, Argentina. gratruol@cordoba.com.ar

Studies conducted on barley crops near Alta Gracia (Province of Córdoba, Argentina) showed aphid colonies of the Diuraphis noxia species, commonly known as "Russian Aphid' or "Wheat Russian Aphid", for the first time. This aphid had already been mentioned in this province in Manfredi but only occasionally were winged individuals captured in Moericke-type yellow traps. Colonized plants displayed sheathed leaves containing aphids in their basal section and featuring pale green longitudinal stripes which usually amounted to three and had different sizes. Samples for serological tests were obtained in order to determine whether symptoms were caused by either the insect itself or barley stripe mosaic virus (BSMV) and/or barley yellow dwarf virus (BYDV) infection, which symptoms are similar to the ones described above. Indirect ELISA was performed for BSMV and DAS ELISA for BYDV (PAV variant) but the assays failed to show any of these virus diseases. Moreover, samples for transmission electron microscopy were processed and no virions could be observed. Yet, severe alterations were noticed in chloroplasts concurrently with the results of visual observation. Aphid colonies could be reared in wheat (Prointa Federal cultivar) under greenhouse conditions and the same symptoms mentioned earlier appeared again. It is believed that such symptoms are due to vector action and attention should be thus paid to both the adaptation of the vector and its ensuing spreading into the cereal growing area in the province of Córdoba not only on account of the direct damage it causes but also on account of its ability to transmit, among other diseases, BYDV (widely spread in Argentinian grasses) with brome mosaic virus (BMV) as a helper.

Index terms: Russian aphid - barley - syptoms

[0565] RELATION BETWEEN THE DIVERSITY OF CARABID BEETLES AND DEER, MICE, AND DWARF BAMBOO IN A DECLINING ALPINE FOREST

<u>A. Ueda</u>, T. Hino, T. Shimada, H. Ito, Y. Takahata & II. Furusawa, Kansai Res. Ctr., Forestry and Forest Products Res. Inst., Kyoto 612-0855, Japan, E-mail akira@fsm.affrc.go.jp

Fragmented alpine forests in western Japan are at a crisis in their existence because of remarkable high density of deer that feeds seedlings and bark of trees, resulting in an impediment to the natural regeneration of trees and the death of adult trees. However, not only deer affect the natural regeneration of trees, but also mice, dwarf bamboo, herbivorous insects and their predators, infectious or mycotrophic fungi, and so on. Thus, to restore these forests while maintaining biological diversity, we need to understand the network of interactions between these organisms. By artificially controlling populations of deer, mice, birds, and dwarf bamboo, we are investigating how these four kinds of organisms individually or additionally affect the survival of seedlings, the occurrence of mycotrophy, the nature of the soil, populations of herbivorous insects, and the diversities of carabid beetles, creeping spiders and medium size soil animals. Our goals are to establish a simulation model for the dynamics of these organisms in relation to the natural regeneration of trees by clarifying their inter-relationships, and to develop technology for adequate management in order to restore these forests while maintaining biological diversity. The project was begun to management in 1997 at a fragmented alpine forest. Since carabid beetles are at the top of the food chain of small animals residing in the soil and understory, the diversity of carabid beetles is strongly related to the diversity of these small animals. Thus, 320 pitfall traps were set to investigate how deer, mice and a species of dwarf bamboo relate to the diversity of carabid beetles. The beetles were collected for 3 or 4 days in June, August and September in 1999. Beetle species present greatly differed between collection times. However, slashing of dwarf bamboo induced an increase in the average diversity (H') of the beetles at all collection times. On the contrary, the average diversity of the beetles was significantly correlated with the biomass of the dwarf bamboo in September at plots in which dwarf bamboo was not slashed. Moreover, although the absence of deer increased the biomass of the dwarf bamboo, the average diversity of the beetles was higher in plots without deer than with deer. An enclosure to exclude mice (also preventing entry by carabid beetles, except for those flying or tunneling) reduced the average diversity of the beetles. These results suggests that deer, mice and dwarf bamboo somehow affect the diversity of carabid beetles. These results are contradictory. Only continuous observations in the future will improve our knowledge from its present incomplete state to a more integrated perspective of these inter-relationships.

[0566] ESTIMATING INSECT DIVERSITY IN CENTRAL ARGENTINA: A COMPARISON AMONG TAXA AND HABITATS

<u>G. Valladares</u>¹, A. Mangeaud¹, S. A. Salvo¹, W. Almirón¹, M. A. Delfino¹ & S. I. Molina¹, ¹Centro de Investigaciones Entomológicas, FCEFYN, Univ. Nac. Córdoba, Av. Vélez Sársfield 299, 5000-Córdoba, Argentina. E-mail: grv@onenet.com.ar.

Natural habitats in Central Argentina are rapidly disappearing while their biodiversity remains poorly known. Fast and reliable estimations of such diversity are therefore needed. This contribution aims to provide comparable estimates of punctual (space / time) diversity and to evaluate the distinctness of local species assemblages, for 5 insect groups (from different trophic and environmental niches) in 4 of those habitats. Comparisons with further collections in space and time were also made in order to assess the accuracy of the former estimations. Leaf-mining Agromyzidae (Diptera), their parasitoids (Hymenoptera) and Aphididae (Homoptera) were collected along 5 transects (100m x 1m each), while Culicidae (Diptera) and Trichoptera were sampled by using 5 specific light traps for each group, Samples were taken in 4 localities representing different phytogeografic units (Chaco Hill Forest, Chaco Dry Forest, Espinal, Pampa). Observed and estimated (using Estimates 5.0) species richness at the studied localities were compared among taxa by Spearman Correlation analysis. Multivariate (cluster) analysis was performed to analyse distinctness of local assemblages regarding their specific composition. A total of 35 Agromyzidae, 19 Aphididae, 11 Culicidae, 37 parasitoids and 22 Trichoptera species were recorded in the punctual collections. Species richness distribution patterns were independent among taxa, though both phytophagous groups were richer in the Hill Forest while both aquatic groups were more diverse in the Chaco Dry Forest area. At the best studied habitat (Chaco Hill Forest), observed values of local species richness for each taxa ranged between 1/5 and 1/2 of the corresponding number of species known to occur throughout the area. Values noticeably closer to the latter were obtained by adding one sample, particularly for leaf miners (70% of the total number of species known in the area, and as many as those recorded after 30 monthly samples in a comparable locality). Proportion of singletons (0 - 0.75 for each group, 0.12 - 0.32 for each habitat), was also considered as an indicator of inventory completeness for each locality. Although each habitat accounted for less than half of the total species recorded in the region, the species assemblages found in the pampean locality showed the strongest and most consistent differences regarding taxonomic composition. The marked similarity of assemblages in the three other habitats could be expected from their closer phytogeographic affinity. Index terms: Agromyzidae, Aphididade, Culicidae, Parasitoids, Trichoptera

[0567] AQUATIC COLEOPTERA ASSEMBLAGES FROM SHALLOW LAKES ASSOCIATED TO THE CANAL DE CASTILLA (CENTRAL SPAIN)

L. F. Valladares¹, <u>J. Garrido² & F. García-Criado¹</u>, ¹Departamento de Biología Animal, Facultad de Ciencias Biológicas y Ambientales, Universidad de León, 24071 León, Spain, E-mail: dbalvd@unileon.es; ²Departamento de Ecología y Biología Animal, Facultad de Ciencias, Universidad de Vigo, 36200 Vigo, Spain, E-mail: jgarrido@uvigo.es.

Aquatic Coleoptera was seasonally sampled during an annual cycle (spring 1998 - winter 1999) in shallow lakes associated to the Canal de Castilla (Palencia province, Spain). These waterbodies are typical plateau wetland ponds with dense vegetation, varying in water permanence (from short-lasting temporary to permanent ponds) and surface (from 3.3 ha to 29.35 ha). Several physico-chemical variables were recorded at the time of sampling: oxygen concentration, conductivity and pH. Pond surface, depth, water permanence and type of vegetation were also taken into account, 92 species (44 Hydradephaga, 48 Polyphaga) belonging to 12 families were collected. Richness was higher than other studies carried out in other wetlands from the Northern Iberian mescta, such as the Laguna de la Nava (50 Coleoptera species collected) and the Lagunas de Villafáfila, where 31 Hydradephaga species were recorded. The assemblage structure was assessed by three parameters: richnes, abundance and diversity (Shannon index). Their relation with the environmental variables was explored by using correlation coefficients. The richness values for each pond ranged from 22 to 43 species. The highest richness and abundance values were recorded in spring (1,406 specimens, 74 species) and winter (1,049 specimens, 72 species). The assemblage composition was analysed by an ordination multivariate technique: Detrended Correspondence Analysis (DCA). Correlation coefficients between the environmental variables and the DCA axes were used as an aid to interpreting the ordination diagram. Both richness and the first DCA axis were significantly correlated with water permanence and conductivity, but they were not with any of the remaining parameters. Conductivity, is not too high in the study area and is significantly inter-correlated with permanence. Therefore, permanence seems the main factor influencing water beetle assemblages.

Index terms: aquatic Coleoptera, community structure, shallow lakes, Iberian plateau, Spain.

[0568] BEETLE DIVERSITY AND FOREST CHARACTERISTICS IN FLANDERS (BELGIUM)

<u>V. Versteirt</u>¹, K. Desender⁴, K. Smets¹, G. Geudens¹, D. Drugmand¹, D. De Bakker¹, P. Grootaert¹, P. Verdyck¹, D. Van Den Meersschaut², K. Vandekerkhove² & B. De Vos², ¹ Dept. Entomology, RBINSc, Vautierstr. 29, B-1000 Brussels, Belgium, E-mail: kdesender@kbinirshbe; ² Inst. Forestry and Game Management, AMINAL, Gaverstraat 4, B-9500 Geraardsbergen.

This study on beetle diversity and forest characteristics in the region of Flanders (Belgium) is part of a larger investigation on the use of terrestrial arthropods as ecological indicators in site assessment studies and forest evaluation. The aims of this study are manifold: (1) gather basic information on the occurrence and recent distribution of these organisms, (2) evaluate and understand species richness and species quality within the framework of nature conservation values and (3) examine how far the studied organisms can be used as indicators for the evaluation of forest site quality and woodland management, by analysis of relationships between relative abundance (habitat and/or microhabitat preference) and environmental parameters. With exception of the ground beetles (Carabidae), data on the occurrence and diversity of Coleoptera in Flemish forests are until now very incomplete. During a one year period (1997-1998), a large scale sampling was performed in 56 forest plots from 40 different forests in Flanders. The sampling techniques involved were three pitfall traps, three while and three yellow pan traps in each studied forest plot. Extensive data were available for most important abiotic and biotic descriptive variables, including vegetation, forest structure, forest soil and forest floor characteristics, and for a number of landscape ecological variables such as area, isolation and distance of study plots to nearest woodland edges. Because of the huge amount of invertebrate material gathered, data presented in this contribution are restricted to the months of April till July and to several beetle families, including Elateridae, Scolytidae, Cerambycidae, Silphidae, Scarabaeidae, Chrysomelidae and Staphylinidae. On the whole about 200 species were caught, belonging to more than 50 beetle families. Results are presented with emphasis on faunal interest, diversity and bio-indication. This study will contribute to the necessary baseline knowledge for future studies on the impact of forest management and within the context of nature development.

Index terms: woodland, Coleoptera, forest management, ecological indicators.

[0570] BIODIVERSITY OF AN'T SPECIES IN NATURAL AND CREATED WETLANDS

D.A. Waller, Biology Dept., Old Dominion Univ., Norfolk, VA, USA 23529.

Wetland habitats have been lost in the United States through development or conversion to agriculture. Recent appreciation of the value of ecosystem services provided by wetlands has resulted in the current policy of no net wetland loss. Now development of wetlands must be mitigated in other sites by either the preservation of pristine wetlands, the restoration of degraded wetlands or the creation of new wetland habitats. However, it is unknown whether created or restored wetlands ever attain the structure and function or provide the ecosystem services of natural wetlands. Most mitigation efforts have focused on vegetation establishment in created wetlands and ignored the invertebrate inhabitants, which are essential in many ecosystem processes. The assumption has been that invertebrates will follow once wetland vegetation is in place. However, invertebrates may be constrained from colonizing created wetland sites by such factors as 1) the distance of the created site from natural source areas, 2) the land area and vegetation structure of the created site, and 3) the dispersal abilities of different invertebrate species. The present study compared the ant faunas of created and natural wetlands in southeastern Virginia, an area that has suffered extensive wetland losses. Ants play vital roles in ecosystems and the presence of some ant species may be critical to the establishment of ecosystem function in created sites. Numerous ant species can occupy a given habitat where different species may serve as herbivores, predators, scavengers, seed dispersal agents, soil modifiers and food for other organisms. Ants were sampled from the soil, litter layer and herbaceous and shrubby vegetation in three created wetland sites and in three natural wetland sites. Collection methods included ant baits of peanut butter and jelly, litter extractions using Berlese funnels, pitfall traps consisting of testtubes filled with soapy water and insect net sweep samples taken along transects established in each site. Ants were returned to the laboratory and identified to species. Shannon's diversity index was calculated to compare the ant fauna at these sites. Diversity values were significantly lower for the ant species inhabiting the created wetland sites than for ants from the natural wetland sites. The few ant species collected from the created sites included widespread species such as Tapinoma sessile (subfamily Dolichoderinae) and Prenolepis imparis (subfamily Formicinae); these species nest in a variety of microhabitats and they can tolerate a large range of environmental conditions. In contrast, dozens of ant species were collected from the natural wetland sites, including many specialized species that are confined to the litter layer and have poor dispersal abilities. These sites will be followed to determine whether created sites ever reach the levels of ant diversity characteristic of natural wetlands. Index terms: Formicidae, Prenolepis imparis, Tapinoma sessile

[0569] AQUATIC HETEROPTERA (GERROMORPHA & NEPOMORPHA) FROM RETIRO DAS PEDRAS, A LOCALITY NEARBY BELO HORIZONTE, MINAS GERAIS, BRAZIL

G. J. C. Vianna¹ & A. L. Melo¹, ¹Dept. of Parasitology, Federal University of Minas Gerais, P.O. Box 486, Belo Horizonte, 30161-970, MG, Brazil, E-mail: guze@icb.ufmg.br

Aquatic insects are important and conspicuous members of freshwater habitats, mainly concerning aquatic Heteroptera. There is some information on the Heteroptera species composition from Minas Gerais, but studies about the fauna of the Belo Horizonte boundaries, which comprise part of the city water supply, are scarce. Aiming to contribute to the current knowledge of the aquatic Heteroptera in M.G., focusing the water bodies from the vicinities of Belo Horizonte, a list of the Heteroptera species collected is presented as well as community structure in different habitats. Samples were taken from January to December 1999, at three sampling stations representing different habitat types (4th order stream, artificial pond and temporary pools), with a hand net, sweeping the edges, water column and bottom. The insects were sampled in order to define faunal affinities between the three habitat types. Cluster Analysis (UPGA) and Principal Component Analysis (PCA) were performed and presence/absence data were used. A total of 24 species, distributed in 11 families were collected, two of which seems to be the first record for M.G. The composition of the community from the three habitat types is clearly distinct from each other. The first axis of PCA analysis (which was defined by artificial pond site at its positive end and by stream site at the negative end) separates lentic from lotic habitats. The second axis (which was defined by temporary pool site at its positive end and by artificial pond site at its negative end) separates species characteristic of temporary habitats from permanent habitats. The cluster analysis, in turn, showed greater similarity between artificial pond and temporary pool, probably due to the lentic characteristic of these two habitats. The nature of habitat preferences remains unknown, but could reflect the physical patterns of the three habitat types and differential colonization abilities and physiological tolerance.

Index terms: Aquatic insects, community structure, habitat preference.

[0571] INSECT HERBIVORES AS PREDICTORS OF PLANT PHYLOGENY: EXAMPLES FROM NEW GUINEA FICUS

G. D. Weiblen¹, V. Novotny², Y. Basset ³ & S. Miller⁴, ¹Dept. of Zoology, 203 Natural Sciences Bldg., Michigan State University, East Lansing, MI 48824, USA, E-mail gweiblen@pilot.msu.edu. ²Institute of Entomology CAS and Faculty of Biological Sciences, University of South Bohemia, Branisovska 31, 370 05 Ceske Budejovice, Czech Republic, E-mail binatangi@datec.com.pg. ³Smithsonian Tropical Research Institute, Apartado 2072, Balboa, Ancon, Panama City, Republic of Panama, E-mail bassety@tivoli.si.edu. ⁴Department of Entomology, National Museum of Natural History, Smithsonian Institution, Washington, DC 20560-0105, E-mail miller.scott@nnnh.si.edu.

The associations between figs (*Ficus* spp., Moraceae) and insect herbivores in several feeding guilds were examined using comparative methods. Feeding records for leafchewing, sap-sucking and infloresence-feeding insects from New Guinea were compared with host plant phylogeny using two approaches. First, the ancestral associations of herbivores were reconstructed on host phylogeny to examine patterns in homoplasy. Colonization of multiple *Ficus* lineages was common in all herbivore guilds and only the associations of larval Lepidoptera feeding on leaves and fig wasps (Agaonidae: Hymenoptera) showed less homoplasy than expected by chance. Second, the faunal similarity of host species was inferred from cluster analysis and compared with host phylogeny. Fig wasp associations of less specialized herbivores. Most *Ficus* herbivores in New Guinea were oligophagous and their patterns of association were not simply explained by host phylogeny, suggesting the importance of ecological factors in the evolution of plant/insect interactions.

Index terms: Agaonidae, Ficus, fig wasps, herbivores, phylogeny

Session 03 – BIOGEOGRAPHY AND BIODIVERSITY

[0572] BIODIVERSITY IN THE SOFT SCALE INSECTS OF CENTRAL AMERICA

M. L. Williams, Dept. of Entomology & Plant Pathology, 301 Funchess Hall, Auburn Univ., Auburn University, AL 36849-5413, USA.

The soft scale insect family Coccidae contains 1088 species in 144 genera, making it the third largest family of the Coccoidea in terms of species. A total of 51 genera and 298 species of Coccidae are known from the Neotropical Region. The soft scale insect fauna of the Neotropics tends to be specialized and rich, with 20 endemic genera and 247 endemic species. The fact that almost all of these records are from a relatively small area of Brazil indicates a pressing need for collecting the entire Neotropical Region. Central America, makes up only a small part of the Neotropical Region, in land area being only about the size of the state of Texas in the United States. However, Central America has provided a continuous land bridge for the mixing of the floras and faunas of North and South America for millions of years. Due to their complex geological and climatic histories, the countries of Belize, Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua and Panama have experienced repeated invasion and establishment of flora and fauna from both North and South America and have served as centers of speciation and biotic diversification. Today this area boasts one of the highest diversities of insect species on earth yet little is known about the scale insects of these countries. Information on the soft scale insects of Central America is scattered throughout the literature and generally includes information and/or descriptions of only a few species. There has not been a comprehensive study of the scale intect fauna for any of the seven countries of Central America. Information presented in this paper represents our current knowledge of the biodiversity of the soft scale insects of Central America, with the exception of two undescribed genera and approximately five undescribed species known to the author. The family Coccidae is represented in Central America by 20 genera and 56 species, discounting the undescribed taxa mentioned above. Taxonomic diversity by country is as follows: Belize - 5 genera, 7 species; Costa Rica - 15 g., 21 spp.; El Salvador - 12 g., 15 spp.; Guatemala - 18 g., 27 spp.; Honduras - 13 g., 24 spp.; Nicaragua - 13 g., 18 spp.; and Panama - 18 g., 36 spp.. Mexico, Central America's neighboring country to the north, is represented by 24 genera and 62 species of soft scales. When comparing soft scale diversity between Central America and Mexico, which is much larger in land area than Central America, one can get an appreciation for the importance in studying this area of the Neotropics before habitat destruction eliminates much of the biodiversity in the scale insect fauna before we can collect, study, identify and catalog them

Index terms: Homoptera, Coccidae, Neotropical Region.

[0573] SOCIEDAD ENTOMOLOGICA ECUATORIANA

N. Zabala, Executive Director, Universidad San Francisco de Quito, Apto 17-12-841, Quito Ecuador, E-mail nelson@mail.usfq.edu.ec.

The Sociedad Entomológica Ecuatoriana (SEE) was founded in 1982 and since then has been actively involved in studies of the entomological biodiversity of neotropical Ecuador and applied entomology. Currently there are more than 150 members of the SEE with some from other countries such as Brazil, Colombia, Peru, Venezuela, and the USA. Most members work in universities and research centers of applied entomology, especially in agricultural, medical, or veterinary areas. The main research centers are in Quito: Museo Ecuatoriano de Ciencias Naturales (MECN), Univ. San Francisco de Quito (USFQ), Univ. Catolica del Ecuador (PUCE), Escuela Politecnica Nacional (EPN), Univ. Central del Ecuador (UC) and Instituto Nacional de Investigaciones Agropecuarias (INIAP). In Guayaquil: Univ. de Guayaquil and Instituto de Medicina Tropical. In Cuenca: Univ. de Cuenca. And in the Galapagos Islands: Charles Darwin Research Station (CDRS). These centers are the principal focus for training entomologists and where most of members are. The most important in number and diversity neotropical entomological collections are in Museo Ecuatoriano de Ciencias Naturales, Univ. Catolica del Ecuador, Escuela Politecnica Nacional, Instituto de Medicina Tropical and Charles Darwin Research Station of the Galapagos Islands. The Ecuador National Congress of Entomology takes place every 4 years since 1982 in Quito; the next one will be in 2003. Ecuadorian scientific activity in entomology is reflected in these events with topics such as biodiversity, biological control, medical and veterinary entomology, ethology and ecology. Since 1988 the SEE has edited the Boletin de la Sociedad Entomológica Ecuatoriana. In 1998 the SEE in collaboration with the Univ. San Francisco de Quito published the book Butterflies of Ecuador. The same year Univ. Catolica de Ecuador published the book families of Ecuadorian Butterflies. Our members also contribute to understanding neotropical biodiversity taking part in national and international meetings and publishing papers and books. The Society has a special library located at the Museo de Ciencias Naturales del Ecuador and maintains relationships with a number of similar institutions in the world, which exchange publications and obtains funding.

[0574] BIONOMICS OF PEPPERTREE PSYLLID CALOPHYA RUBRA (HOMOPTERA: PSYLLIDAE) IN MEXICO

R. Alvarez-Zagova¹ & D. Cibrián-Tovar², ¹ Instituto Politécnico Nacional, CIIDIR Unidad Durango, Lab. Entom., Sigma s/n, Apdo. Postal 57, Fracc. 20 de Noviembre II, Durango 34220, Dgo., México. Becario/COFAA-IPN, E-mail: raz_ciidir@yahoo.com² Universidad Autónoma Chapingo, Div. Cien. For., Lab. Entom. For., Apdo. Postal 37, Chapingo 56230, Edo. de Méx., México. E-mail: dcibrian@taurus1.chapingo.mx

Peppertree psyllid, Calophya rubra, is an insect highly associated to peppertree, Schinus molle L., which has been dispersed in South America along with its native host. In the last decade, C. rubra has become the cause of the reduction of aestethic quality on introduced peppertree in central México and California, USA, where it has been used as an ornamental species. Field and laboratory-reared observations were carried out in 1997 and 1998, at Chapingo, Texcoco, Mexico State. In this work, the aims were to describe the psyllid life cycle, mating, ovipositing and feeding behaviour, nymphal instars description, damage, distribution, natural enemies of the psyllid and peppertree phenology. Life cycle variation depends on temperature having 48 to 68 days from egg to adult; females live two days more than males do. Each female deposits a mean of 50 eggs, even though they can oviposite 110 eggs. Long and width measurements on 523 exuvies and nymphs showed that exist five nymphal instars. Long mean in milimeters from nymphal instars N1 to N5 were: 0.23, 0.34, 0.50, 0.68 and 1.07 mm; mean width for N1 to N5 were: 0.17, 0.28, 0.40, 0.58 and 0.99 mm, respectively. Nymphal instars separation were statistically analized with y2-test and principal component analysis. C. rubra was similar in field and laboratory. Disc gall forming is the damage derived from feeding behavior on the leaves, giving them a cinder green color. There are seven potential predator species and a new parasitoid species, *Tamarixia schina* Zuparko. This Eulophid wasp is an outstanding natural control species of C. rubra population. Its life cycle lasts 20 days from egg to adult and 96% of adults emerged were females. Parasitism percentage was from 10 to 28% on psyllid nymphs N3 to N5 with a 1:1 rate, without hyperparasitism.

Index terms: Insecta, Calophya rubra, psyllids, biological control, Tamarixia schina Z., Schinus molle L.

[0575] CHEMISTRY OF OLFACTORY LANDSCAPES; ODOR SIGNAL COMPLEXITY, EVOLUTIONARY CONVERGENCE AND DECEPTION

R. A. Raguso, Dept. of Biol. Sci., Univ. of S. Carolina, Coker Life Sci. Bldg., 701 Sumter St., Columbia, SC 29208, USA, E-mail Raguso@biol.sc.edu

One critical challenge to the evolution of sex-related chemical communication is the need to effectively attract the desired party from a distance without attracting an unwanted third party. In floral pollination systems, the third party often consists of non-pollinating florivores or seed predators, whereas in pheromone-driven insect mating systems, either predators or related species (inappropriate mates) constitute the unwanted third party. In these examples, reproductive fitness is decreased or abolished by third party exploitation of a chemical signal, through mortality or hybrid infertility. Ideally, sex pheromones should provide their users with a private channel of communication. Given the staggering chemical complexity of natural odorants, and the versatility of most insect olfactory abilities, chemical specificity of sexual signals should not be difficult to achieve. Furthermore, the pheromone detection and processing cauabilities of most insects generally have evolved such that the olfactory "noise" provided by complex background odors does not seriously impact the salience of pheromone signals. However, the biosynthetic pathways that generate volatile compounds are ancient and shared among biological kingdoms, providing opportunities for semiochemical convergent evolution, mimicry and deception between insects, plants and fungi. For example, orchids with floral fragrances that mimic hymenopteran sex pheromones have evolved independently in Mediterranean Europe/N. Africa and in Australia, exploiting the sexual behaviors of male wasps for pollination services. Certain chemical classes of insect pheromones may be more vulnerable to exploitation by plants than others, and the combination of biochemical and phylogenetic analyses are needed to better discern the constraints under which pheromones evolve in different insect lineages.

Index terms: fragrance, mimicry, pheromone, pseudocopulation, semiochemistry

Symposium and Poster Session

[0577] THE MOLECULAR BIOLOGY OF *DROSOPHILA* ODORANT RECEPTORS

L. B. Vosshall, H. Amrein, P.S. Morozov, A. Rzhetsky & R. Axel, Center for Neurobiology and Behavior, Columbia Univ., 701 West 168th St., Box134, New York, NY 10032 USA. Email: LV25@columbia.edu

Drosophila fruit flies display robust olfactory-driven behaviors with an olfactory system far simpler than that of vertebrates. Endowed with approximately 1500 olfactory receptor neurons, these insects are able to recognize and discriminate among a large number of distinct odorants. Candidate odorant receptor molecules responsible for this specificity were identified by complimentary approaches of differential cloning and genome analysis The Drosophila odorant receptor (DOR) genes encode a novel family of proteins with seven predicted membrane-spanning domains, unrelated to vertebrate or nematode chemosensory receptors. There are approximately 60 members of this gene family in the Drosophila genome, far fewer than the hundreds to thousands of receptors found in vertebrates or nematodes. DOR genes are selectively expressed in small subsets of olfactory neurons, in expression domains that are spatially conserved between individuals, bilaterally symmetric, and not sexually dimorphic. Double in situ RNA hybridization with a number of pairwise combinations of DOR genes fails to reveal any overlap in gene expression, suggesting that each olfactory neuron expresses one or a small number of receptor genes and is therefore functionally distinct. How is activation of such a subpopulation of olfactory receptor neurons in the periphery sensed by the brain? In the mouse, all neurons expressing a given receptor project with precision to 2 of 1800 olfactory bulb glomeruli, creating a spatial map of odor quality in the brain. We have employed DOR promoter transgene that recapitulate expression of endogenous receptors visualize the projections of individual populations of olfactory receptor neurons to subsets of the 43 glomeruli in the Drosophila antennal lobe. The results suggest functional conservation in the logic of olfactory discrimination from insects to manunals.

Index terms: Drosophila melanogaster, antennal lobe, glomeruli, olfactory receptor genes

[0576] AIR FLOW THROUGH PECTINATE INSECT ANTENNAE AND ODORANT INTERCEPTION RATES

C. Loudon¹ & M.A.R. Koehl², ¹Dept of Entomology, Univ. of Kansas, Lawrence, KS 66045, USA, E-mail loudon@ukans.edu; ²Dept. of Integrative Biology, Univ. of California, Berkeley CA 94720-3140.

Many organisms increase the air or water flow adjacent to olfactory surfaces when exposed to appropriate chemical stimuli; such "sniffing" samples fluid from a specific region and can increase the rate of odorant molecule interception. We used hot wire anemometry, high-speed videography and flow visualization to study air flow near the pectinate antennae of male silkworm moths (Bombyx mori). When exposed to conspecific female sex pheromone, male B. mori flap their wings through a stroke angle of 90 to 110° at about 40 Hz without flying. This behavior generates an unsteady flow of air (mean speed 0.3 to 0. 4 m/s) towards the antennae from the front of the male. A pulse of peak air speed occurs at each wing upstroke. The Womersley number (characterizing the damping of pulsatile flow through the gaps between the sensory hairs on the antennae) is <1, hence pulses of faster air (at 40 Hz) should move between sensory hairs. Calculation of flow through arrays of cylinders and random walk simulations suggest that this wing fanning can increase the rate of pheromone interception by the sensory hairs on the antennae by at least an order of magnitude beyond that in still air. Although wing fanning produces air flow relative to the antennae that is about fifteen times faster than that generated by walking at top speed (0.023 n/s), air flow through the gaps between the sensory hairs is about 560 times faster because a dramatic increase in the leakiness of the feathery antennae to air flow occurs at the air velocities produced by fanning. The pressure drop across single antennae was measured for both male and female antennae mounted over orifices such that air was forced to pass through the antennae. Resistance to flow of both male and female antennae (PaAs/m) was approximately independent of air speed and was higher for male antennae. Drag forces were measured on both male and female antennae using a novel terminal velocity assay. By combining the measured resistance and the drag forces, the proportion of approaching air that passes through the antenna was estimated as about 15% for both male and female antennae. This approximate "bluff body" behavior is likely to be exhibited by pectinate antennae from a variety of insect taxa in ambient air speeds of 1 m/s or less.

Index terms: biomechanics, diffusion, chemosensory, Bombyx mori.

[0578] DIVERSITY, PHYLOGENY, AND FUNCTIONS OF ODOR RECEPTION PROTEINS: OBP, ODE AND SNMP

<u>R.G. Vogt</u>¹ & M.E. Rogers^{1,2}, ¹Dept. of Biological Sciences, Univ. of South Carolina, Columbia SC 29208, USA, E-mail vogt@biol.sc.edu; ²Dept of Biological Sciences, 922 Fairchild, Columbia Univ., New York NY 10027, USA, E-mail mt959@columbia.edu. Support: NIH-NICDC DC00588; NSF-IBN9731005; USDA-CGRP94373020615.

Three classes of antennal specific proteins have been identified, in the course of our studies; Odorant Binding Proteins (OBPs) and Odorant Degrading Enzymes (ODEs), and the neuronal membrane protein SNMP (sensory neuron membrane protein). prevailing models of odor reception suggest odors are solubilized into the sensillum lymph by interaction with OBPs, and so transported to receptor proteins in the neuronal membranes, and subsequently inactivated and degraded by ODEs. OF these proteins, OBPs have received the most attention, and are recognized in part by their homologous relationships to the Pheromone Binding Proteins (PBPs) of lepidoptera or the OS-E/OS-F proteins of *Drosophila melanogaster*. OBPs are present in individual species as a multigene family, with members differentially expressing in morphologically distinct sensilla, or in various combinatorial patterns. These OBPs have been identified from a wide range of insect species, but to date appear restricted to the holometabolous and hemipteran lineages which together are thought to form a single clade distinct from other Neopteran insects. A distinctly different family of protein, recognized by its homology with the Drosophila protein OS-D, is widely distributed throughout the Neoptera, and may represent a second type of OBP-like protein. ODEs, have been less studied, and are known primarily from the sensilla esterase of Antheraca polyphemus and the aldehyde oxidases of several lepidoptera. ODEs are also present as body surface enzymes, and recently as potentially dual purpose detoxification / odor termination enzymes of the olfactory support cells, such as GSTolf from Manduca sexta. SNMP is an antennal specific protein uniquely expressing in olfactory neurons and abundantly distributed in the receptive membranes of olfactory neurons. SNMP homologues have been identified from A. polyphemus, Heliothis virescens and Bombyx mori, as well as from M. sexta where two were identified. SNMP is homologous with a pan-phyletic family of dual-transmembrane domain receptors, recognized in part by their similarity to the vertebrate CD36 protein; this family typically interacts with proteinaceous ligands. SNMP is incorporated into the model of odor reception in several possible sites, including interactions with OBP-odor complexes to induce off loading of odors in proximity to odor-receptor proteins, and We interacting with odor-receptor proteins to enhance or support receptor function. suggest sensillar class odor specificities are strongly influenced by combinatorial expression of these proteins.

[0579] THE NITRIC OXIDE – SOLUBLE GUANYLYL CYCLASE SIGNALING SYSTEM IS INVOLVED IN THE PROCESSING OF OLFACTORY INFORMATION IN THE HAWKMOTH, MANDUCA SEXTA

A. Nighorn & T. Christensen, ARL Division of neurobiology, University of Arizona, Tucson, AZ 85721 USA, E-mail: nighorn@neurobio.arizona.edu

We are examining the role of the NO/sGC pathway in the processing of olfactory information in the hawkmoth, Manduca sexta. The role of this pathway was first examined in the antennae where this signaling system was hypothesized to play a role in the adaptation of the olfactory receptor neurons. Examining the expression of the candidate proteins however, we found that nitric oxide synthase (NOS), the enzyme that generates nitric oxide (NO), is expressed in the axons, but not cell bodies or dendrites of apparently all olfactory receptor neurons. The best characterized target of NO, soluble guanylyl cyclase (sGC), is not present in olfactory receptor neurons at all, strongly suggesting that this pathway does not play a role in olfactory adaptation in the antenna. In the antenna lobe however, we found that NOS continued to be highly expressed in the axons of apparently all olfactory receptor neurons. Moreover, sGC was found to be expressed in a subset of antennal lobe neurons. These expression patterns suggest the possibility that odorant stimulation of olfactory receptor neurons causes the release of NO in the antennal lobe and that this phenomenon plays an important role in the subsequent processing of that odor signal. We are testing this hypothesis in two ways. First, we are using the NOsensitive dye Daf-2DA to visualize NO in the antennal lobes. Second, we are recording from antennal lobe neurons using both single and multi-unit recording methods before and after treatment with agonists and antagonists of NO pathways. Using Daf-2DA, we have found labeling antennal lobe glomeruli in response to odorant stimulation. This staining was eliminated by preincubation with the NOS inhibitor, L-NAME. Direct electrical stimulation of the antennal nerve also resulted in an increase in fluorescence in the caps of some glomeruli. Using single-unit responses of antennal lobe neurons, we found that agents that interfered with NO signaling, including L-NAME and Carboxy-PTIO, caused a dramatic and reversible change in response latency and a desynchronization of the response to repeated stimulation. SNP, an NO donor, caused a dose-dependent depolarization of antennal lobe neurons. The phosphodiesterase inhibitor IBMX, an agent that should potentiate the NO/sGC response, caused depolarization of the cells and also blocked spiking. These data point to an important role for the NO/sGC signaling system in maintaining synaptic efficacy in the olfactory pathway. Index terms: Daf-2, nitric oxide, olfaction, antennal lobe

[0580] PHEROMONE BINDING PROTEINS: STRUCTURAL, FUNCTIONAL AND GENETIC IMPERATIVES IN TORTRICID MOTHS

D.R. Greenwood¹, R.D. Newcomb¹, M. Rasam¹, T. Sirey¹, C. Baldock^{1, 2}, H.M. Baker² & E.N. Baker², ¹ Plant Health and Development Group, The Horticulture and Food Research Institute of New Zealand Ltd., Mt Albert Research Centre, Private Bag 92-169, Auckland, New Zealand; ² Structural Biology Group, School of Biological Sciences, University of Auckland, Private Bag 92-019, Auckland, New Zealand.

Pheromone binding proteins (PBPs) are involved in the perireceptor events surrounding the highly sensitive and specific semiochemical detection system used by insects to detect potential mates. In most male moths, specialised sensory organs (sensilla) residing on their antennae are tuned to respond to components of the sex pheromone blend produced by females. Volatile pheromone molecules diffuse through wax-filled pores into the aqueous lumen of these sensilla, where they are bound to PBPs. These proteins are thought to facilitate the transport of pheromone molecules to membrane-bound receptors. We are examining in detail the PBPs from the light brown apple moth, Epiphyas postvittana, a horticultural pest in both Australia and New Zealand. These PBPs have been compared with those from a number of other New Zealand indigenous species of leafroller moths (Tortricidae) that use different pheromone blends, in addition to comparisons with PBPs from other more distant species. There are principally two E. postvittana PBPs; we have expressed both of these in baculovirus-infected SF9 cells and purified them to homogeneity for 3-D structural studies by X-ray crystallography. This paper will describe our studies into the structural attributes of this novel family of small (15-18 kDa) proteins that are essentially α -helical and globular in nature with a hydrophobic pheromone binding pocket. This contrasts to the lipocalin family of ligand carriers that perform a similar function in the vertebrate olfactory system but possess a Bbarrel structure. Analysis of the structure will help us determine what role PBPs have in pheromone specificity and assist in resolving the molecular events occurring at the receptor surface, resulting in triggering of the signal transduction process via the G protein-linked seven transmembrane domain pheromone receptor, and ultimately in the guiding of a pheromone-directed flight response.

[0581] INSECT PHEROMONE BINDING PROTEINS FORM DIMER IN SOLUTION

W. S. Leal, Dept. Entomology, University of California, Davis CA 95616, USA, Email: wsleal@ucdavis.edu

Insects primarily rely on their olfactory system to detect chemical cues from the environment and initiate the transduction of these chemical signals into neuronal activities, which ultimately lead to the appropriate behavioral responses, such as mating, the location of food and oviposition sites, etc. There is growing evidence in the literature that the inordinate sensitivity and selectivity of the insect olfactory system is achieved by a combination of various olfactory-specific proteins, namely, odorant-binding proteins (OBPs), odorant receptors, and odorant-degrading enzymes. It is widely believed that OBPs play a part in the selectivity of the olfactory system by "filtering" chemical signals during the carly olfactory processing (perireceptor events). Nevertheless, the function(s) of these proteins is(are) still a matter of considerable debate, with postulated functions, altering their conformation and oligomeric state in pH-dependent ways. Using a comprehensive approach (Western immunobloting experiments, mass spectral analysis, gel filtration estimation of molecular masses, and cross-linking reactions), it was clarified that the pheromone-binding protein of *Bombyx mori* is a monomer at acid pH and a dimer at basic, neutral, and slightly acidic pH. The relevance of the duality monomer-dimer for binding and release of the pheromone ligand will be discussed.

Index terms: Bombyx mori, electrospray ionization mass spectrometry, Western blotting, cross-linking reactions

[0582] MATE RECOGNITION IN NEZARA VIRIDULA (HETEROPTERA, PENTATOMIDAE): A MATTER OF SONGS AND PHEROMONES

N. Miklas¹, <u>M. Renou¹</u>, A. Cokl² & M. Virant Doberlet², ¹ INRA, Unité de Phytopharmacie et Médiateurs Chimiques, Route de Saint Cyr, 78026 Versailles Cedex, France. E-mail : renou@versailles.inra.fr; ² NIB, Laboratory for Neurobiology Laboratory, Veena Pot 111, P.O.B. 141, 1001 Ljubljana, Slovenia.

Premating behavior in the southern green stink bug, Nezara viridula, involves vibratory and chemical communication. Males produce a volatile pheromone. The song repertoire of male and female Nezara is composed of a variety of substrate-transmitted signals. It was first postulated that the sex pheromone is mediating long range mate finding whereas vibratory signals modulate close range attraction. However, recent investigations suggest that both sensory modalities interplay during courtship behavior. A conjunction of techniques including olfactory stimulation, volatile collection, song recording and playback of acoustic signals, was used to determine the precise temporal and spatial pattern of the interactions between olfactory and vibratory communication. Males start to produce pheromone at age 8-10 days. We did not observe any conspicuous calling behavior and pheromone production does not follow a circadian rhythm. Stimulation of males with female calling song (FCS) failed to trigger the pheromone production and isolated males emit as well. Virgin females rarely emit the FCS spontaneously, but they respond with FCS emission to the presentation of male volatiles or of synthetic pheromone. When put on a new plant, males spontaneously emit male courtship song (MCrS) and when a couple of bugs was observed on a loudspeaker, it was usually the male who started singing first. On a plant, males alternate with the pre-precorded FCS by emitting MCrS and they increase their locomotion. Male bugs are able to locate the source of the female song on a plant. The ratios of terpenoid pheromone components and the temporal parameters of the songs show variability between geographicaly isolated populations. The specificity of the responses of male and female to signals of their own population or other population was investigated. Signals of both modalities interact to improve mate finding and recognition.

[0583] SENSORY AND BEHAVIOURAL RESPONSES OF TRIATOMINE BUGS TO ODOURS OF VERTEBRATE HOSTS AND TO CONSPECIFIC SEMIOCHEMICALS

P. M. Guerin, P. Guerenstein, M. Vlimant & S. Wicky, Inst. of Zoology, University of Neuchâtel, Rue Emile-Argand 11, 2007 Neuchâtel, Switzerland, E-mail patrick.guerin@unine.zool.ch.

Triatomine bugs search for vertebrate hosts to procure a blood meal and host odours mediate this behaviour. Perception of vertebrate odours occurs via an array of olfactory receptors in wall-pore and grooved-peg olfactory sensilla on the antennal flagellum. Electrophysiological recordings show that three of these receptors respond selectively to the host odour components nonanal, ammonia and isobutyric acid. Whereas nonanal causes increased displacement by the bugs, both anunonia and isobutyric acid attract triatomines walking on a servosphere. There is evidence for parsimony in the use of these semiochemicals in triatomines. As isobutyric acid occurs in the headspace of both *Rhodnius prolixus* and *Triatoma infestans* it may have an additional function as an aggregation stimulus in triatomines. Refuges occupied by triatomines are marked with their own faeces and are attractive to triatomines. Ammonia released from fresh faeces contributes to this attractivity. The bugs also perceive uric acid, a major constituent of their faeces, via receptors in a set of terminal pore gustatory sensilla on the distal flagellum of the antenna.

[9585] IDENTIFICATION OF SEX PHEROMONES OF ECONOMICALLY IMPORTANT STINK BUG PESTS OF AGRICULTURE

J. G. Millar¹, **H. L. McBrien¹**, **H.-Y. Ho¹ & R. E. Rice²**, ¹Dept. of Entomology, Univ. of California, Riverside CA 92521, USA, ²Dept. of Entomology, Univ. of California, Davis CA 95616, USA.

Phytophagous stink bugs (Heteroptera: Pentatomidae) are occasional to chronic pests in all types of cropping systems, including annual crops such as grains, alfalfa, beans, and tomatoes, and perennial crops such as tree fruits and nuts. Damage is caused by both immatures and adults, but only adults are winged and capable of long-distance movement. Injury to young seeds, fruits, or nuts produces necrotic lesions and often results in premature abortion, while attacked leaves may will and die. Stink bugs are also known or implicated as vectors of plant pathogens such as yeast, fungi, and bacteria. Many stink bug species are polyphagous and the adults are highly mobile, which exacerbates problems with their monitoring and control. Bugs migrate into crops in response to natural events such as the senescence of native vegetation in the habitat, or in response to mowing or harvesting of nearby crops harboring large bug populations. Effective bug control hinges on the rapid detection of these invasions so that appropriate control measures can be implemented before serious crop damage occurs. However, sampling methods for most bug species are still relatively primitive, consisting mainly of sweep-net or beating tray sampling, or visual inspection of fruits for feeding damage or excrement. Monitoring methods based on pheromones or other attractants, have not yet been developed for the major pest bug species. We report here identification, synthesis, and bioassay results for five phytophagous pest species, Thyanta pallidovirens, Acrosternum hilare, Chlorochroa ligata, C. uhleri, and C. sayi. Pheromones produced by sexually mature male bugs were collected by aeration and identified by bioassay-driven fractionation, and reconstructed blends were optimized in both laboratory and field bioassays. Furthermore, the pheromone of T. pallidovirens also attracted a predatory wasp which specializes on stink bugs. Problems encountered during identification and bioassay of the pheromones, and ongoing research on the development of practical applications for the pheromones will be discussed.

Index terms: Thyanta pallidovirens, Acrosternum hilare, Chlorochroa ligata, Chlorochroa uhleri, Chlorochroa sayi, pheromone

[0584] SEMIOCHEMICALLY-MEDIATED HOMO- AND HETEROSEXUAL BEHAVIOR IN TRUE BUGS

<u>W. S. Leal,</u> Dept. Entomology, University of California, Davis CA 95616, USA, Email: wslcal@ucdavis.edu

Chemical communication requires the release of specific chemicals from a producer, the transmission of these chemicals to a receiver, and the processing of these chemical signals leading to the appropriate behavioral responses in the receiver. To date, male-released pheromones of true bugs have been identified from a number of species and they are captured in pheromone-baited traps. However, our observation that *Piezodorus hybneri* (Heteroptera: Pentatomidae) males responded to the male-released pheromones and that by referring to the seniochemicals that attract both sexes as aggregation pheromones may be misleading. In this presentation, I will discuss previous and some ongoing projects for the identification of pheromones in true bugs.

Index terms:Riptortus clavatus, R. lineolaris, Leptocorisa chinensis, Piozodorus hybneri, Tynacantha marginata

[0586] PHEROMONE BIOLOGY OF A PENTATOMID PEST OF AUSTRALIAN CITRUS AND A REDUVILD PREDATOR

D.G. James, Irrigated Agriculture Research and Extension Center, Washington State University, 24106 North Bunn Road, Prosser, WA 99350, USA. Email: diames@tricity.wsu.edu.

Reproductive males of the Australian stink bug citrus pest, Biprorulus bibax, possess large dorsal abdominal glands (DAG's) containing an aggregation pheromone ((3R,4S,1'E)-3,4-bis(1'-butenyl)tetrahydro-2-furanol, linalool, farnesol and nerolidol). Glasshouse and orchard studies showed post-diapause (pre-reproductive), reproductive and early diapause (migrating) B. bibax were significantly attracted to sites (bunches of citrus foliage/fruit or citrus trees) baited with the major component or a synthetic blend of the pheromone. Reproductive, but not reproductively inactive bugs, were also attracted to citrus trees baited with (E)-2-hexenal. B. bibax did not enter pheromone-baited cylinder or funnel traps. Pheromone-baited baffle/funnel traps positioned on posts 2m above ground level around a citrus block captured five bugs during a six week period during spring. Pristhesancus plagipennis is a large reduviid predator of B. bibax in northern areas of the citrus pest's range. Adults of *P. plagipennis* have three median DAG's with the anterior and posterior much larger in males than females. In Laboratory olfactometer and outdoor flight cage bioassays, female P. plagipennis were significantly attracted to calling males, male posterior DAG extracts and the (2R) enantiomer of the major component of the secretion, (Z)-3-hexenyl 2-hydroxy-3-methylbutyrate. The male secretion also includes 3methylbutanol, 2-phenylethanol, (Z)-3-hexenol, decanal, (E)-2-hexenoic acid and three minor hexenyl esters. Males were also attracted to the major ester. Females appear to produce a pheromone from their anterior DAG that attracts males at close range and may facilitate mating. The potential and prospects for developing synthetic aggregation pheromones of B. bibax and P. plagipennis as tools in a single or separate integrated pest management systems, are discussed.

Index terms: Biprorulus bibax, Pristhesancus plagipennis, baits, traps, integrated pest management

[0587] EFFECTS OF PHEROMONES IN ARTIFICIAL DIETS FOR PREDATORY BUGS

J. C. Zanuncio¹, J. B. Torres², E. F. Vilela¹ & M. D. A. Coracini¹, ¹ Dep. de Biologia Animal, Univ. Federal de Viçosa. 36.571-000 Viçosa, Minas Gerais, Brasil. E-mail: zanuncio@mail.ufv.br; ², Univ. Federal Rural de Pernambuco. Recife, Pernambuco, Brasil.

Predatory bugs can present satisfactory results with alternative prey but rearing them represents an additional cost. For this reason artificial diets are been used but development and reproduction of these bugs with them are inferior than with natural or alternative prey because these predators feed on diet for short periods of time than with prey. Two studies were developed aiming to increase attractiveness of an artificial diet to Podisus nigrispinus and Supputius cincticeps. The first evaluated possible attractant and feeding stimulant effects of extracts of dorsal abdominal glands of these predators in the diet of their nymphs compared to those fed factitious prey. The extract spread over the diet attracted 88% of the nymphs of P. nigrispinus. Nymphs feeding on diet with extract (spread over and added-84%) or M. domestica larvae showed similar results. Nymphs of S. cincticeps feeding on the same diet showed maximum value of 60 and 56% but lower than that achieved on the factitious prey Tenebrio molitor (92%). Second instar nymphs of P. nigrispinus and S. cincticeps showed similar lower weights when reared on the artificial diet (2.7 mg and 1.2 mg), diet with extract (2.8 and 1.6 mg), extract spread over the diet (2.1. and 1.0 mg), or spread over and added to the diet (2.4 and 1.3 mg) than that on the factitious prey (3.1 and 3.0 mg). Effect of the synthetic sexual pheromone of P. nigrispinus on the localization and acceptance of an artificial diet and also on nymphal development and female fecundity of P. nigrispinus were evaluated. The complete synthetic sexual pheromone or its components were applied to the diet at 0.05 µg/µg concentration. The artificial diet with pheromone promoted an weight gain similar to that with M. domestica larvae, but did not improve the development of this predator over several generations compared to those fed only pure diet. Nymphal development period was longer for nymphae with pure diet, diet with pheromone, with a-terpinol or with (E)-2-hexenal; and it was shorter in the treatments: diet with linalool, M. domestica larvae, diet with the three major components, with trans-piperitol or with benzyl alcohol. During three generations nymph survival was generally lower when fed M. domestica larvae than with pure diet or diet containing complete pheromone. Females fed M. domestica larvae presented shorter longevity and greater egg production than those fed pure diet or diet containing complete pheromone. Extracts of dorsal abdominal glands or sexual pheromone of P. nigrispinus or S. cincticeps added to artificial diet can increase performance of these predators in such diets

[0588] A PHEROMONE COMPONENT OF THE BEAN BUG, *RIPTORTUS CLAVATUS*, ATTRACTS AN EGG PARASITOID, *OOENCYRTUS NEZARAE*

N. Mizntani¹, T. Wada¹, H. Higuchi², M. Ono³ & W. S. Leal⁴, ¹Kyushu Natl. Agr. Expt. Stn., Suya 2421, Nishigoshi, Kumannoto 861-1192, Japan, E-mail nobuo@knaes.affrc.go.jp; ²Hokuriku Natl. Agr. Expt. Stn., Inada 1-2-1, Joetsu, Niigata 943-0193, Japan; ³Fuji Flavor Co., Ltd., Midorigaoka 3-5-8, Hanura, Tokyo 205-8503, Japan; ⁴Natl. Inst. Seric. Entomol. Sci. Owashi 1-2, Tsukuba 305-8634, Japan.

The egg parasitoid, Ocencyrtus nezarae, is a predominant natural enemy of the bean bug, Riptortus clavatus, which is one of the economic important soybean pests in south Japan. Parasitic females of O. nezarae are attracted by the synthetic aggregation pheromone of R. clavatus. The female parasitoids utilize the host pheromone as a chemical cue to locate their hosts. The synthetic pheromone comprises three chemical components. In this study, we first checked the attractiveness of each component for O. nezarae and R. clavatus, using sticky traps baited with the component. Then, we investigated the effect of the field application of the pheromone and its component upon the density and the parasitic activity of O. nezarae. The trap experiment indicated that one of the three components, (E)-2 hexenyl (Z)-3-hexenoate (E2HZ3H) attracted females of O. nezarae as the pheromone did. However, E2HZ3H did not attract R. clavatus. Therefore, we applied E2HZ3H in experimental soybean fields. The parasitoids attracted by E2HZ3H immigrated into the field earlier than the invasion of R. clavatus. High densities of the parasitoid were observed in E2HZ3H-treated field compare to untreated field. E2HZ3H did not increase the density of R. clavatus as we had expected. High parasitism rates of R. clavatus eggs artificially set on soybean plants in E2HZ3H-teated field were observed when compare to untreated field. The difference in parasitism rate was only observed in autumn when O. nezarae densities were high. However, this was not the case when the parasitoid density around the soybean fields was low in summer.

Index terms: synthetic aggregation pheromone, (E)-2-hexenyl (Z)-3-hexenoate, natural enemy, parasitism, soybean

[0589] SEMIOCHEMICAL COEVOLUTION BETWEEN HETEROPTERA AND THEIR TACHINID FLY PARASITOIDS: GAS CHROMATOGRAPHY-ELECTROANTENNOGRAM DETECTION AND BEHAVIOR

J. R. Aldrich & A. Zhang, USDA-ARS Insect Chemical Ecology Laboratory, Agricultural Research Center-West, B-007, Beltsville, MD 20705, USA, E-mail: jaldrich@asrr.arsusda.gov.

Many, if not most, of the known heteropteran pheromones also attract certain tachinids which exploit the bug pheromones as host-finding kairomones. The system we will describe involves the sympatric predaceous stink bugs, Podisus maculiventris and P. neglectus (Pentatomidae: Asopinae). Male-produced pheromones and the nymphal defensive secretions of these Podisus spp. are usurped as kairomones principally by two tachinid species: Euclytia flava (a generalist pentatomid parasitoid) and Hemyda aurata (a specialist asopine parasitoid). The pheromone of P. maculiventris consists mainly of (E)-2-hexenal and D-terpineol, while that of P. neglectus is predominantly (E)-2-hexenal with linalool. Curiously, the nymphal secretion of P. maculiventris contains linalool, along with (E)-4 oxo-2-hexenal and tridecane; whereas nymphs of P. neglectus secrete linalool and \Box -terpineol, plus (E)-4-oxo-2-hexenal and tridecane. GC-EAD experiments with P. maculiventris, E. flava and H. aurata revealed that the tachinids are much more electrophysiologically sensitive to the pheromone of the bug than are the bugs themselves. Furthermore, the antennae of E. flava are more responsive to D-terpineol than linalool, but H. aurata antennae respond to D-terpineol and linalool more equally. In addition, the antennae of both tachinids respond strongly to minute amounts of (E)-2-octenal and (E)-2decenal, alkenals that are characteristic defensive compounds of stink bug adults. Captures of E. flava and H. aurata individuals in traps baited with blends containing either Dterpineol or linalool were positively correlated with the respective antennal sensitivities of the tachinids toward these monoterpenoids. Field tests in which some pheromone-baited traps also contained a high dose of (E)-2-octenal showed that the addition of (E)-2-octenal tended to repel the bugs. However, (E)-2-octenal significantly increased attraction of E. flava females to the pheromone of P. neglectus, whereas attraction of E. flava individuals to P. maculiventris pheromone was either unaffected (female flies) or sometimes reduced (male flies) by the presence of (E)-2-octenal. Our working hypothesis to explain these results is that the intensity of a tachinid's antennal response toward particular host volatiles is directly proportional to host suitability. This interpretation is substantiated by GC-EAD showing that methyl (E,E)-2,4-decadienoate-the main pheromone component of Euschistus spp., acceptable but not preferred stink bug hosts of E. flava-elicited significantly weaker responses from the antennae of E. flava females than seen for Dterpineol and linalool.

[0590] SUBSTRATE-BORNE HOST KAIROMONE FOR THE EGG PARASITOID TRISSOLCUS BASALIS: BEHAVIORAL AND CHEMICAL ECOLOGY ASPECTS

<u>S. Colarza</u>, Inst. of Agricultural Entomology, Univ. of Palermo, viale delle Scienze13, Palermo, 90128, Italy, E-mail colazza@unipa.it.

Behaviors leading to the host location by the egg parasitoid Trissolcus basalis are trigged by the perception of host cues during various phases of the foraging process. The eggs of Nezara viridula, one of the main hosts of T. basalis, are immobile, do not interact with the plants and do not emit odours. Therefore T. basalis female might have to rely mainly on cues that do not directly originated from the altacked host stage. Laboratory investigations have demonstrated the importance in the short-range host finding process of the traces deposited on substrate by both the immature $(3^{sd}, 4^{sh} \text{ and } 5^{sh} \text{ instar larvae})$ and the adult stages of N. viridula. These chemicals play a role as contact cues since T. basalis female must contact the contaminated area with its antennae before it can perceive it. Then the wasps are flight inhibited for a certain amount of time, and, throughout the entire time, they are stimulated to an ambulatory-searching behavior. Because the host's traces seems to serve as a general kairomone to the possible presence of host eggs, an increment in the amount of time which a wasps allocate to the contaminated area with kairomones left by host stages more correlated with the host egg presence is predicted. Then, the actual encounters with host eggs in the presence of the kairomone should provide more reliable estimation for parasitoids than would the contact with the kairomone alone do. Our data agreed with these predictions. When wasps encounter a patch contaminated by immature stages and adults of N. viridula their resident time was longer and their walking pattern was different compared to uncontaminated areas. However, the longest wasp's resident was recorded only when in contact with the trace left by N. viridula mated females in a pre-ovipositional condition. The different in the resident time in the host-contaminated area for naive versus experienced females (those that have oviposit in the presence of the contact kairomone) indicates the importance of experiences with the host eggs. Observations were also done with both potential and non-host pentatomid bugs in which results should aim at defining predictability of T. basalis's host specificity. Solid-phase microextraction (SPME) fibers, subsequently analyzed by gas chromatography/mass spectrometry (GC/MS), were used to detect the compounds from the headspace of sample filter papers treated with males or females of N. viridula. Also selectively solvent extractions confirmed a different chemical composition on the cues left by male or mated female. These broader understanding of host-parasitoid interactions can enhance the possibility to improve the efficacy of this world wide used parasitoid in biological control programs

Index terms: Nezara viridula, host location, arrestment, foraging behavior.

[0591] MULTIPLE MATINGS AND EFFECTS ON FECUNDITY AND ATTRACTION IN LYGOCORIS PABULINUS

A.T. Groot¹ & H.M. Smid², ¹Plant Research International, Wageningen UR, P.O. Box 16, 6700 AA Wageningen, The Netherlands. e-mail: a.t.groot@plant.wag-ur.nl; ²Lab. of Entomology, Wageningen Univ., P.O. Box 8031, 6700 EH Wageningen, The Netherlands.

Lygocoris pabulinus (emales are polyandrous under laboratory conditions. Before determining effects of multiple matings, we studied the female reproductive tract and the process of sperm transfer and storage in detail, as in mirids female genitalia have only been studied partially so far. The bursa copulatrix consists of 4 plates, wich are dorsally enclosed by a circular-shaped plate of the median oviduct, posteriorly and ventrally by a membrane. A spermatheca is connected anteriorly to the bursa. At copulation a spermatophore is formed in the spermatheca. The spermatophore is compartmentalized, consisting of a sperm-containing portion, a large sperm-free portion and a mating plug. After 24 h the spermatophore is partially disintegrated, the mating plug is still intact but reduced, and sperm is found throughout the spermatheca and in the median and lateral oviducts, where most likely fertilization takes place. We conducted two oviposition experiments to determine effects of multiple matings on fecundity and longevity. Neither factor seemed to be influenced by multiple matings. We also determined sexual attraction of mated females at long range and at close range. At long range females were unattractive for only 1-2 h after mating, while they remained attractive at close range. Mated males did not respond to virgin females for 2 h after mating, and only 23 % of the tested males mated again within 24 h. Hence, females may not cease to attract males, but males may be unresponsive to females after mating.

Index terms: Heteroptera, Miridae, female reproductive tract, spermatophore, mating effort, fecundity, longevity, sexual attraction, sexual communication

[0592] PROSPECTING WITH INSECT CHEMOSENSORS FOR BIOACTIVES IN PLANT AND ANIMAL STRESS

J. A. Pickett, Biological & Ecological Chemistry Department, IACR-Rothamsted, Harpenden, Hertfordshire, ALS 2JQ, United Kingdom, E-mail john.pickett@bbsrc.ac.uk.

Plants and higher animals under stress from predation and disease, and also undergoing normal physiological changes such as hormone cycling, produce compounds released externally which have signalling roles with other organisms and within their own species. Plant receptors involved in these interactions are little understood, and such systems are difficult to exploit within higher animals because of welfare considerations and the disturbance caused to these organisms by invasive techniques. However, where such signals interact with insects, the highly developed techniques of electrophysiology used traditionally in identification of insect semiochemicals can be employed. Furthermore, relatively robust monitoring devices can be made using organ or whole organism preparations for exploiting the external signalling compounds in diagnostic systems. With the prospect of further exploitation by means of molecular genetics, in which overexpressed molecular recognition proteins will be used directly in biosensors, these aspects of insect chemical ecology are likely to have considerable bearing on areas as diverse as agricultural crop plant nutrition and human health and forensic science.

[0593] REPELLENTS: NATURE'S FIRST LINE OF CHEMICAL DEFENSE

D. M. Norris, Univ. of Wisconsin, Madison, WI 53706, U.S.A., E-mail: dalekim@msn.com

Chemical defenses of plants, against especially insects, involve a continuum of compounds ranging from volatile repellents: through relatively non-volatile feeding and oviposition deterrents and inhibitors; to inhibitors and disrupters of most, if not all, aspects of the insect's nutrition and physiology of growth, development including metamorphosis, sexual maturation and reproduction, and aging and longevity. The evolved, natural wild (i. e., not genetically altered by humans) survivor plant thus is usually chemically able to affect most insects in the plant's environment adversely at a multitude of critical target sites. The first tier, or order, in such plants' chemical defenses thus involves volatiles (c. g., allomones). Volatile repellents have the supreme ability to prevent, or to discourage significantly, the insect from even arriving at the source plant. This first-order chemical defense thus may yield the plant protection not only from herbivory, but also against ovipositional and pathogen (including toxin)-transmission ill effects. This paramount chemical defense involves a mixture of volatile phytochemicals per plant and variety. It thus provides a relatively stable protection as compared to the single-chemical defense so frequently applied to a cultivated plant by humans. A plant's bouquet of volatiles, of course, is not repellent to all herbivores; however, plants have coevolved with parasites and predators of herbivores that attack them so some of their volatiles are kairomones for the pertinent biological-control agent. Thus, the plant, even before, but especially when experiencing herbivorous attack, extrinsically emits kairomones for its ally parasites and predators of the attacking herbivore. Through volatiles, plants therefore practice both intrinsic (direct) and extrinsic (indirect) chemical defenses against their herbivores. In situations where a parasite or predator is highly selective, or specific, in attacking a given species of herbivore, plants attacked by that herbivore cause the attacker to ingest precursor(s) which metabolically force the herbivore to release in its feces kairomones for the specific parasite or predator. These quite marvelous chemical-communication happenings in nature are surely not random events, but in fact both the chemical releases and perceptions are biophysically regulated as information by a unifying sulfhydryl disulfide dependent redox protein electrochemistry. Details of this unifying informationcoding electrochemistry will be discussed further in the lecture. Index terms: plant, defense, chemical.

[0594] PHYTOCHEMICAL PROSPECTING FOR INSECTICIDES: IMPROVING THE ODDS OF DISCOVERY

<u>M.B. Isman</u>, Faculty of Agricultural Sciences, Univ. of British Columbia Vancouver, BC, Canada V6T 1Z4, Email: murray.isman@ubc.ca

Many investigators have screened plant material in search of natural products possessing insecticidal or antifeedant properties against pest insects. Some of these efforts have identified useful lead chemistries for the subsequent development of synthetic insecticides, while others suggest potential direct utility of extracts as botanical pesticides. In our investigations, we have focussed on tropical plants in the families Annonaceae, Meliaceae and Olacaceae. Crude methanolic extracts are evaluated via incorporation into artificial media on which neonate tobacco cutworms, Spodoptera litura are allowed to feed and grow for 10 days at 26°C. Initial screening takes place with dietary concentrations of 1000 ppm (0.1% fwt); extracts reducing growth by more than 75%, relative to controls, are subjected to further bioassay at a range of concentrations to establish the the EC₅₀ (dietary concentration reducing growth by 50%). Extracts with EC50 values below 100 ppm then proceed to bioassay-driven fractionation in an effort to isolate and identify the active principle(s). From over a decade of experience utilizing this approach, it has become apparent that the probability of finding natural insecticides in plants can be improved by: 1. Collecting as many individuals from each plant species as is practical, rather than just one; 2. Screening different tissues from each plant species; 3. Focussing on particular genera where bioactivity has previously been documented. Results from our recent investigations of *Trichilia* species from Costa Rica and *Annona* species from Indonesia show considerable intraspecific variability (temporal, geographical and among plant tissues) in bioactivity against the tobacco cutworm. In concentrating on taxa in the genera Aglaia and Trichilia (both Meliaceae), our 'hit' rate for bioactivity was approximately 35% and 50% respectively. In contrast, random screening of the family Olacaceae had a hit rate of 22%, and a random screening of tropical timber species of Indonesia and Malaysia led to a single hit among 20 species examined. Given the extremely limited success in the development of new botanical insecticides in recent years, and the difficulties in production and registration of botanicals for use in industrialized countries, academic and industrial researchers would do best to focus their efforts on plants already identified as being bioactive, or at least limiting their search to closely related taxa (e.g. congeneric species).

[0597] MOLECULAR MECHANISM OF SEX PHEROMONE PRODUCTION IN THE SILK WORM, BOMBYX MORI

S. Matsumoto¹, N. Yokoyama^{1, 2}, T. Yoshiga^{1, 3}, K. Okano⁴ & A. Fonagy⁵, ¹Molecular Entomology and Baculovirology, RIKEN, Wako-shi, 351-0198, JAPAN, E-mail smatsu@postman.riken.go.jp; ²Dept. of Agricultural & Life Sciences, Univ. of Tokyo, Tokyo 113-8657, JAPAN; ³Lab of Nematology, Saga Univ., Saga 840-8502, JAPAN; ⁴Lab of Cell Biology, Akita Pref. Univ., Akita 010-0195, JAPAN; ⁵Plant Protection Inst. Hungarian Acad. of Sciences, Budapest, II. 1525, P. O. Box 102, HUNGARY.

Female moths attract conspecific males by producing and releasing species-specific pheromone blends. Biosynthesis of pheromone components takes place specifically in the pheromone gland generally associated with the intersegmental membrane between the 8th and 9th abdominal segments. Production of sex pheromones in many Lepidoptera is (PBAN), which has been identified as a 33-34 amino acid peptide with a C-terminal FSPRLamide sequence responsible for pheromonotropic activity. In order to understand the molecular as well as cellular mechanisms of pheromone production regulated by PBAN, we have isolated functional clusters of viable pheromone producing cells of B. mori. One of the prominent morphological features of the pheromone producing cells is the abundance of large refractile granules in the cytoplasm at adult eclosion. Precise analysis on these granules revealed that the large granules at adult eclosion dramatically reduced their size and increased the number of small granules by 28 hrs after eclosion, and then reduced both number and size. These changes were prevented by decapitation and proceeded by PBAN injection. Nile Red staining and chemical characterization using FAB-MS indicated that these granules were triacylglycerols mainly composed of pheromone precursor fatty acids. Therefore, it is likely that the granules work as storage or carriers of sex pheromone precursors. Present results also suggest that the isolated cell preparation can be used for quantitative visualization of the cellular dynamics during pheromone production in B. mori. We will also discuss the expression of functional proteins and their genes involved in the process of pheromone production in B. mori. Index terms: PBAN, cellular dynamics, pheromone biosynthesis, hormonal control, triacylglycerol.

[0596] PHEROMONE BIOSYNTHESIS: UNIQUE DESATURASE GENES

W. L. Roelofs & W. Liu, Dept. of Entomology, Cornell Univ., Geneva, NY 14456, USA. E-mail: WLR1@cornell.edu

Research on biosynthetic pathways of sex pheromones in moths has revealed that the majority of known pheromone components are produced by various combinations of two unique enzyme systems, desaturases and chain-shortening enzymes, that produce an array of unsaturated long-chain fatty acetates, aldehydes and alcohols. The unusual desaturases discovered in moth pheromone glands are of interest because they function to produce different unsaturated products than the normal metabolic Z9-desaturases found in the rest of the insect body. Not only do they produce various Z11 fatty acids, but some generate mixtures of Z and E geometrical isomers, which are rare in nature. The evolution of these desaturases has played a key role in the generation of the diversity of chemical blends used as species-specific mating signals by many moth species, and, thus, is significantly involved in the speciation process. Full-length cDNA that encodes a Z11 desaturase from sex pheromone gland of the cabbage looper moth, Trichoplusia ni, and another that encodes a Z9 desaturase from the fat body of this species was characterized. A functional assay was developed for these desaturases based on a previous report that the unsaturated fatty acid auxotrophy of a desaturase-deficient ole1 strain of the yeast saccharomyces cerevisiae can be complemented genetically with plasmid encoding a rat stearoyl-CoA Z9desaturase cDNA. Genetic transformation of this mutant yeast with expression plasmids encoding either the T. $ni \triangle 11$ or $\triangle 9$ desaturase resulted in complementation of the strain's fatty acid auxotrophy and the production of Z11- or Z9- unsaturated fatty acids, respectively. cDNA that encodes the metabolic Z9 desaturase from redbanded leafroller moth, Argyrotaenia velutinana, fat body was characterized and functionally defined using the mutant yeast assay. However, cDNA that encodes desaturases in the sex pheromone gland of this species could not assayed with the mutant yeast assay. The ole1 strain's unsaturated fatty acid auxotrophy cannot be rescued by supplementation of the growth medium with Z11- or E11-14: Acid, which are the acids produced by desaturases in this sex pheromone gland. Therefore, other functional assays were researched, including the use of a pYES2 yeast system, an insect select system, and injection of xenopus eggs. The successful assay will be used as genes are characterized for other unique desaturases in some New Zealand leafroller species.

Index terms: Trichoplusia ni, Argyrotaenia velutinana, functional assay, cDNA

[0598] REGULATION OF PHEROMONE BIOSYNTHETIC PATHWAYS IN MOTHS

<u>R. A. Jurenka</u>, Dept. of Entomology, Iowa State University, 411 Science II, Ames, IA 50011-3222, USA, e-mail rjurenka@iastate.edu.

Pheromone biosynthesis in female moths will be discussed especially with regard to the regulation of biosynthetic pathways. Most moth pheromones utilize a hydrocarbon chain with a functional oxygen group (acetate ester, aldehyde, alcohol, or epoxide) or the absence of any oxygenated functional group (hydrocarbon). The biosynthesis of these molecules is determined by the type and specificity of the enzymes involved in the biosynthetic pathway. The production of the oxygenated molecules is usually under the control of the peptide hormone PBAN (Pheromone Biosynthesis Regulating Neuropeptide). Background information will be presented on the biosynthesis of the regulation of hydrocarbon pheromones is not clearly understood but may not require the presence of PBAN. Hydrocarbons are produced by oenocyte cells and then transferred to other cells for use. The biosynthesis and regulation. Index Terms: Helicoverpa zea, Lymantria dispar, Scoliopteryx libatrix, PBAN

[0599] ENDOCRINE REGULATION AND MECHANISM OF HYDROCARBON PHEROMONE PRODUCTION IN THE HOUSEFLY, MUSCA DOMESTICA

<u>G. J. Blomquist</u>¹, A. G. Bagneres², C. Schal³, M. Kuenzli¹, X. Shen¹ & C. Tittiger¹, ¹Dept. Biochem, Univ. Nevada, Reno, NV 89557, USA E-mail: blomquis@unr.edu; ²Lab. de Neurobiolgie, CNRS-UPR, Comm. Chimique, Marseille, Cedex 20, France; ³Dept. Entomol., Univ. North Carolina, Raleigh, NC 27695.

The major pheromone component, (Z)-9-tricosene, of the female housefly, Musca domestica, is produced about two days after emergence to the adult. Ovarian-produced ecdysteroids induce a change in the chain length of the cuticular alkenes from producing primarily (Z)-9-heptacosene to produce (Z)-9-tricosene (muscalure) by altering the chain length specificity of fatty acyl-CoA elongases. (Z)-9-Tricosene appears in the hemolymph, associated with lipophorin, about one day prior to similar amounts appearing on the surface of the insect. Other pheromone components include epoxide and ketone derivatives of (Z)-9-tricosene. The C23 epoxide and ketone pheromone components are not present in the hemolymph, suggesting that (Z)-9-tricosene is converted to the epoxide and ketone in the cells that transport hydrocarbon from the hemolymph to the surface of the insect. Cytochrome P450s are involved in both converting a C24 aldehyde to (Z)-9-tricosene and subsequently converting (Z)-9-tricosene to the epoxide and ketone. Three integument enriched cytochrome P450s have been cloned and sequenced and are in the process of being expressed and assayed.

[0601] MICROSOMAL REACTIONS INVOLVED IN THE FORMATION OF HYDROCARBONS AND THE CONTACT SEX PHEROMONE IN *BLATELLA GERMANICA* INTEGUMENT

<u>M.P. Juárez</u>¹ & G. J. Blomquist², ¹Inst. Investig. Bioquím. La Plata, Fac. Cs. Méd. UNLP, calles 60 y 120, La Plata 1900, Argentina. ²Dept. Biochem., Univ. Nevada, Reno, NV 89557, USA. E-mail: mjuarez@isis.unlp.edu.ar.

The major cuticular hydrocarbon component of the german cockroach Blatella germanica, 3.11-dimethylnonacosane, and the major female contact sex pheromone, 3.11-dimethyl-2nonacosanone, are metabolically linked through hydroxylation and oxidation steps. We report that the integument is the site of pheromone synthesis. Integumental fatty acid synthetases (FASs) were shown to produce the methylbranched fatty acid precursors. Elongation of fatty acyl-CoAs to very long chain fatty acids, and the final step in the synthesis of the major component of the sex pheromone, the conversion of 3,11-dimethyl [11,12 ³H]nonacosane to 3,11-dimethyl [11,12 ³H]-2-nonacosanone, were studied in integumental microsomes. Incubation of [1-¹⁴C]palmitoyl-CoA, malonyl-CoA and NADPH resulted largely in the production of [¹⁴C]C18-CoA with minor amounts of C20, C22, C24, C30 and C32 acyl moieties. Similar experiments with [1-14C]stearoyl-CoA rendered C20-CoA as the major product, minor peaks of C22 and C24-CoAs were also detected. After solubilization of the microsomal FAS, kinetic parameters were determined radiochemically or measuring NADPH consumption by spectrophotometry. The reaction velocity was linear up to 10 min incubation time, and with protein concentration up to 0.025 Dg/Dl. The effect of the chain length on the reaction velocity was compared for block light in the effect of the end frequencies of the relation velocity was compared to palmitoyl-CoA, stearoyl-CoA and eicosanoyl-CoA, the optimal sustrate concentration was 12 \square M for C16-CoA, 9 \square M for for C18-CoA, and 4 \square M for C20-CoA. Studies were performed to examine in vitro the last steps in the synthesis of the contact sex pheromone after incubation of microsomal preparations with [11, 12-3H]3,11-dimethylnonacosane or [11,12-3H]3,11-dimethyl-2-nonacosanol. After 30 min at pH 7.8, in O2 atmosphere, the alkane was converted into methylketone and the corresponding alcohol. When the sustrate was the C29-ol, almost 90% was metabolized into the sex pheromone. Index terms: elongases, acyl-CoA, hydrocarbons, german cockroach

[0600] SYNTHESIS OF HYDROCARBONS AND SEX PHEROMONES AND THEIR TRANSPORT THROUGH THE HEMOLYMPH IN INSECTS

C. Schal & Y. Fan, Department of Entomology, North Carolina State Univ., Raleigh NC, 27695, USA

The outer surface of insects is covered with a lipid layer that provides water-proofing and protection against environmental stresses. Hydrocarbons are major constituents of this epicuticular wax and in some insects they are also exploited as biosynthetic precursors for contact pheromones. In the German cockroach hydrocarbons and pheromones are synthesized by oenocytes which are situated in the integument. Synthesis of hydrocarbons is dependent to a large extent on food availability, but its sex-specific conversion to pheromone in the adult female is regulated by juvenile hormone. An important site for deposition of hydrocarbons in females is the ovary. Shuttling of hydrocarbons from the abdominal integument to the epicuticle, fat body, and gonads uses a versatile lipoprotein, lipophorin, which carries both hydrocarbons and the contact sex pheromone, and also serves as a juvenile hormone-binding protein. In several tiger moth species and in the housefly, short- and medium-chain hydrocarbons sex pheromones are also transported by lipophorin from integumental biosynthetic sites to sex pheromone glands or the epicuticle. In Holomelina tiger moths pheromone is synthesized by tissues associated with the abdominal integument. Lipophorin transports the pheromone to an abdominal gland that stores and releases the pheromone only during active calling behavior. We suggest that such transport pathways are common not only among insects that emit hydrocarbon pheromones, but also among insects that sequester hydrophobic plant-derived metabolites.

[0602] MOLECULAR STUDIES ON THE ENDOCRINE REGULATION AND TISSUE LOCALIZATION OF *DE NOVO* MONOTERPENOID PHEROMONE COMPONENT BIOSYNTHESIS IN PINE BARK BEETLES

C. Tittiger¹, J. A. Tillman¹, G. Hall¹, C. S. Bengoa¹, C. O'Keeffe¹, F. Lu¹, L. S. Barkawi², G. J. Blomquist¹ & S. J. Seybold², ¹ Dept. Biochem., Univ. Nevada, Reno, Reno, NV 89557 USA, E-mail: crt@unr.edu.² Dept. Entomol., Univ. Minnesota, St. Paul, MN 55108 USA

Male pine engraver beetles, Ips spp., produce the isoprenoid pheromone components ipsdienol and ipsenol while feeding on pine phloem. The de novo, mevalonate-derived synthesis of monoterpenoids in these beetles is an unusual biochemical system with great potential for targeted insect control strategies. Since pheromone production is controlled by juvenile hormone III (JH III), we studied the effects of JH III on the two most likely regulators of the mevalonate pathway: HMG-CoA reductase and HMG-CoA synthase (HMG-R and HMG-S, respectively). JH III raises HMG-R transcript levels in male and female *1. pini* and *I. paraconfusus* in a dose- and time-dependent manner, with males responding more strongly than females. HMG-R activity levels also respond to JH III in male I. pini, but not in I. paraconfusus. Post-transcriptional control of HMG-R in male I. paraconfusus requires an additional, unidentified factor. Similarly, male Jeffrey pine beetles (Dendroctonus jeffreyi) produce the bicyclic acetal frontalin following topical JH III treatment. Both HMG-R and HMG-S transcript levels respond to JH III in male D. *jeffreyi*. The time course for mRNA induction precedes the appearance of frontalin by approximately four hours, suggesting this semiochemical is a monoterpenoid synthesized de novo via the mevalonate pathway. A combination of northern blotting and in situ hybridization localizes the site of HMG-R gene expression to the ventriculus in male l. pini and D. jeffreyi. Biochemical studies confirm that this is also the site of pheromone Thus, pheromones are synthesized by insect tissues, and likely not by biosynthesis. symbiotic bacteria. A genomics-based approach to identify additional targets for control is underway.

Index terms: Ips pini, Ips paraconfusus, Dendroctonus jeffreyi, juvenile hormone, isoprenoid

[0603] SEX PHEROMONE BIOSYNTHESIS IN SCARAB BEETLES

<u>W. S. Leal,</u> Dept. Entomology, University of California, Davis CA 95616, USA, Email: wsleal@ucdavis.edu

In scarab beetles, chemical communication is achieved using a wide variety of pheromone structures ranging from ubiquitous anisole to a unique medicinal alkaloid. A typical structure of the sex pheromone of rutelines is the five-member gamma-lactones having a long unsaturated hydrocarbon chain, such as (R,Z)-5-(--)-(oct-1-enyl)oxacyclopentan-2one (buibuilactone) and (R,Z)-5-(--)-(dec-1-enyl)oxacyclopentan-2-one (japonilure), which are pheromones for a number of species. Using deuterated precursors, it has been demonstrated that the biosynthesis of these compounds starts from saturated fatty acids (palmitic and stearicacid), involves their desaturation followed by stereospecific 8hydroxylation, chain shortening and cyclization. Various scarab species have developed pathways to produce unique pheromone molecules by changing either storeospecificity or regiospecificity of the hydroxylation step. Anomala cuprea and Popillia japonica utilize the (R)-8-hydroxylase, whereas the hydroxyylase of A. osakana is specific to the (S)substrate. It seems that A. rufocupren is devoid of the enzyme so it makes the methyl Z-(5)-tetradecenoate. The pheromone biosynthesis in scarabs is regulated by a PBAN-like factor. The pheromone liter in the glands of decapitated females dramatically decreased 24 hr after surgery, but it resumed after the injection of the brain extracts of virgin females. The activity of the brain extracts is lost after treatment with proteinase K. Because BmPBAN is also active, characterization of the gene encoding the peptide was pursued by library screening and PCR. Hitherto, none of the molecular approaches' have led to the identification of the PBAN gene in scarab beetles. On the other hand, a bioassayoriented strategy lead to isolation of the active peaks by reversed phase HPLC and ionexchange chromatography. The small amount of the isolated peptide prevented any further characterization.

Index terms: hydroxylase, PBAN, PCR, Anomala cuprea, Popillia japonica

[0604] HORMONAL REGULATION OF OLFACTORY DEVELOPMENT: DIAPAUSE ACCOMODATION?

<u>R.G. Vopt</u>¹ & M.-D. Franco^{1,2}, 1Dept. of Biological Sciences, Univ. of South Carolina, Columbia SC 29208, USA, E-mail vogt@biol.sc.edu; ² Dept. of Molecular and Cellular Biology, Univ. of Arizona, Tucson, AZ, 85721, USA E-mail franco@U.Arizona.edu. Support: NIH-NICDC DC00588; NSF-IBN9731005; USDA-CGRP94373020615.

Olfactory sensilla include 3 support cells (trichogen, tormogen, thecogen) and 2-3 odor receptor neurons; in adult holometabolous insects, these cells derive from proliferative processes occurring early in antennal development. Adult antennae of the hawkmoth Manduca sexta derive from imaginal discs which grow primarily during the final larval instar, everting about 2 days before pupation. At pupation, the antenna is laid along the body surface as a tubular structure with a monolayer epithelium which secretes the pupal antennal cuticle with the sensory epithelium facing outward. Mitoses yielding sensilla cells were previously reported between 20 and 60 hrs after pupation (S-phase, Sanes and Hildebrand, 1976). Antennal epidermis detaches from the pupal cuticle around 72 hrs (apolysis), and sensillar cells begin acquiring morphologically recognizable phenotypes by We have re-evaluated mitotic activity in the M. sexta antenna using BrdU 96 hrs. incorporation (S-phase, accumulative) or immuno-detection of the phosphorylated state of the H3 histone (M-phase, momentary). Mitotic activity was both temporally and spatially dynamic. No mitotic activity was observed during the first 24 hrs a.p., a low level of activity occurred during the second 24 hrs a.p., and a dramatically high level of activity occurred during the third 24 hrs a.p., culminating around the time (shortly after) apolysis at 72 hrs. Mitotic activity initiated along the presumptive proximal and distal borders of each annulus, restricted to the sensory epithelium. Over the course of the third 24 hr period, these peripheral zones broadened, meeting in the middle of each annulus shortly after apolysis. The homeobox gene distal-less (Dll) showed an overlapping temporalspatial pattern of expression. Both mitotic activity and Dll expression were enhanced by culture in the presence of either ecdysone (500 ng/ml) or 20-hydroxy ecdysone (20-HE, 200 ng/ml). Tissue from animals entering pupal diapause showed no mitotic activity, while animals induced to break diapause by injection of 20-HE initiated and completed proliferation during the initial 36 hrs after injection (non-injected controls resembled tissue entering diapause). We suggest the temporally asymmetric pattern of proliferation and its hormone sensitivity is a developmentally plastic accommodation to the decision of diapause. Under continuous development, high mitotic activity occurs only after a 48 hr check point is past which would otherwise be the entry point for diapause. Since development of central olfactory pathway requires sensory afferents, peripheral hormone sensitivity may coordinate diapause decisions for much of this pathway. Index terms: pheromone binding protein, olfaction, receptors, odor

Symposium and Poster Session

[0605] MOLECULAR, PHYSIOLOGICAL AND ETHOLOGICAL PERSPECTIVES ON INSECT OLFACTION

<u>B.H. Smith.</u> Department of Entomology, 1735 Neil Ave., Ohio State University, Columbus, OH 43210-1220, USA Email: smith.210@osu.edu

Research on insect olfaction has made significant progress on a number of fronts. Recent advances highlight the molecular and biochemical bases for transduction of chemical information into signals projected to the CNS. Further work has revealed the bases for processing those signals and integrating them with motor systems. Finally, work under both laboratory and field conditions have revealed behavioral mechanisms that insects use to approach or avoid important odors. Even in the case of pheromonal systems, these behavioral mechanisms always involve reasonably stereotypical responses to odors that can be modified by one or another learning process. In many cases important correlations have been established across molecular, physiological and behavioral levels of analysis. For example, odor stimulation activates defined spatial and temporal activity patterns that are characteristic for different odorants. More recently, several lines of evidence have revealed synaptic plasticity in the antennal lobes, which are the first-order processing centers for olfactory information in the brain. This plasticity is correlated to learned recognition of the association of odors to food reinforcement. Yet there have only been a few attempts to establish a causal link between any these neural events and behavior, and these attempts have met with limited success. Thus causal relationships are bound to be complex. The seminar will briefly review what has been done to link olfactory processing across different levels of analysis and highlight the need for these kinds of studies in the near future.

[0606] CHEMICAL VOCABULARY OF THE COLORADO POTATO BEETLE

J. C. Dickens, U. S. Department of Agriculture, Agricultural Research Service, Beltsville Agricultural Research Center, Plant Sciences Institute, Vegetable Laboratory, Beltsville, MD 20705, USA, E-mail jdickens@asrr.arsusda.gov.

The chemical vocabulary of an insect requires specialized receptors that are exquisitely tuned and uniquely sensitive to chemical signals emitted by conspecifics and their hosts. Communication within a species is extremely important for resource utilization and reproduction; especially for specialized feeders such as the Colorado potato beetle (CPB) in which both immature and adult forms exist on the same host plant. Investigations into chemical communication by CPB have yielded little until recently when blends of chemicals emitted by potato plants were identified that were attractive to CPB and some of its predators (Dickens 1999; Dickens 2000a, b). However, the question of whether immature and adult CPB might communicate by way of chemical signals and the nature of this vocabulary remained unknown. Now we have determined textual differences among chemical signals emitted during larval and adult feeding on potato plants. These differences are detected by antennal chemoreceptors in adult CPB and their detection may result in attraction or avoidance of occupied host plants, as well as other behaviors. The messages are comprised of at least nine chemicals emitted as different blends during insect feeding. Behavior elicited by the chemical messages may be modified by previous experience. Thus, intraspecific communication occurs in CPB and is likely to be present in other species where larval and adult forms compete for the same resource. The expanded vocabulary inherent in these intraspecific "chemical conversations" demands a corresponding enhancement of receptor types, plasticity of the central nervous system, and a diversity of behaviors in response to overlapping syntax of the blends.

[0607] PLASTICITY OF OLFACTORY AND BEHAVIORAL RESPONSES OF HAWKMOTHS TO FLORAL FRAGRANCE

R. A. Raguso, Dept. of Biol. Sci., Univ. of S. Carolina, Coker Life Sci. Bldg., 701 Sumter St., Columbia, SC 29208, USA, E-mail Raguso@biol.sc.edu

The reproductive fitness of adult hawkmoths (Lepidoptera: Sphingidae) depends to a large extent on detecting and tracking relevant odors. Neuroethological studies have shown that male Manduca sexta detect, process and respond to female sex pheromone in reproducible and stereotypical ways. Recent work has documented similar responses of female M. sexta and other hawkmoths to hostplant odors. Both sexes of M. sexta and other nocturnal hawkmoths also use olfactory cues, in combination with visual inputs, to forage for floral nectar, a critical source of energy for long-distance dispersal and hovering flight. However, studies of M. sexta foraging behavior reveal that adult feeding is much less predictable than odor-driven sexual behaviors, such as mate finding and oviposition. Although EAG responses to floral odors remain keen throughout adult life, behavioral responses to fragrance may be modified by larval diet, stored fat reserves, mating status, photoperiod, temperature and experience (associative learning). Such flexibility raises questions as to how floral odorants, particularly those with some similarity or overlap with hostplant odors, are processed by the hawkmoth brain. The specific effects of larval dietary components on adult feeding behavior will be discussed.

[0609] ATTRACTION OF PLUM CURCULIOS TO INTERACTING, HOST ODOR, PHEROMONAL AND VISUAL STIMULI

R.J. Prokopy¹ & T.C. Leskey¹, ¹Dept. of Entomology, Univ. of Massachusetts, Amherst, MA 01003, USA, E-mail prokopy@ent.umass.edu

Plum curculios overwinter in woods near orchards. They move into orchards around blossoming of trees and commence to feed upon and oviposit in developing fruit, causing severe injury. In laboratory assays in large still-air arenas, males were not attracted to odor of females alone or males alone but were attracted to odor of plums alone and females feeding on plums (a native host fruit). Females were attracted to odor of males alone, but attraction disappeared in presence of plum odor. Combined findings suggest greater response of each sex to host odor than to pheromone released by conspecifics. Sixty compounds have been identified from host plum or apple fruit at the stage most susceptible to plum curculios (2 weeks after bloom). Thirty of these (each at 3 release rates) were evaluated in field tests. The following were attractive to adults: E-2-hexenal, limonene, decanal, benzyl alcohol, benzaldehyde, hexyl acetate, geranyl propionate and ethyl isovalerate. Synthetic male pheromone (grandisoic acid) did not enhance attractiveness of compounds but release vehicle (rubber septum) may have been inappropriate. Attractive odor may be developed effectively when in combination with a visual trap, such as clear or colored panel near woods to intercept immigrating adults, a trunk-mimicking black pyramid next to an orchard tree to attract adults entering trees by crawling, or a branch-mimicking black cylinder in a tree canopy to attract adults foraging for branches with fruit. Prospects for using odor-baited visual traps for monitoring and controlling plum curculios will be discussed.

Index terms: Conotrachelus nenuphar, host odor, pheromone, vision, attraction.

[0608] SENSORY INPUTS GOVERNING UPWIND FLIGHT OF MALE MOTHS ALONG PHEROMONE PLUMES

R.T. Cardé¹, K. Justus¹ & J. Murlis², ¹Dept. of Entomology, Univ. of California, Riverside, CA 92521, USA, E-mail ring.carde@ucr.edu; ²Inst. for Environmental Policy, University College London, 29/30 Tavistock Square, London WC1H 9EZ, UK

Mate-location in most moths is mediated by a plume of female-emitted pheromone that induces flight by males along that plume. In wind, the principal mechanism governing the direction of flight along pheromone plumes is optomotor anemotaxis in which the upwind heading is gauged by transverse image flow. Maintenance of forward progress appears contingent on the rate of encountering individual filaments of odor within the plume. If the rate of filament encounter falls below about 10 Hz, moths head more toward the crosswind. If contact with odor is lost for a large fraction of a second, casting or zigzagging flight without upwind progress ensues. Rapid and often nearly straight flight toward upwind is prompted by rates of filament encounter > 10 Hz. Some intermittency of the odor signal appeared requisite for upwind movement, because two moth species have been found not fly upwind when they are in a homogenous plume. We have explored in a wind tunnel how the fine-scale structure of the pheromone plume dictates flight along the plume in the almond moth, Cadra cautella. To verify the plume's structure we have used a tracer gas and monitored the concentration of a variety of plume types at 330 Hz. Plumes which were pulsed from 10 to 25 Hz produced many rapid flights upwind and no arrestment of upwind progress. Homogeneous plumes also produced rapid upwind flights over a wide range of concentrations. Together these findings suggest that a rapidly flickering pheromonal signal is not requisite for upwind flight in Cadra. Index terms: optomotor, anemotaxis, pheromone, attraction, moths

[0610] MASS TRAPPING OF RHYNCHOPHORUS PALMARUM USING PHEROMONE IN COCONUT PLANTATION, IN BRAZIL

J. L L. Moura¹, E. F. Vilela¹, G. H. Brasil³ & R. Canguçu³, ¹ Estação Experimental 'Lemos Maia', CEPLAC/CEPET, Una, BA, 45600-00; ² Dept. de Biologia Animal, Universidade Federal de Viçosa, MG, Brazil, 36571-000. e-mail: evilela@mail.ufv.br; Fazenda Novo Horizonte, Porto Seguro, BA, Brazil.

The weevil *Rhynchophorus palmarum* is one of the most serious pest of coconut and palm oil plantations in Central and South America, not only because of the damage they can cause to trunk trees, but also because of the transmission of a nematode to plants, which causes the 'red ring disease'. Food attractants have been used since a long time for trapping the pest. More recently, the species aggregation pheromone {2(E)-6-methyl-2-hepten-4-ol} became commercially available in Brazil. Using this pheromone associated with a food attractant (sugar cane), we tested the mass trapping technique in the 'Novo Horizonte' Area, in Porto Seguro (BA), Brazil. From May 1997 to September 1999, we captured 97,835 insects, in an area of 54 hectares (4634 plants). The disease reduction in the area, due to the decrease in the insect pest population was significantly high, from 206 attacked trees in May 1997 to only three trees in September 1999. Pheromone traps seem to be a very interesting tool for the control of *R. palmarum*.

[0611] THE USE OF ATTRACT AND CONTROL TECHNOLOGIES IN THE CONTROL, PREVENTION, SUPPRESSION AND ERADICATION OF THE COTTON BOLL WEEVIL

T.A. Plato, J.C. Plato, J.S. Plato & S.E. Plato, Plato Industries, Inc., 2020 Holmes Road, Houston, Texas 77045, USA, E-mail: plato@nol.net

The use of attract and control technologies in boll weevil (Anthonomus grandis Boh.) control, prevention, suppression and eradication is making substantial progress in area wide programs in Argentina, Bolivia, Brazil, Colombia, Paraguay and the USA. Discoveries by early workers as reported in the literature and a USDA-ARS monograph (Agriculture Handbook Number 259, Ridgeway et al. 1983) led to the isolation, identification and synthesis of the boll weevil pheromone and the subsequent design and production of effective boll weevil traps. In the 1980s, the traps as designed by Dr. Dick Hardee and Dr. Bill Dickerson evolved into commercial production for use in early IPM and early boll weevil eradication programs (BWEPs) in the Southeast USA. The traps were more effective as detection devices than as control devices and this lead to research and development of the boll weevil bait stick at the USDA-ARS-Boll Weevil Research Laboratory. Technology surrounding the bait stick was patented by the USDA and transferred as an exclusive license to Plato Industries, Inc. under the US Government's Technology Transfer Act. During the years of 1990, the bait stick was modified, improved, commercialized and evaluated as the Boll Weevil Attract and Control Tube (BWACT) in more than 200 IPM tests in the USA. The use of the BWACT (Tubo Mata Picudo or Tubo Mata Bicudo) in Central and South America was heavily influenced by the outstanding results of a two-year area wide program in Nicaragua. Through collaboration with the USDA-ARS, State Extension Agencies and Latin America cooperators the BWACT technology was implemented as a "preventative" approach against the boll weevil, the number one cotton pest in the Americas. It has been adopted by Paraguay (210,000 ha.) and Colombia (100,000 ha.) as a strategic component in their National Cotton Reactivation Programs and as a key component in the IPM programs of Brazil (150,000 ha.). Argentina (50,000 ha.) and Bolivia (20,000 ha.) have implemented the use of the BWACT and traps to detect and prevent the establishment of the boll weevil in their major cotton zones. BWACT results from an area wide program in Paraguay are exemplary of the potential for using the attract & control technology; cotton yields have been increased an average of 400 kgs. per ha., insecticide usage for boll weevil control has been reduced from 6 - 8 applications per crop to less than 1. As a consequence, the incidence of secondary pests and damage to beneficial insects has been drastically reduced. Results from the aforementioned programs will be presented. Index terms: Anthonomus grandis, BWACT, Grandlure.

[0612] PHEROMONE-BASED MASS TRAPPING OF THE BANANA WEEVIL, COSMOPOLITES SORDIDUS & THE WEST INDIAN SUGARCANE WEEVIL, METAMASIUS HEMIPTERUS IN BANANA & PLANTAIN

A.C.Ochlschlager,¹ D. Alpizar,² M.Fallas,² L.M. Gonzalez¹ & S. Jayaraman³ ¹ChemiTica Int., S. A., Apdo. 159-2150 San José, Costa Rica, E-Mail chemitica@sol.racsa.co.cr; ²Min. de Agric., Guapiles, Costa Rica; ³Dept. of Chem., Simon Fraser Univ., Burnaby, B.C., V5A 156, Canada

Cosmopolites sordidus is the most important insect pest of banana & plantain. Surveys in the Atlantic region of Costa Rica revealed that larvae & adults of both C. sordidus & Metamasius hemipterus (West Indian sugarcane weevil) were present in corm of both banana & plantain. C. sordidus predominated in banana & M. hemipterus in plantain. Larval feeding causes corm damage that is assessed by inspection of crosscut sections of corms of recently harvested plants. In plantations that routinely used nematicideinsecticide applications (e.g. Counter, Furadan) to combat root damage by Radopholus spp. nematodes surveys determined C. sordidus associated corm damage of 15-35%. In 1995 we demonstrated that the male-produced aggregation pheromone of C. sordidus was attractive in the field. Since 1996 we have conducted studies to determine the extent to which pheromone-based mass trapping reduces corm damage due to C. sordidus & increases fruit bunch weight. Trapping of C. sordidus revealed that initial capture rates in pheromone-baited traps correlated well with banana corm damage & capture rates of M. hemipterus correlated well with plantain corm damage. Mass trapping C. sordidus using a pheromone-baited pitfall trap (soapy water as killing agent) & M. hemipterus using a pheromone-sugarcane-baited open gallon trap were conducted in commercial banana & plantain. Four traps for each insect per ha were placed in each of three 1 ha plots of plantain & two 5 ha plots of banana during 10-17 months. Capture rates of C. sordidus & M. hemipterus in both plantain & banana declined by > 75% over 10-12 months. Corm damage decreased by 61-64% over the same period. Fruit bunch weights increased by 27% in plantain & 23% in bananas relative to control plots after 11-12 months of trapping. Trapping only for C. sordidus in several large plantations (>200 Ha each) reduced corm damage by 62-86% relative to pre-trapping levels after 4-5 months. In all plantations in which trapping was conducted for more than 5 months corm damage was reduced to less than 10%. After completion of these trials a new above ground ramp trap was developed for C. sordidus that is 25-40% more effective than the pitfall trap. The cost of year round trapping is less than a single insecticide application & is recovered by a 1-2% increase in vield.

Symposium and Poster Session

[0613] FIELD EVALUATION OF FEMALE-TARGETED TRAPPING SYSTEMS FOR DETECTION AND USE IN POPULATION SUPPRESSION/ERADICATION OF CERATITIS CAPITATA (DIPTERA: TEPHRITIDAE)

<u>R. R. Heath¹</u>, N.D. Epsky², B. I. Katsoyannos³ & J. Hendrichs⁴, ¹United States Department of Agriculture, Agricultural Research Service, South Atlantic Area, Subtropical Horticulture Research Station, 13601 Old Cutler Road, Miami, FL 33158-1334 USA, E-mail mianh@ars-grin.gov. ²USDA/ARS, CMAVE, P.O. Box 14565, Gainesville, FL, USA, ³32604 University of Thessaloniki, Department of Agriculture, Laboratory of Applied Zoology and Parasitology, 540 06 Thessaloniki, Greece, ⁴ International Atomic Energy Agency, Insect & Pest Control Section, Wagraumer Strasse 5, P.O. Box 100, A-1400 Vienna Austria.

Field trials were conducted in Argentina, Guatemala, Greece, Costa Rica, Honduras, Israel, Mauritius, Mexico, Morocco, Portugal, South Africa, Spain and Turkey to compare captures of the Mediterranean fruit fly, Ceratitis capitata (Wiedemann), among several types of traps baited with female-targeted attractants. Female-targeted trapping systems were baited with a new food-based three component synthetic attractant composed of ammonium acetate, putrescine and trimethylamine lures or with liquid protein bait. The synthetic attractants were tested in either wet traps (with water) or dry traps (with pesticide or sticky insert) and compared to capture of flies with McPhail-type traps baited with an aqueous solution of NuLure and borax. Traps baited with the three component attractant captured equal or greater numbers of flies than the McPhail-type traps baited with NuLure/borax. In trials with low C. capitata population levels, traps baited with the three component attractant captured more flies than the trimedlure (TML)-baited Jackson traps or NuLure/borax baited traps. Females accounted for 48 - 90% of the total capture in the female-targeted trapping systems. Traps baited with the three component attractant were more C. capitata specific than the other female-targeted trapping systems. In high density trapping (15 pairs/Ha) synthetic lures captured flies 4 weeks earlier than TML-baited Jackson traps. In low density trapping (1 pair/Ha + 1 TML/Ha), 3 weeks earlier than TML-baited Jackson traps. Results from these experiments has afforded the development of control strategies using mass trapping and bait stations. Index terms: Ceratitis capitata; Mediterranean Fruit Fly; Trapping; Suppression

[0614] PHEROMONE TECHNOLOGIES FOR MANAGING DOUGLAS-FIR TUSSOCK MOTH IN WESTERN NORTH AMERICA

G. E. Daterman¹, J. M. Wenz² & K. A. Sheehan³, ¹U. S. Forest Serv., Pacific NW Research Station, 3200 Jefferson Way, Corvallis, OR 97331, USA, E-mail gdaterman@fs.fcd.us; ²U.S. Forest Serv., Stanislaus National Forest, 19777 Greenley Rd., Sonora, CA 95370, USA; ³U. S. Forest Serv., Pacific NW Region, P. O. Box 3623, Portland, OR, 97208, USA.

The Douglas-fir tussock moth (DFTM)), Orgyia pseudotsugata, is a severe defoliator of conifer forests in western North America. Populations of DFTM are cyclic, with outbreaks that develop suddenly and with little warning. When a sex attractant pheromone, (Z)6-heneicosen-11-one, was identified in 1975, a trapping system was developed for early detection of outbreaks. The focus was to calibrate a trap lure that would result in minimal moth captures in low-density populations, while providing a quantitative measure of increasing population densities in areas where an outbreak might be developing. The system emphasizes low cost and simplicity to encourage use. Trapping was implemented in 1980 when several hundred five-trap plots were placed in Oregon, Washington, Idaho, and California forests. For the past 20-years at least 750 trapping plots have been maintained in susceptible forests in those states. Eleven DFTM outbreaks of varying size and intensity have occurred during that time period. Seven of those were predicted by the trapping system. Trapping also helped detect the remaining four outbreaks, but in those cases too few traps were located in the vicinity of the high populations for effective early detection. Effectiveness of the system depended on number of trap plots and their proximity to areas with high populations. Interpretation of trapping records, and sampling of other life stages of DFTM in the vicinity of high trap counts, also influenced system effectiveness. Pheromones also have been successfully tested in the USA and Canada to demonstrate mating disruption as a method to control DFTM. If a pheromone product were registered it would likely be used in DFTM management, particularly in the early phases of an outbreak. The (Z)6-heneicosen-11-one monoene is effective for mating disruption. However, the addition of a new pheromone compound, the dienone (Z)6,(E)8heneicosadiene-11-one, reported in 1997, would likely improve effectiveness if a dispenser system could be formulated to maintain isomeric stability. Use of pheromone plus an insecticide as an "attract-and-kill" method of control has not been evaluated for DFTM. This may be a useful approach to manage DFTM, but it would almost certainly require use of both pheromone components, because the monoene by itself is ineffective inducing male contact with pheromone dispensers. Index terms: Orgyia for pseudotsugata, monitoring, mating disruption, forest insects.

Index terms: corm damage, aggregation pheromone, banana yield, plantain yield

[0615] MATING DISRUPTION OF LEPIDOPTERA IN AUSTRALIA – TRIALS, TRIBULATIONS AND TOMORROW

R. A. Vickers, Commonwealth Scientific & Industrial Research Organisation, Entomology, PB 3 Indooroopilly, QLD Australia 4068

The chemical identification of the silkworm moth's sex pheromone by Butendandt et al in 1959 was the first of many hundreds of identifications made over subsequent decades. Entomologists were quick to recognise the potential of sex pheromones as tools in insect pest management and chemists soon began to focus their attention on insects of economic importance. In 1969 the major component of the oriental fruit moth (OFM), Grapholita molesta, was identified and in the following year CSIRO Entomology commenced trials in Australia to evaluate its potential as a mating disruptant. Fortuitously, the compound contained in approximately the right amount a contaminant that subsequently proved to be a minor pheromone component. From the very beginning of the trials, and despite the rather crude dispensing system used, it became clear that mating disruption offered real prospects for controlling this key pest of Australia's stone fruit industry. Minimum pheromone release rates were established, effective dispenser distribution patterns determined and protocols for establishing and assessing mating disruption trials developed. Successful area-wide trials followed and a mating disruption system that is now used by more than 90% of Australia's commercial pome fruit producers became commercially available soon after. Codling moth, Cydia pomonella, was our next target but, in contrast to OFM, proved to be a much more difficult candidate. Within the chemical ecology community there was considerable debate about the identity and behavioural role of the minor components and their influence on mating disruption, the major component was inherently unstable and, despite almost total suppression of catches at monitoring traps, there were many occasions when damage levels far exceeded thresholds tolerated by growers. After numerous trials and tribulations we (and others) eventually recognised that the larger the area treated and the lower the initial pest density the more likely it was that mating disruption would succeed. This scenario is of course not confined to codling moth. A commercial mating disruption product became available in Australia in 1993 and is currently used by about 20% of Australian commercial producers. A mating disruptant has also been identified for the two heliothine pests of cotton in Australia. But fears of physical contamination of the crop and labour costs has made our cotton industry unwilling to consider mating disruption in anything other than a sprayable formulation and further trials have been put on hold. However an effective sprayable formulation is believed close to market. If so, it will revolutionise mating disruption, making it an attractive option in broad-acre crops, very tall tree crops and forests. Index terms: Grapholita molesta, Cydia pomonella, heliothine moths, pheromone

[0616] MATING DISRUPTION TO MANAGE ORCHARD PESTS IN THE PACIFIC NORTHWEST OF NORTH AMERICA: PAST, PRESENT AND FUTURE

D.R. Thomson¹ & O. Knutson², ¹DJS Consulting, 3015 SW 109 Street, Seattle, WA 98146, USA, E-mail dthomso@pacifier.com, ²Alamo Orchards, Mattawa, WA 99349, USA.

There are 100,000 hectares of pome fruit grown in the Pacific Northwest of North America. The first pheromone-mediated mating disruption product for control of an orchard pest, codling moth, Cydia pomonella was registered in 1991. In 1997, the first leafroller mating disruption product was registered for control of 2 orchard pests, Choristoneura rosacena and Pandemis pyrusana. Currently, there are 6 and 4 products registered for codling moth and leafrollers, respectively. Commercially available delivery systems include microdispersible sprayable formulations, and reservoir-type dispensers. In 1999, codling moth and leafroller mating disruption technologies were used on approximately 25,000 and 1,500 hectares, respectively. Pheromone-based IPM programs based on the deployment of mating disruption technologies in conjunction with the judicious use of insecticides can be as or more cost-effective than the use of insecticides alone. Other benefits include reduced environmental residues of broad spectrum insecticides, decreased costs associated with worker protection and labour management, higher populations of natural enemies, and decreased potential for the development of insecticide resistance. Grower concerns include the high initial costs of transition to pheromone-based IPM programs, the often unpredictable impacts of insect population density, micro climate, canopy structure and topography on efficacy, the need for intensive monitoring and the potential for outbreaks of secondary pests. A case study will be presented to illustrate the economics, and problems associated with pheromone-based IPM practices in organic and conventional orchards. Research is still needed to improve the efficacy and reliability of pheromone-based IPM programs. There are extensive research efforts by industry into modifying and developing new delivery systems. Recent registrations include new formulations of microdispersibles and novel large aerosol dispensers. By identifying effective blends, measuring the spatial and temporal distribution of pheromones and then correlating those measurements with pheromone-mediated behaviours, the mechanisms of mating disruption will be better understood. The development of improved monitoring techniques in conjunction with the use of economic thresholds to determine the need for and timing of supplemental controls is essential. The continued adoption of pheromone-based IPM will depend on how well such programs meet grower concerns about risk, efficacy and cost.

Symposium and Poster Session

[0617] WIDELY SPACED, HIGH-EMISSION-RATE PHEROMONE SOURCES FOR MATING DISRUPTION OF LEPIDOPTEROUS PESTS

T. C. Baker & D. L. Mahr¹, Dept. of Entomology, Iowa State Univ., Ames, Iowa USA 50011; ¹ Dept. of Entomology, Univ. of Wisconsin, Madison WI USA 53706

Widely spaced, high-emission-rate pheromone dispensers are being explored as a possible effective way to deploy pheromone disruptants on large contiguous acreages of crops such as corn and cranberries. One of these systems, called Metered Semiochemical Timed Release System, or MSTRSTM, consists of a bottle containing pheromone that is placed in a machine that, on a timed basis (e.g., every 15 min) delivers an aerosol spray of pheromone to a pad. Pheromone is then emitted from the pad at extremely high rates, ca. 20 times higher than most existing disruptant dispensers. Fewer dispensers are therefore needed for effective disruption, and pheromone is not wasted by being passively emitted from the reservoir during periods of the day when the insects are inactive. Only 4 or 5 machines are needed per treated hectare, and they are retrievable. A second, newer system has also been explored that uses 20 to 25 dispensers per hectare, and these are also retrievable. In the past few years we have conducted pheromone disruption experiments using MSTRSTM technology against the most distructive pest of corn in the midwest United States, the European corn borer, Ostrinia nubilalis, in Iowa cornfields containing significant proportions of grassy borders and waterways in the fields' interiors that serve as mating aggregation sites. We have also conducted $MSTRS^{TM}$ disruption experiments against the blackheaded fireworm, Rhopobota naevana, and Sparganothis sulfureana, two pests of cranberry, in Wisconsin cranberry marshes. These experiments have shown much promise in disrupting males' ability to locate synthetic pheromone sources or calling females up to 99% for an entire flight period. We have also been able to assess the ability of the disruptant systems to suppress mating by freely flying females. For instance, during the first flight of the European corn borer, we have been able to reduce the percentage of feral females mating in grassy aggregation areas by up to 50% early in the flight. As the flight period progresses, all the females become mated, but the $MSTRS^{TM}$ treatment suppresses the number of matings that females achieve by 30-50% compared with the untreated check plots. These levels of mating disruption are similar to those achieved in plots treated with Shin-Etsu/Mitsubishi "ropes" using higher levels of pheromone per hectare. The mating disruption results in cranberry marshes against the blackheaded fireworm also showed significant reduction of mating by free-flying females of that species. Recent results have shown the new MSTRSTM formulation to be equivalent in disruption efficacy to both the old MSTRSTM formulation as well as a commercially available sprayable pheromone formulation for us against the blackheaded fireworm and S. sulfureana.

Key Words: Ostrinia nubilalis, Rhopobota naevana, Sparganothis sulfureana, sex pheromones, mating disruption

[0618] REGULATORY ISSUES IN THE COMMERCIAL DEVELOPMENT OF PHEROMONES AND OTHER SEMIOCHEMICALS – GLOBAL ASPECTS

I. Weatherston¹ & <u>R. R. Stewart²</u>, Technology Sciences Group Inc., 4061 North 156th Drive, Goodyear, AZ 85338, USA¹; 110 17th Street, N.W., Suite 500, Washington, D.C. 20036, USA E-mail rstewart@tsgusa.com²

The commercialization of pheromones and semiochemicals requires regulatory approval in most countries. Applications for approval must be accompanied by a variety of data. In the United States, regulatory officials have developed an abbreviated set of data requirements in recognition of the natural occurrence and low toxicity of these compounds. Additional regulatory relief has been granted for well understood groups of chemicals. In other countries, especially Europe, pheromones and semiochemicals are initially subject to the same data requirements as all chemical pesticides. While some of these requirements may be waived, the uncertainties surrounding the data requirements and cost of developing these data appear to have had a chilling effect on the pheromone and semiochemical industry. As a result there are far fewer approved products and the value of the resulting markets is much less. The specificity of pheromones places practical limits on the size of the potential market. In addition, the costs for user education and competition from the more traditional chemical pesticides place financial burdens in the marketplace. In the face of business pressures, overly burdensome data requirements to support registration can easily deter companies from pursuing the development and registration of pheromones and other semiochemicals.

[0619] OVIPOSITION ATTRACTANTS AND OVIPOSITION STIMULANTS FOR CULEX MOSQUITOES

J. G. Millar, Dept. of Entomology, Univ. of California, Riverside CA 92521, USA

Culer mosquito ovinosition is mediated by chemical and physical cues that are associated with typical oviposition sites such as ponds and other bodies of stagnant water that contain decomposing plant debris. We have identified a number of volatile chemical cues that influence mosquito oviposition from aqueous infusions of decaying plant materials mimicking natural oviposition waters. Compounds were identified both by traditional bioassay-driven fractionation of solvent extracts of infusions, and by collection of headspace volatiles, followed by analysis by coupled gas chromatography-electroantennogram detection. Behaviorally and physiologically active compounds included indole and 3-methylindole, phenols, aldehydes, and sulfur compounds. We also investigated the development of bioassays to determine which steps in the oviposition sequence (attraction or oviposition stimulation) were influenced by various chemical cues. Several general conclusions could be drawn from experiments with Culex First, concentration was critically important; quinquefasciatus and Cx. tarsalis. compounds which were attractive or stimulatory at parts per billion levels in water became repellent at higher concentrations, particularly to Cx. tarsalis. Second, oviposition stimulation (treatment vs. control frequently > 10:1) appeared to be more strongly mediated by chemical cues than attraction (treatment vs. control, ~3:1). Third, blends of compounds were more biologically active than individual compounds, with the increase in activity being approximately additive rather than synergistic. Fourth, correct formulation of blends was important because the release rates of compounds from aqueous solutions was dependent on their hydrophobicity and hydrogen bonding abilities. Thus, if the relative proportions of compounds in the headspace volatiles from infusions were used to formulate synthetic blends, hydrophobic compounds were overrepresented, and hydrophilic compounds were underrepresented. Once blends had been adjusted to compensate for these effects, the corrected blends were more biologically active than the unadjusted blends. Overall, considerable progress has been made in identification of compounds that mediate Culex mosquito oviposition, but even the best synthetic blends are not yet as active as crude infusions of decaying plant material, indicating that further compounds remain to be discovered.

Index terms: Culex tarsalis, Culex quinquesfasciatus, oviposition stimulant, oviposition attractant

[0620] CHEMICAL ECOLOGY OF TRIATOMINAE

<u>M. G. Lorenzo</u>, Laboratório de Triatomíneos e Epidemiologia da Doença de Chagas-CPqRR-FIOCRUZ. Brazil. Supported by Capes-SeTCIP, FIOCRUZ, PRONEX, PAPES, UNDP/World Bank/WHO(TDR), UBA and CONICET.

Triatominae is a subfamily of the Heteroptera-Reduviidae, that represent a total of 126 species of haematophagous insects. They include all vector species of the flagellate parasite *Trypanosoma cruzi*, the etiological agent that causes Chagas disease. This health burden affects approximately 17 million people in Latin America. Triatomine bugs obtain their blood meals mostly from endothermic vertebrate hosts. For this task they use CO2 and other host odours, probably short chain aldehydes, amines and carboxylic acids, as orientation cues. In the close range, warmth is the most powerful attractant. We have shown that odours released by yeast cultures are attractive for several species, probably because of their intense liberation of CO2 and, perhaps, for some other volatiles they emit. These cultures have been successfully tested in our laboratory as baits in traps for capturing Triatoma infestans, T. sordida, Rhodnius prolixus and Panstrongylus megistus, all important vectors of the disease. These traps exploit a characteristic behaviour exhibited by triatomines during host search, i.e., falling down from walls or ceilings in the presence of host-related stimuli. Besides, chemical communication has been reported in many species of this group in different contexts. Two kinds of aggregation pheromones have been described, a volatile and a contact one (footprints), for several species of triatomines, and in all cases studied, interspecific aggregation responses to these signals have been found. In addition, sexual and alarm pheromones have been reported to exist in triatomines. Since some time ago, we are dealing with the isolation and chemical characterization of these substances. Recently, we have studied the chemical composition of the alarm pheromone of T. infestans by means of SPME and GC-MS techniques. We were able to find three substances in the blend, that had not been previously described in the literature. These are: 3-Pentanone, 2-methyl-butyl alcohol and 2-methyl-butyric acid. The complete mixture we found was: 3-pentanone, isobutyl alcohol, isobutyl isobutyrate, 2-methyl-butyl alcohol, acetic acid, propionic acid, isobutyric acid, butyric acid, 2-methyl-butyric acid, and phenylethyl alcohol. Isobutyric acid was the major component of the mixture, as already described in the literature. Thus, we have found a blend that is more complex than those reported by previous authors. SPME sampling showed to be highly effective for this analysis, as it allowed to detect previously described compounds as well new components in the volatile blend liberated by triatomines. These studies with vectors of Chagas disease may assist control strategies providing new tools for their detection or capture.

Index terms: triatomine, chemical baits, aggregation, alarm pheromone, contact pheromone.

[0621] EFFICACY OF NEW ATTRACTANTS AND TRAPS FOR MOSQUITO SURVEILLANCE AND CONTROL

D.L. Kline, USDA, ARS, CMAVE, P.O. Box 14565, Gainesville, FL, 32604, USA; Email: dkline@gainesville.usda.ufl.edu

New mosquito management strategies that reduce reliance on chemical insecticides by utilizing combinations of attractants and traps have been developed. This presentation will focus on laboratory and field evaluation techniques used to determine the efficacy of these combinations. Volatile chemicals, primarily those which emanated from human skin, were initially evaluated in a triple cage, dual port olfactometer to assess the attraction of 6 8 day old laboratory reared nulliparous female *Aedes aegypti*. Over 125 chemicals have been screened for activity. Many of these compounds produce attraction at high chemical emission rates. Blends of multiple compounds have been eveloped that provide collection efficiencies, measured by percent attraction, equal to or greater than that of the human hand. Some of these blends have also been evaluated against laboratory reared mosquitoes in a large outdoor screened cage and against natural populations by means of Counter Flow Geometry traps. Data will be presented that show the importance of species-specific attractant blends, trap type, and trap spacing in obtaining meaningful population reduction. The future prospects of removal trapping for control of nuisance and vector mosquito species will also be discussed.

Index terms: Mosquitoes, human emanations, kairomones, traps, targets, olfactometer

[0622] THE ROLE OF GRASS INFUSIONS AS OVIPOSITION ATTRACTANTS AND OVIPOSITION STIMULANTS FOR *AEDES AEGYPTI* MOSQUITOES

<u>Á. E. Eiras</u>, Dept. of Parasitology, Universidade Federal de Minas Gerais, Brazil (alvaro@icb.ufmg.br). Supported by CNPq, FAPEMIG, FUNASA, IFS (Sweden)

The mosquito A. aegypti is the main urban vector of dengue and yellow fever, arboviral diseases that can spread rapidly in explosive epidemics in South America. Oviposition traps (ovitrap) provide a very sensitive and economical method for detecting Aedes mosquitoes") when the population density is low, whereas general larval surveys and adult collections produce unsatisfactory results. The addition of grass infusion in the ovitrap enhances significantly the number of eggs collected, thus increasing the trap efficacy. We evaluated grass infusions aiming to identify the volatiles that attract gravid Ae. aegypti female mosquitoes to ovitraps. We screened infusions of four grasses (Pennisetum purpureum; Panicum maximum; Cynadon plectosa chyus and Cynadon dactylon) and the results showed that P. maximum associated traps collected a significantly higher number of eggs than the control. Infusions of fresh and dried leaves of P. maximum were also evaluated and showed that the egg detection of ovitraps baited with fresh leaves infusions was significantly higher than other treatments. The volatiles from grass infusions are likely to be produced by microorganisms, as ovitraps baited with aerobic fermentation collected significantly more eggs than those with anaerobic and sterilized infusions. The fermentation period and concentration of infusions are also important to produce a blend of active compounds. The identification of the volatiles released from grass infusions that attract gravid Ae. aegypti female mosquitoes to ovitraps has being carried out in order to use specific synthetic chemicals to eliminate the need to create infusions. We also evaluated in laboratory and field, larval holding water as oviposition attractant and in combination with grass infusions. The highest? concentration of larval holding water increased significantly the number of eggs collected and a synergistic effect was observed when both stimuli were presented in combination. Video recordings of the oviposition behavior of gravid A. aegypti females showed that there is a pattern of behavioral sequences during the pre-oviposition and oviposition period. Discrimination between oviposition attractants and stimulants, and how gravid female mosquitoes exploit baited ovitraps will be discussed.

Index terms: Aedes aegypti, infusions, oviposition stimulants.

Symposium and Poster Session

[0623] UTILIZATION OF PCR FOR DETECTION OF WUCHERERIA BANCROFTI IN BARRA DE GUABIRABA - PE, NON-EDEMIC CONSIDERED AREA

A. L. Albuquerque¹, <u>R. M. R. Barbosa²</u>, L. N. Regis¹& A. F. Furtado¹, ¹Dept. de Entomologia, Centro de Pesquisas Aggeu Magalhães/HOCRUZ, Av. Moraes Rego, CEP-50670-420, Brazil, E-mail ale@epqam.fiocruz.br.² Mest. em Biologia Animal, Dept. de Zoologia, Univ. Fed. de Pernambuco, Av. Moraes Rego, CEP-50670-420, Recife, PE, Brazil. Supported by CNpQ/HOCRUZ

Lymphatic filariasis is caused by Wuchereria bancrofti and is transmitted by the insect Culex quinquefasciatus. PCR technique has been used in molecular diagnosis by the amplification of a repeated fragment of 188bp from W. Bancrofti, utilizing two species-specific oligonucleotides (NV1 and NV2). In the evaluation of PCR viability in epidemiologic surveys of non-endemic considered areas, we run our experiments in the municipality of Barra de Guabiraba-PE. 775 mosquitoes were collected and subdivided into 31 pools of 25 mosquitoes each, as well as 114 blood samples from the inhabitants. DNA extraction, PCR and electrophoresis were the techniques used. We also proceed the purification of DNA from the agarose gel, southern-blot, hybridization and markage with SspI cold probes in the insect pools. The blood samples were filtered in membranes. Bands of 188bp and 1050bp were amplified in 74,19% of the pools 19,35% presented only the band of 1050bp and 6,45% were negative. The bigger fragment was investigated by purification and amplification and besides the band of 1050bp the one of 188bp was equally present, suggesting that the fragment of 1050bp contains the 188bp. SspI-DIG (188bp) probe hybridizes with the 1050bp fragment. From the 114 blood samples, 8 (7,02%) showed to be positive by PCR. The PCR technique confirmed the presence of W. Bancrofti in the city of Barra de Guabiraba-PE. We suggest that the 1050bp may also be used for the diagnosis of filarial infection in the vector, improving the efficiency an efficacy of control programs.

Index terms: Wuchereria bancrofti, Culex quinquefasciatus, PCR, diagnosis.

[0624] IDENTIFICATION OF CHEMICAL DEFENSE SECRETION OF A DUNG BEETLE

<u>A. Aliabadi</u>¹, R. J. Bartelt² & D. W. Whitman³, ¹4160 Chemistry, Illinois Sta. Univ., Normal, IL 61790, USA, E-mail aaliab@ilstu.edu; ²USDA, ARS National Center for Agricultural Utilization Research, Bioactive Agents Research Unit, Peoria, IL 61604, USA, E-mail bartelrj@mail.ncaur.usda.gov; ³4120 Biological Sciences, Illinois Sta. Univ., Normal, IL 61790, USA, E-mail dwwhitm@ilstu.edu.

Dung beetles are not generally known to be chemically defended; however, some species in the genus *Canthon* (fam.: Scarabaeidae; subfam.: Scarabaeinae) emit tiny droplets of a fetid-smelling liquid from two small glands on the posterior margins of the elytra when disturbed. We analyzed this secretion via GC/MS and found the chemical components of this foul-smelling emission included indole, *m*-cresol, phenol, and creosol. The beetles discharged their odorous secretion when attacked; bird, mammal, and reptile predators, refused to eat them.

Index terms: Canthon, Scarabaeidae, Scarabaeinae, allomone.

[0625] CHEMOSENSORY PROTEINS IN SCHISTOCERCA GREGARIA

<u>S. Angeli^{1, 2}</u>, ¹Scuola Superiore di Studi Universitari e Perfezionamento "S. Anna", 56100 Pisa, Italy; ²Dipart. di Chimica e Biotecnologie Agrarie, University of Pisa, 56100 Pisa, Italy, e-mail: angeli@sssup.it

The desert locust Schistocerca gregaria is one of the major crop pests in Africa and the Middle East. Recently, chemoreception of the species has been investigated with regard to ecological, behavioural and physiological aspects. An aggregation-maturation pheromone and an egg-pod attraction pheromone have been isolated and characterized and the finestructure of antennal sensilla was studied. Here we describe the biochemical characterization and the immunocytochemical localization of the first family of chemosensory proteins (CSP) expressed in Orthoptera. Three acidic and soluble proteins of 14 kDa were purified, each from distinct chemosensory organs (antennae, tarsi and labrum) of crowd-reared locusts. The N-terminal sequences were obtained and were found to be similar to each other. They exhibit significant homology with a subclass of putative chemoperception proteins, expressed from Phasmids to Diptera. A large quantity of the tarsi-specific protein was purified from females and used for chemical characterization, polyclonal antibody preparation and binding assays. In TEM-immunocytochemical of chemosensory organs, the antibody labelled specifically the receptor lymph of contact, terminal-pore sensilla. Therefore we designed degenerate primers from the N-sequence and were able to amplify, by RT-PCR, the nucleotide sequences from mRNA isolated from the tarsi of one female. After cloning and sequencing, the sequence analysis showed five isoforms, all encoding for proteins 109 amino acids long. Comparison of peaks of the mass-spectrometry analysis of the native protein with the theoretically calculated molecular mass from the five cDNAs, shows a complete overlap, suggesting that these isoforms are all expressed in single animals without any post-translational modifications. Therefore, we decided to express an isoform in E. coli. The chemical analysis of soluble recombinant protein showed no differences with the native protein in terms of PAGE analysis, mass-spectrometry, disulfide bridges dispositions and circular dichroism. Crystallization experiments and ligand-binding assays of the recombinant form are now in progress. Although the specific function of these proteins is still unknown, their high degree of homology with the 4 conserved cysteines, and their expression in chemosensory organs of large number of species have suggested a role in chemoreception. Recently a member of this family was found to bind the Drosophila pheromone vaccenyl acetate. In Orthoptera, our experimental data suggest a role for these proteins in contact chemoreception, for instance in response to chemicals on surfaces like cuticular hydrocarbons. No binding of radioactively labelled glucose or bicarbonate was detected. Index terms: Schistocerca gregaria, chemoperception, chemosensory proteins.

[0626] DIVERSITY OF DUNG BEETLES (COLEOPTERA: SCARABAEIDAE) IN BORDER-INNER TRANSECTS IN A FOREST OF THE COLOMBIAN ANDES

<u>**J. M. Ardila¹**</u> & G. Fagua¹, ¹Laboratory of Entomology, Dept. of Biology, Pontificia Univ. Javeriana, Carrera 7 No. 43 – 82. (Edificio 52 – Piso 5). Santalé de Bogotá, D.C., COLOMBIA, E-mail elitros@yahoo.com

The variation in the composition, abundance, richness and structure of dung communities beetles (Coleoptera: Scarabacinae and Aphodiinae) was determined in a submountain rain forest in the "Farallones de Medina" (Colombia). Samples were collected between June 1999 and January 2000 along six transects each with eight sampling stations; five in the interior of the forest, one along the border and two outside of the forest. At each station six pitfall traps were set up with a distance of 20 m between each one and a bait of human feces. A total of 1,606 beetles were captured, distributed in two subfamilies and 22 species, during 13,824 trap - hours. Species richness was greater than reported in previous studies. Grouping analysis using the program Syntax was undertaken. Syntax reported differences between the composition of forest zones species and open zones. For each transect, species composition varied depending upon the vegetation present during the sampling. The results showed the difficulty that forest species have when moving into open areas. The highest abundance index was observed at the border stations. Index terms: Abundance, Aphodinae, Scarabacinae, Similarity, Richness

[0627] IDENTIFICATION OF FEMALE AND MALE SEX PHEROMONES IN THE SOLITARY BEE OSMIA RUFA (HYMENOPTERA: MEGACHILIDAE)

<u>M. Ayasse¹</u>, G. Dutzler¹, F. Schiestl¹, F. Ibarra² & W. Francke², ¹Inst. of Zoology, Althanstrasse 14, 1090 Vienna, Austria, E-mail Manfred.Ayasse@univie.ac.at; ²Inst. of Organic Chemistry and Biochemistry, University of Hamburg, D-20146 Hamburg, Germany. Supported by a grant of the FWF Austria (P09773-BIO).

The reproductive biology of the solitary bee Osmia rufa has been well studied, in order to investigate this species' potential for crop pollination. Almost no data exist so far on the chemical communication involved in the mating biology. Males search for receptive females at feeding areas and nests. Most females of this monandrous species mate immediately after having emerged. Therefore, it should be an advantage for males to distinguish between receptive and unreceptive females. Males show a characteristic postcopulatory behaviour of rubbing the female wing surfaces with their sternites, which leads to the hypothesis that they mark the females with an antiaphrodisiac. In behavioural experiments, combined gas chromatography - electroantennography recordings (GC-EAD) and chemical analyses, we studied the function of female and male pheromones in mating biology. Bioassays with different samples obtained from attractive females showed extracts of the cuticular surface to be most attractive, indicating that the female sex pheromone is evidently located there. In GC-EAD analyses of surface extracts, we found that fatty acids, ethyl esters, hydrocarbons and aldehydes triggered receptor potentials in the antennae of males. Odourless dummy bees impregnated with synthetic compounds mixed according to the proportions found on the cuticular surface of unmated females were significantly more attractive to males than dummies impregnated with solvent only. In bioassays, O. rufa males clearly distinguished between newly emerged females and those that mated one or two days prior to a dual-choice experiment. Chemical analyses showed different odour bouquets of unmated and mated females and the total amount of odour decreased within three days after mating. The assumption that males mark females during copulation with an antiaphrodisiac, that is produced in the sternal glands, was confirmed by means of behavioural experiments, GC-EAD analyses and chemical analyses. Solvent extracts of wings obtained from just mated females yielded an increase of the total amount of odour as compared to that of unmated females and many of the main chemical compounds identified in the male sternal glands contributed to this increase. In dual-choice experiments, unmated females impregnated with sternal gland extracts proved significantly less attractive than females impregnated with solvent only. In a further bioassay we identified Ethyl (Z)-7-hexadecenoate as a male antiaphrodisiac. Index terms: Osmia rufa, mating biology, chemical communication

[0628] EFFECTS OF SQUASH GENOTYPES ON BIOLOGY AND FEEDING PREFERENCE OF LEPTOGLOSSUS GONAGRA

E. L. L. Baldin¹, A. C. Caetano² & F. M. Lara², ¹Dept^o de Biologia, Univ. de São Paulo, Avenida Bandeirantes, 3900, Ribeirão Preto, SP, 14040-901, Brasil, E-mail elbaldin@usp.br; ² Dept^o de Fitossanidade, Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, Jaboticabal, SP, 14884-900, Brasil, E-mail fmlara@fcav.unesp.br.

Among the bugs of Coreidae family, the most is considered agricultural pests, and Leptoglossus gonagra (Fabr., 1775) is one of them. In Brazil, this insect is known as a polyphagous pest, damaging the squash, orange, watermelon and passion fruit. The adults and nymphs of this species suck floral-buttons, flowers, small fruits, branches and leaves, leaving characteristic points and harming the yield and physiologic development of the plants. Due to occurrence of these damages and wishing to investigate the existence of squash genotypes resistant to this bug, feeding preference and biological assays were accomplished under laboratory conditions. For the feeding preference assay were used seedlings (15-20 days after emergence) of thirty three squash genotypes of Cucurbita moschata and one commercial genotype of C. maxima (used as standard). These plants were placed inside of cages with five adults of L. gonagra, in four replications. The preference index (attractivity) at 45, 60, 90 and 120 minutes after the releasing was calculated. After analysis of the obtained results in this assay, twelve genotypes were selected, being three very attractive (BRA 015024, BRA 003531 and BRA 003603), two intermediary attractive (BRA 014737, Exposição) and six few attractive (BRA 015113, BRA 014664, BRA 014711, BRA 014770, BRA 014788, BRA 014869) to study some biological parameters. Seedlings of the different genotypes (15-20 days after emergence) were placed inside of glass cages, with 50 nymphs recently-hatched (each one corresponding to one replication). These insects were observed daily, evaluating the duration and mortality per instar. The results showed that seedlings of all genotypes caused 100% of mortality in the second instar, except BRA 003531 that allowed that 6% of the nymphs reached to the third instar. These results indicate the presence of antibiotic components in the seedlings and also suggest that the nymphs of second instar of L. gonagra need other structures of the squash, such as branches, floral-buttons, flowers and fruits to complete its biological development.

Index terms: Coreidae, host plant resistance, antibiosis, antixenosis

[0629] RESISTANCE OF FRUITS OF PASSION FRUIT GENOTYPES TO ANISOSCELES FOLIACEA MARGINELLA

E. L. L. Baldin¹, A. C. Caetano², A. L. Boiça Júnior² & F. M. Lara², ¹Dept^o de Biologia, Univ. de São Paulo, Avenida Bandeirantes, 3900, Ribeirão Preto, SP, 14040-901, Brasil, E-mail elbaldin@usp.br; ² Dept^o de Fitossanidade, Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, Jaboticabal, SP, 14884-900, Brasil, E-mail fmlara@fcav.unesp.br; aboicajr@fcav.unesp.br.

Some species of the Coreidae family are the main pest bugs of passion fruit. These insects, associated with the caterpilars and phytopatogenic agents are responsible for the low productivity of this crop in Brazil. The bug Anisosceles foliacea marginella (Dallas, 1852) is big, generally with yellow-orange coloration, similar to Diactor bilineatus. These bugs are harmful for the crop, once, both youngest and adult forms attack the fruits, floral buttons and branches. The attacked fruits fall down and when stay on the plant, they show twisted forms, making disable its consumption. Due the need of new control methods, the objective of this research was to identify the resistance of passion fruit genotypes to A. foliacea marginella and to verify the mechanisms involved. Attractivity and consumption (in free choice and no choice) tests were evaluated, using Passiflora alata, P. edulis f. flavicarpa, P. cincinata and P. giberti fruits, releasing one adult bug/fruit/genotype, in a completely ramdonized design. Ten replications were made, evaluating the number of attracted insects at 1, 3, 5, 15, 30, 45, 60, 90, 120 and 180 minutes after the releasing, the total number of pricks, the total time of feeding (min.) and the mean time of feeding per prick (min.). To evaluate antibiosis, 24 nymphs recently-hatched per genotype (each one corresponding to one replication) were daily accomplished in glass cages, evaluating the duration and mortality per instar. The results showed that in free choice test, the *P. edulis* f. flavicarpa and P. giberti fruits revealed to be less attractive than P. cincinnata and P. alata, although there was not statistical differences; in antibiosis tests, all genotypes caused 100% of nymphs' mortality on the second instar (except P. cincinata), indicating the presence of antibiotic components in its fruits and showing to be inadequate to development of nymphs of A. foliacea marginella,

[0630] ATTRACTIVITY OF PASSION FRUIT GENOTYPES TO HOLHYMENIA HISTRIO AND FEEDING PREFERENCE

E. L. L. Baldin¹, A. C. Caetano², F. M. Lara² & A. L. Boiça Júnior², ¹Depl^o de Biologia, Univ. de São Paulo, Avenida Bandeirantes, 3900, Ribeirão Preto, SP, 14040-901, Brasil, E-mail elbaldin@usp.br; ² Dept^o de Fitossanidade, Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, Jaboticabal, SP, 14884-900, Brasil, E-mail fmlara@fcav.unesp.br; aboicajr@fcav.unesp.br.

The brazilian yield of passion fruit is sensibly reduced by the attack of insects on this crop. Among the main responsible pests are the bugs and caterpilars; the first ones for the direct attack to the branches, floral buttons and fruits, reducing the productivity and the second ones for the significant leaf area reduction of the plants, harming its development. The bugs Holhymenia histrio (Fahr., 1803) are characterized by the fast flight and high colors, similar to wasps, with which are frequently confused. In this work was evaluated the adult bugs feeding preference for fruits of the following passion fruit genotypes: Passiflora edulis t, flavicarpa, P. coccinea, P. giberti, P. cincinata and P. setacea. Free choice attractivity and consumption tests were accomplished, with 15 replications in a completely randomized design, releasing one adult/fruit/genotype. The number of attracted insects at 1, 3, 5, 15, 30, 45, 60, 90, 120 and 180 minutes after the release; the total number of pricks; the total time of feeding (min.) and the mean time of feeding per prick (min.) were evaluated. The results showed that in free choice test, the P. giberti and P. coccinea fruits were the least favorite ones, suggesting to be resistant. P. edulis f. flavicarpa, P. setacea and P. cincinata, unlike the first ones, were more preferred for feeding, indicating to be susceptible to the attack of this insect.

Index terms: Passiflora spp., host plant resistance, antixenosis

Symposium and Poster Session

[0631] RESISTANCE OF BEAN GENOTYPES TO THE BEAN WEEVIL ACANTHOSCELIDES OBTECTUS

E. L. L. Baldin¹ & F. M. Lara², ¹Dept^o de Biologia, Univ. de São Paulo, Avenida Bandeirantes, 3900, Ribeirão Preto, SP, 14040-901, Brasil, E-mail elbaldin@usp.br; ² Dept^o de Fitossanidade, Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, Jaboticabal, SP, 14870-000, Brasil, E-mail fmlara@fcav.unesp.br.

During the grain storage of Phaseolus vulgaris bean there usually appear some problems caused by bruchids. This insects' attack may destroy the embryo, affecting plant germination, and also giving an unpleasant taste to the product, which affects its marketing. The bean grains are severely attacked by bruchids all over the world and one of the most frequent species in Brazil is Acanthoscelides obtectus (Say, 1831). Due to these damages and to the need of developing more efficient control techniques against these pests, tests were done, aiming to detect under lab conditions, genotypes that are resistant or susceptible to this pest's attack. Eighteen different genotypes were submitted to no choice tests in plastic recipients containing 10g/genotype, together with 6 adult insects (48 hours age) for a period of 7 days, in a completely randomized design with four replications. These recipients were maintained in B.O.D. (T= 25 \pm 2 °C, RH= 70 \pm 10 % and L/D = 12/12 h). From the 26th day of storage the recipients were observed daily and the number of emerged insects was counted. After counting, these insects were put into glass vials and immediately conducted to a freezer. By the end of emergences the vials with insects were maintained in a stove (T=50°C) for two days and thereafter the dry weight/replication/genotype was evaluated. The life cycle of the insects/genotype was also calculated. The results showed that the material containing arceline, mainly Arc. 1 and Arc.2, presented antibiosis as resistance mechanism to the bean weevil, making its cycle longer and differing significantly from the other genotypes. Differences towards the number of emerged insects and adults' weight were not observed among the genotypes. Index terms: Acanthoscelides obtectus, host plant resistance, antibiosis

[0633] EVALUATION OF FEEDING PREFERENCE OF *EPICAUTA ATOMARIA* FOR PASSION FRUIT GENOTYPES

<u>E. L. L. Baldin¹ & F. M. Lara²</u>, ¹Dept^o de Biologia, Univ. de São Paulo, Avenida Bandeirantes, 3900, Ribeirão Preto, SP, 14040-901, Brasil, E-mail elbaldin@usp.br; ² Dept^o de Fitossanidade, Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, Jaboticabal, SP, 14884-900, Brasil, E-mail fmlara@fcav.unesp.br.

The passion fruit crop counts a rich fauna of insects, being some of them extremely useful and other ones highly harmful (caterpilars, bugs and beetles). Epicauta atomaria (Germar, 1821) is a polyphagous pest and in great populations it can destroy totally the leaves of the passion fruit, leaving just the veins, affecting the yield. The use of resistant genotypes in pest control is increasing once do not harm the environment and to reduce sensibly the yield costs. The feeding nonprefernce of E. atomaria adults for leaf disks and leaf extracts of five passion fruit genotypes (Passiflora alata, P. edulis f. flavicarpa, P. nitida, P. setacea and P. giberti) were evaluated under laboratory conditions. The consumption (free and no choice) and attractivity tests were evaluated with 2 leaf disks per genotype (2,54 cm of diameter), being an used as treatment and another as standard. In free choice tests, leaf disks were placed inside Petri dishes, releasing one adult per genotype in ten replications, in a ramdomized block desing. The attractivity was evaluated at 15, 30, 60, 90, 120, and 180 minutes after the releasing and the consumption evaluated through diference of fresh weight. In consumption no choice test, the same methodology was proceeded, however one disk/dish/genotype was placed with 2 adults in a completely ramdomized design. In attractivity test with olfactometer, it was used cotton with 1ml of leaf extract (1g of leaves + 5 drops of H2O2) per genotype, placed inside of the olfactometer, releasing 2 insects per genotype. The number of attracted adults at 1, 5, 15, 30, 45 and 60 minutes after the releasing was counted in 10 replications in a randomized block design. The results showed that in attractivity tests accomplished in Petri dishes and olfactometer, the leaf disks and leaf extracts of *P. setacea* and *P. edulis* f. *flavicarpa* were the most preferred by adults of E. atomaria, while P. giberti, P. nitida and P. alata were the least preferred in the two kinds of recipients. In consumption tests (free and no choice), using leaf disks, P. setacea was the most consumed, confirming to be susceptible; P. giberti, P. nitida, P. alata and P. edulis f. flavicarpa were not very consumed by the insect, presenting feeding nonpreference as resistance mechanism. Index terms: Meloidae, Passiflora spp., host plant resistance, leaves

[0632] FEEDING PREFERENCE OF *DIABROTICA SPECIOSA* FOR SQUASH GENOTYPES

E. L. L. Baldin¹, F. M. Lara² & M. F. Batista³, ¹Dept^o de Biologia, Univ. de São Paulo, Avenida Bandeirantes, 3900, Ribeirão Preto, SP, 14040-901, Brasil, E-mail elbaldin@usp.br; ² Dept^o de Fitossanidade, Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, Jaboticabal, SP, 14884-900, Brasil, E-mail fmlara@fcav.unesp.br; ³Embrapa/Cenargen, E-mail fatima@cenargen.embrapa.br.

The Cucurbitaceae are very affected by the insects and among these are the beetles of Chrysomelidae family. Diabrotica speciosa (Germar, 1824) attacks the squash from the germination to the crop, destroying the leaves, causing characteristic damages. Beside these direct damages they can also transmit virus of great importance. Several control methods exist for this pest, and among them the use of resistant genotypes appears as an alternative and efficient method. In this aspect, was tried to select squash genotypes less preferred for feeding by adults of D. speciosa, in assays with seedlings and leaf disks. Initially, attractivity tests were accomplished in cages, being used seedlings (15-20 days after emergence) of thirty three squash genotypes of Cucurbita moschata and one commercial genotype of C. maxima (used as standard). Five insects per genotype were released in a completely randomized design, with four replications, being evaluated the number of attracted insects at 30, 75 and 120 minutes after the releasing. To observe the consumption in seedlings, free and no choice tests (10 and 5 replications, respectively) were accomplished with eight selected genotypes from the attractivity test. Eight insects per genotype were released in a completely ramdomized design and the damages caused were evaluated using a visual scale. The attractivity and consumption tests (free and no choice) in Petri dishes, using leaf disks (2.54 cm of diameter) of those eight genotypes also were accomplished, releasing two insects per disk, with 10 replications in a ramdomized block design. Feeding nonpreference was measured through leaf area consumption. The results showed that in free and no choice tests with seedlings and leaf disks, the BRA 015024 and BRA 015059 genotypes were less preferred for feeding by adults of D. speciosa, while BRA 014958, BRA 014869 and BRA 014737 were the most preferred. In the Exposição (commercial), BRA 014745 and BRA 003531 genotypes the adults showed intermediary behaviour.

[0634] RESPONSE OF GRAVID FEMALE CULEX QUINQUEFASCIATUS (DIPTERA - CULICIDAE) TO NATURAL PHEROMONE IN THE CHOICE OF AN OVIPOSITION SITE

R. M. R Barbosa¹ & L. N. Regis², ¹Mestrado em Biologia Animal, Dept. de Zoologia. Universidade Federal de Pernambuco, Av. Moraes Rego, CEP50670-420 Recife, PE, Brazil. ²Dept. de Entomologia, Centro de Pesquisa Aggeu Magalhães/FIOCRUZ, Cx. Postal 7472, CEP50670-420, Brazil. E-mail leda@cpqam.fioeruz.br. Supported by FACEPE and FIOCRUZ

The choice of an oviposition site by gravid females is the principal factor responsible for the distribution of the mosquitoes in breeding sites and it is of great relevance for the dispersion of the species in the nature. Therefore, accurate monitoring of *Culex* abundance is critical in forecasting the risk of disease outbreaks. Previous studies have demonstrated the atractiveness of natural oviposition pheromone in some Culex. quinquefasciatus, strains. Our objective is to determine the effects of natural pheromone as oviposition attractants for C. quinquefasciatus from in endemic area of lymphatic filarioses in Recife, Brazil. To examine the effects on mosquito oviposition behaviour, six cages (30x22x20cm) were used; two glass cups (200ml) were placed inside the cage, with one containing 10 egg-rafts and the other containing tap water as a control. The positions of treatment and control cups were alternated between replicates. Twelve replicates of 20 gravid females per cage were used. The egg-rafts were counted 24:00h after the beginning of the experiment. The results of this oviposition bioassay have shown that 76% females oviposite in the test site and 24% in the control site. These bioassays demonstrated that natural pheromone strongly attracted oviposition by C. quinquefasciatus gravid female. These data are of great usefulness to improve the atractiveness of an oviposition traps model under development.

Index terms: Culex quinquefasciatus, oviposition attraction, vectors control, pheromone.

[0635] CASSAVA HORNWORM, *ERINNYIS ELLO*, CONSUMPTION RATES AND PERFORMANCE ON FOUR CASSAVA VARIETIES

J. A. F. Barrigossi¹, ¹National Rice and Bean Research Center (Embrapa Arroz e Feijão), Caixa Postal 179, Santo Antônio de Goiás, GO, Brazil, 75375-000. E-mail: alex@cnpaf.embrapa.br.

Cassava hornworm, Erinnyis ello, is one of the most important defoliators of cassava in South America. Information about damage potential to cassava is necessary before economic injury levels are established. We conducted laboratory experiment to determine the consumption rates of cassava and characterize the injury potential by E. ello. First instar E. ello larvae (<3 h old), that hatched from field collected eggs, were individually reared on excised cassava leaves of four varieties, at 27 °C. A randomized block design with 9 replications was used. Leaves and larvae were kept in plastic containers. Leaves were maintained with petiole placed in water picks to prevent wilting. Fresh leaves were provided to the larvae daily beginning from the 3rd day of the experiment. Leaf areas were determined for each leaf using a leaf area meter (Model 3100, LI-COR, Lincoln NE, USA) before the leaves were provided to the larvae. After every molt, leaves were removed from the containers and leaf areas were determined. Then, leaves were either replaced or returned to the plastic containers. Foliage consumption per instar, developmental time and weight of larvae and pupae were recorded. Total leaf area consumption (square cm) for the varieties were: 1030.45 ± 63.2 (Fio de Ouro), 971.45 ± 34.24 (Aipim Bravo), 968.57 ± 75.73 (Urubu), and 956.08 \pm 37.3 (Jaburu). There were no significant differences in the larval consumption on the four varieties at p < 0.05. About 85% of the feeding occurred during the last two larval stages. Varieties also had no effect on larval development. Mean larval weight (g) were: 4.92 ± 0.35 (Jaburu), 4.82 ± 0.23 (Fio de Ouro), 4.73 ± 0.18 (Urubu), and 4.61 ± 0.24 (Aipim Bravo). These data indicate that the varieties tested in this study had similar impact on the fitness and biology of E. ello. In addition, because the consumption rates of E. ello is the same economic injury levels can be used to manage E. ello on these varieties.

Index terms: leaf consumption, EIL

[0636] INTENSITY OF LOSSES IN MAIZE CULTIVATED UNDER MINERAL AND ORGANIC FERTILIZATION SYSTEMS

C.S. Bastos¹, M. Picanço², J.C.C. Galvão¹, A.H.R. Gonring² & A.R.R. Tavares¹, ¹Dept. de Fitotecnia, ²Dept. de Biol. Animal, Univ. Fed. Viçosa, CEP: 36571-000, Viçosa, MG, Brasil. E-mail: csbastos@alunos.ufv.br.

This research was accomplished in the Experimental Station of the Federal University of Vicosa at Coimbra, State of Minas Gerais, Brazil, during the agricultural year 1996/7 and it aimed to study the losses that occur in the production components of maize cultivated under mineral and organic fertilization systems, using the possible life table of the cultures. The treatments were represented by the possible combinations of three doses of mineral fertilization (zero, 250 Kg of 4-14-8/ha + 100 Kg of ammonium sulfate (AS)/ha and 500 Kg of 4-14-8/ha + 200 Kg of AS/ha) and two doses of organic fertilization (zero and 40 m³ of organic matter/ha). The losses were evaluated in the production components: plants, ears of corn, ovule and grains. Maize's productivity and cultivation losses were estimated. This data was made the basis for life table of the culture. The production component with major losses was ovule, and the main cause of it was the absence of ovule fecundation (responsible for 97.42% of the losses in the component and 80.02% of the total losses). These losses were correlated positively with Dalbulus maidis (Homoptera: Cicadellidae) attack to the plants (r = 0.31, n = 24 and p = 0.068). Another factor associated to the losses in ovule the *Helicoverpa zea* (Lepidoptera: Noctuidae) attack (causing 2.58% of losses). The attack of Spodoptera frugiperda (Lepidoptera: Noctuidae) to the plants caused 20.21% of losses while seeds perforation by immature Coleoptera: Elateridae caused 10.49% of losses. The losses in the component ears were due to occurrence of maize's ears without ovule or grains. Twenty point ten percent (20.10%) of the losses in grains were caused by H. zea attack and 31.04% by Sitophilus zeamais (Coleoptera: Curculionidae) attack. The largest losses happened due to absence of ovule fecundation in the treatments that received organic fertilization (about 4,660 Kg/ha of losses). Index Terms: Life table, Dalbulus maidis, Helicoverpa zea, Sitophilus zeamais,

[0637] SELECTION OF TROPICAL STEM BORERS FOR RESISTANCE TO CRYLAB IN MAIZE

D.J. Bergvinson¹, S. García-Lara¹ & S. McLean¹, ¹Int. Maize and Wheat Improvement Center, Apdo Postal 6-641, Col. Juárez, CP 06600 México, D.F., México, E-mail d.bergvinson@cgiar.org.

Transgenic maize expressing CryIAb toxins derived from Bacillus thuringiensis Berlinger have been commercially grown since 1996. Insect resistant management programs based on high-dose and refugia have been implemented in maize to reduce the probability of resistance development in target pests. The impact this technology will have on secondary pests of maize will be an important consideration as Bt-maize moves into more topical ecologies. The objective of this study was to document population changes in Diatraea saccharalis (sugar cane borer, tropical) and Diatraea grandiosella (Southwestern corn borer, subtropical) when selected using maize plants expressing CryIAb toxin. Neonate larvae (ca.400) were placed onto maize at the 6-leaf stage of development for 48h, with surviving larvae transferred to artificial diet to complete development, with a subsample of 300 larvae returning to Bt-maize to monitor survivorship. Survivorship, pupal weight, days to pupation, egg production and fertility were recorded for each cycle of selection After 14 and 18 cycles of selection for *Diatraca sacchardis and Diatraca grandiosella*, respectively, significant increases were observed for pupal weight and survivorship. Survivorship increased at a rate of 1.8 and 1.7%/cycle while pupal weight increased at a rate of 2.2 and 1.5mg/cycle for Diatraea saccharalis and Diatraea grandiosella, respectively. Significantly more larvae from the latest cycle of selection survived to 6d on Bt-maize than unselected populations; however, no larvae survived beyond 8d. Monitoring pupal weight and duration of larval survival when exposed to Bt-maize under controlled conditions my serve as practical tools for monitoring insect resistance in areas grown to Bt-maize.

[0638] BIOCHEMICAL BASIS FOR STORAGE PEST RESISTANCE IN MAIZE

D.J. Bergvinson¹, S. García-Lara¹ & A. Savidan¹, ¹Int. Maize and Wheat Improvement Center, Apdo Postal 6-641, Col. Juárez, CP 06600 México, D.F., México, E-mail d.bergvinson@egiar.org.

Storage pests are a major constraint to resource poor farmers in developing countries. Developing maize grain with improved resistance to storage pests is one component of storage pest management that has been lacking in modern variety development. The International Maize and Wheat Improvement Center has screened maize germplasm bank accessions for resistance to storage pests. Caribbean accessions with elevated levels of resistance have been used a recurrent selection scheme under artificial infestation to improve resistance levels. This germplasm has enabled the development of surrogate screening technologies, identification of biochemical traits correlated with resistance and to study the interaction between kernel resistance and biological controls. The rapid screening technique involves measuring the break force of equilibrated kernels which correlates well with resistance for both Prostephansu truncatus (r=0.88) and Sitophilus zeamais (r=0.85). Using a peril mill, enriched tissue fractions were isolated for the pericarp, germ and endosperm for biochemical characterization. Four forms of diferulie acid located within the pericarp cell wall correlated with *Sitophilus zeanais* resistance (>0.85) and kernel hardness (r>0.82). Diferulic acids within the endosperm cell wall showed similar results while no significant correlation was observed for germ tissue. This resistance mechanism does not appear to alter the nutritional quality of the grain as measured by nitrogen content. Resistance to both pests is negatively correlated with grain moisture content. Breakdown of kernel resistance occurred at 14% moisture for Sitophilus zeamais and 16% moisture for Prostephanus truncatus. Kernel resistance did not affect the performance of the parasitoid Anisopteromalus calandrae when Sitophilus zeamais densities were calibrated. The importance of kernel resistance within the context of other management techniques will be discussed.

Index terms: maize, storage pests, resistance, selection

[0639] DEVELOPMENT AND CHARACTERIZATION OF MAIZE POPULATIONS RESISTANT TO TROPICAL STEM BORERS AND ARMYWORM

<u>D.J. Bergvinson</u>¹ & S. García-Lara¹, ¹Int. Maize and Wheat Improvement Center, Apdo Postal 6-641, Col. Juárez, CP 06600 México, D.F., México, E-mail d.bergvinson@cgiar.org.

Maize production in tropical ecologies can be severely reduced by stem borers and armyworm. Moreover, grain quality can be reduced further by ear rots associated with borer attack. Host plant resistance has traditionally been considered the cornerstone of integrated pest management. At the International Maize and Wheat Improvement Center, tropical and subtropical maize has been improved for insect resistance by artificial infestation of Diatraea grandiosella, Diatraea saccharalis and Spodoptera frugiperda. After five cycles of S3 recurrent selection, good levels of resistance to both artificial and natural infestation have been achieved. The basis of resistance appears to involve both increased epidermal cell wall toughness and reduced nitrogen content in the leaf. Since reduced leaf nitrogen content adversely affect yield, germplasm development efforts have focused on increasing leaf toughness. Using a force displacement meter fitted with a 1mm dia. probe, epidermal cell wall toughness is measured between the primary veins. Leaf feeding damage and leaf toughness are correlated (r=-0.8), with advanced cycles of selection having significantly tougher leaves. The biochemical basis for increased leaf toughness appears to be increased levels of phenolic acids that cross-link the hemicellulose of the epidermis. Mapping of insect resistance and leaf toughness has identified chromosomes 1, 5, 7 8, 9 to contain important quantitative trait loci, with both traits mapping to the same regions. On-farm testing of resistant germplasm has shown good yield stability under natural infestation and improved grain quality due to reduced incidence of Stenocarpella maydis. Leaf nitrogen content is currently being investigated within the context of fertilizer management to exploit low leaf nitrogen during the early stages of crop development and higher nitrogen levels before flowering for incorporation into the grain. Future research in maize resistance research will be discussed within the context conventional breeding.

[0641] TRIALS OF CONTROLLING LEPIDOPTERAN PESTS WITH SEX PHEROMONES IN KOREAN APPLE AND PEAR ORCHARDS

K. S. Boo¹, S.W. Lee², K.S. Hau¹, J.K. Jung¹, K. Choi¹ & C.Y. Yang², ¹Seoul Natl. Univ., Graduate School of Agric. Biotechnol., Suwon 441-744, Korea; ²Natl. Hort. Res. Inst., RDA, Suwon 440-310, Korea

History of research on application of insect sex pheromones are quite young in Korea. We have been investigating sex pheromone composition of lepidopteran pest insects damaging apple tree and fruit for last 5 years and pear for 3 years or so. In Korean apple orchards major pest insects are the Oriental fruit moth (Grapholita molesta) and the peach fruit moth (Carposina sasakii) on fruits, two leafminers of the apple leafminer (Phyllonorycter ringiniella) and the apple lyonetid (Lyonetia prunifoliella), and two leafrollers of the smaller tea tortrix (Adoxophyes orana) and the asiatic leafroller (Archippus breviplicanus). Their sex pheromones were found to be composed of Z-8-dodecenyl acetate : E-8dodecenyl acetate : Z-8-dodecenol (95:5:1) for G. molesta, Z-7-eicosen-11-one for C. dodecenyl acetate : Z-8-dodecenol (93:3:1) for *G. motesta*, Z-7-etcosen-11-one for *C. sasakii*, Z-10-tetradecenyl acetate : E4,Z10-tetradecedienyl acetate (4:6) for *P. ringiniella*, Z-9-tetradecenyl acetate : Z-11-tetradecenyl acetate (95:5) for *A. orana* and *E*-11tetradecenyl acetate : Z-11-tetradecenyl acetate (7:3) for A. breviplicanus. The sex pheromone of L. prunifoliella are under investigation for their stereochemistry, after finding of three different components including the major component of 10.14dimethyloctadec-1-ene(Gries et al., 1997). During last two years we deployed polyethylene tubes containing sex pheromones premixed at the rate of 100-150g/ha for C. sasakii, G. molesta and P. ringiniella. The preliminary results were not comparable to those by insecticide treatments yet, partly due to small size of orchards, but promising, Beginning this year we are going to work at a larger scale at farmers' orchards. Korean apple growers are still spraying insecticides 7.5 times and acaricides 3.5 times in a year, which were reduced from previous 10.3 and 4.5 times thanks to sex pheromone monitoring. We are also working on controlling of G. molesta in pear orchrads. Besides G. molesta and A. orana, we have Adoxophyes sp. in pear orchards. Adoxophyes sp. was found using Z-9-tetradecenyl acetate : Z-11-tetradecenyl acetate (7:3) as their sex pheromone in Korea. We will go after the control of lepidopteran pest insects in apple and pear orchards with sex pheromones and mites and aphids with their natural enemies. Index terms: apple insects. Pear insects. Sex pheromone, mating disruption

[0640] NO PLEIOTROPIC EFFECT OF INSECTIDE RESISTANCE ON SEXUAL COMMUNICATION IN CYDIA POMOMELLA

D. Beslay¹, B. Frérot², C. Malosse², M. Renou², J.C. Bouvier¹ & <u>B. Sauphanor¹</u>, ¹Unité de Zoologie-Apidologie - INRA, Agroparc, F 84914 AVIGNON Cedex, E-mail sauphano@avignon.inra.fr; ²Unité de Phytopharmacie et médiateurs chimiques, INRA - Route de St-Cyr- F 78026 VERSAILLES Cedex.

Monitoring codling moth, Cydia pomonella, by sex trapping is an important part of integrated pest management in apple and pear orchards. Discrepancy between C, pomonella catches in traps and level of infestations was observed in a number of orchards in Southern France. Insecticide in Insecticide resistance is widespread in these areas and as a consequence, it was hypothesised that the specific mate recognition system (SMRS) was modified in resistant populations. Both pheromone production and perception were compared on a susceptible and two laboratory strains resistant to diflubenzuron or deltamethrin respectively. GC and GC-MS analyses showed that females of resistant strains (ou resistant females) produced the same pheromone blend as sensitive females. In wind tunnel females of both strains induced the same levels of behavioural responses wether males are sensitive or resitant. EAG studies showed the same response spectra to minor components within the three strains. Finally, EAG and wind tunnel studies revealed identical dose-response curves to codlemone in both resistant and sensitive strains. Captures in traps baited with virgin females belonging either to the susceptible strain or both resistant strains were similar all over the season in field situation., Traps baited with synthetic pheromone captured the same rate of susceptible? and resistant males released in the orchard. Thus, the hypothesis of pleiotropic modifications in the SMRS of C. pomonella was rejected. The study allowed to assert that resistance mechanisms did not affect the flight capacity of the male moths, and that the sex pheromone can be used for monitoring or for direct control of resistant populations.

Index terms: codling moth, sex pheromone, codlemone, wind tunnel, electrophysiology.

[0642] RESPONSE SPECTRA OF SENSILLA TRICHODEA (A2-TYPE) OF FEMALE AEDES AEGYPTI TO HUMAN VOLATILES

O. J. Bosch¹ & J. Boeckh¹, ¹Inst. für Zoologie, Univ. Regensburg, Universitätsstr. 31, D-93040 Regensburg, Germany, E-mail oliver.bosch@biologie.uni-regensburg.de

Recent behavioral findings in female yellow fever mosquito *Aedes aegypti* (L.) (Diptera: Culicidae) led us to investigate the electrophysiological response spectra of sensilla trichodea A2-type in more detail. This sensillum type houses two receptor cells which can be distinguished by their different spike-amplitudes in single-sensillum recordings. We have classified these receptor cells based on their odor-evoked response spectra to volatiles emitted from humans. These stimuli included the natural multicomponent odors breath and body odor as well as different concentrations of following single compounds, which have been found in human sweat: (1) L-(+)-lactic acid, the indispensable synergist for other attractive components in behavioral studies, (2) ammonia, and (3) n-aliphatic carboxylic acids with chain length from C_1 to C_6 . Our results show several functional classes of receptor cells with distinct overlapping response spectra. These classes are mingled within the A2-type sensillum in varying pairs.

Index terms: Mosquito, olfaction, host odor, single-sensillum recording, sensillum trichodea.

[0643] BIOPROSPECTING FOR NOVEL PEST MANAGEMENT CHEMISTRY

W. S. Bowers, Laboratory of Chemical Ecology, Dept. of Entomology. The University of Arizona, Tucson, AZ 85721 USA. Email: wbowers@ag.arizona.edu

The application of chemistry to the control of insect pests of agriculture and public health provided an abundance of high quality food and a health status heretofore unimagined. Nevertheless, the residues of a few indifferent toxicants, poisonous to the basic and shared biochemistry of eukaroytic organisms, continues to threaten planetary ecology. Unable to return to the pastoral deficits of yesteryear we must adopt revolutionary research priorities seeking environmentally pacific methods for future pest management strategies. Bioprospecting among insect and plant chemistry yields novel chemistry leads for the development of biorational pest management strategies. Although vertebrates and invertebrates continue to share a similar physiology, biochemistry and genome we recognize certain mechanisms regulating these shared life processes have undergone significant evolutionary divergence. Thus, hormones regulating growth, development and reproduction in insects have no counterpart in vertebrates. Similarly, infochemicals lacking any complement in higher animals are employed by invertebrates for communication. Clearly, manipulation of these unique biological regulators represents a biorational approach to pest management. Bioprospecting among insect and plant chemistry has provided an abundance of natural products that have been optimized into insect growth and behavior regulator products for pest management with outstanding efficacy and environmental safety. We have focused our efforts on searching among insects and plants for hormonal and behavior regulators with potential for application. Utilizing novel biological assays capable to detecting activities previously unrecorded we have isolated and identified insect hormones and anti- hormones, pheromones, repellents, fungicides and antibiotics. We have also shown that plants respond to stress and certain signaling chemistry by deploying their defenses against insects and nematodes.

[0644] POSSIBLE ROLE OF AMMONIA IN HOST-SEEKING BEHAVIOR OF BLOOD-FEEDING INSECTS

<u>M.A.H. Braks</u>^{1,2}, J. Meijerink^{1,3} & W. Takken¹, ¹ Wageningen Univ. & Research Center, PO Box 8031, Wageningen, NI, E-mail marietabraks@hotmail.com, ² Florida Med. Entomol. Lab. 200 9th Str. Vero Beach, FL 32962 USA, ³ Dept. of Ecology Lund Univ., Ecology Building SE-22362 Lund, Sw.

Since the beginning of the century it has been recognized that malaria mosquitoes use host odors for host-seeking. It is vital for any blood-feeding insect to discriminate volatiles emanating from a living host from residues on materials in absence of the host. Carbon dioxide present in expired air is considered to be reliable 'life sign' of a living host and is a proven kairomone for many blood-feeding insects, including mosquitoes. However, in addition to expired air, olfactory stimuli may also originate from the skin. Studies on the anthropophilic Afrotropical malaria mosquito, Anopheles gambiae, showed that volatiles from the human skin, specifically sweat, play an important role in host-finding. Behavioral responses of An. gambiae to freshly collected sweat samples were variable; the females were attracted to some fresh sweat samples but not to others. However, responses to sweat samples that had been incubated for two days at body temperature were stable; mosquitoes were attracted to every incubated sweat sample. The pH of the sweat samples changed from acidic (pH 5-6) when fresh to alkaline (pH 8-9) after incubation. During incubation microbes in the sweat proliferated exponentially. The pH shift was caused by the production of animonia from urea and other nitrogen-rich components by the action of cutaneous microbes. In bioassays, An. gambiae was highly attracted to a wide range of ammonia concentrations. This is the first report of An. gambiae being attracted to a single compound other than carbon dioxide. As ammonia is continuously produced on the skin of a living host but evaporates quickly from non-living material, it may function as a reliable 'life sign', in addition to carbon dioxide, for blood-feeding insects.

Index terms: Anopheles gambiae, sweat, body odor

[0645] SIRENE® 6.0 GS: ATTRACT AND KILL, A NOVEL WAY TO CONTROL CODLING MOTH WITH AN AGE OLD VICE

J.A. Brits, H.J. Weideman & C.F. van Eeden, Novartis South Africa (Pty) Ltd., Crop Protection Sector, P.O. Box 92, Isando, 1600, South Africa, E-mail johann.brits@cp.novartis.com.

Codling moth, (Cydia pomonella) a cosmopolitan pest of pome fruit has been notoriously difficult to control owing to the prerequisite of residue free fruit demanded by the consumers world wide. Currently, codling moth in South Africa is being controlled chemically or by means of mating disruption. Both these avenues poses certain disadvantages. With chemical control there is always the risk of residues, while for mating disruption the treated orchards have to meet specific geographic requirements. SIRENE is a combination of both these control methods without the disadvantages. SIRENE comprises of a grease carrier containing female codling moth pheromone and an insecticide, which is applied as droplets on the branches of the trees. Male moths are lured to the droplets by the pheromone and when trying to mate with the droplets, they are killed by the insecticide. SIRENE has been extensively tested against Codling moth in South Africa.

Index terms: Pheromone, SIRENE, codling moth

[0646] BARK BEETLE RESPONSE TO AGGREGATION PHEROMONE INHIBITED BY MONOTERPENES RELEASED BY A PIEZOELECTRIC SPRAYER

J. A. Byers¹ & A. M El-Sayed², ¹Dept. Plant Protection, Swedish Univ. Agricul., SE 230 53 Alnarp, Sweden; ²Southern Crop Protection & Food Research Centre, Agricul. & Agri-Food Canada, Vineland Station, Ontario L0R 2E0, Canada.

A piezoelectric sprayer for dispensing semiochemicals was developed and used for a field test of bark beetle semiochemicals. The sprayer consists of a geared pump that pushes a syringe slowly to dispense semiochemicals in solvents through a micro-tube to a glass micropipette fixed to a piezoelectric high-frequency vibrator. The frequency is adjusted via a function generator to about 120 KHz until the harmonic properties of the glass micropipette, drawn by an electrophysiological pipette puller, cause vibrations that atomize the solvent from the micropipette tip. The sprayer, syringe, pump, function generator, and power supply were hung on one arm of a rotating trap pair (traps 6 m apart) that was slowly rotated at 2 rph to even out the position effects on trap catches. The aggregation pheromone components of Pityogenes bidentatus (Hbst.) (Coleoptera: Scolytidae), grandisol and cis-verbenol, were released by standard tube dispensers in one trap and compared to the release of similar amounts by the sprayer in the other trap. No significant differences in catch were observed. No effect of the solvent hexane on aggregation could be observed. The trap pair also caught approximately equal numbers of bark beetles when the baits were identical. The release of (+)- and (-)- α -pinene, (+)-3carene, and terpinolene, monoterpenes of host Scotch pine Pinus sylvestris L., at increasing rates from 0.01 to 10 log-equivalents in decadic steps (each at 0.1 to 100 µg/min) resulted in decreasing responses to aggregation pheromone (only 9% at highest rate). Inhibition by the individual monoterpenes tested at the 100 µg/min rate was significant for (+)- and (-)- α -pinene and terpinolene (12, 13, and 15% of control, respectively). The inhibition by the host Scotch pine monoterpenes may allow P. bidentatus to avoid resistant trees that release large amounts of toxic monoterpenes in their resin and instead colonize dying and diseased limbs or slash, the usual host substrate. The piezoelectric sprayer should prove generally useful to dispense precise amounts of semiochemicals in field and laboratory experiments.

Index terms: Pityogenes bidentatus, Pinus sylvestris, host selection, dispenser, release rates, Coleoptera, Scolytidae, Scotch pine, conifers

[0647] THE HARMFUL INSECTS ON PINUS BRUTIA TEN

<u>P.Can.</u> Ege Ormancılık Araştırma Müdünlüğü Karşıyaka/İZMİR- 35530 TÜRKİYE, E-mail: Peymancan@yahoo.com.

Pinus brutia Ten. forests cover on area of more than 3 million hectares in Turkiye being the most extensive of the forest tree species in this country. In the Mediterranean basin, the largest pure and the largest natural stands of *P.brutia* are found in Turkiye. There are different harmful insects on different parts of this species. Defoliators are *Thaumetopoea pityocampa* Schiff (*Lep., Thaumetopoeidae*), *Diprion pini* L. (*Lep., Diprionidae*), pests of cones and seeds are *Dioryctria mendacella* Stgr (*Lep., Pyralidae*), *D. pinea* Stgr (*Lep., Pyralidae*), bark beetles are Orthotomicus .erosus (Wall) (Col., Scolytidae), *Ips sexdentatus* (Boerner), Blastophagus piniperda L. (Col., Scolytidae), Bminor (Hartig) (Col., Scolytidae); one of borers is Dioryctria splendiella H.S. (*Lep., Pyralidae*) such as these insects cause significant economic losses. While using different treatments against these insects, studies have been carried out about IPM.

Index terms: Defoliators, sucking insects, borers, bark beetles, P.brutia

[0649] INSECTICIDE ACTIVITY OF COTTON CRUDE OIL ON ADULTS OF CYDIA POMONELLA (LEPIDOPTERA:TORTRICIDAE)

M. Cariac¹, A. Ferrero¹, T. Stadler² & <u>A.A. Suarez</u>³, ¹ Dept. Biología, Bioquímica y Farmacia, Univ. Nac. Del Sur, San Juan 670, (8000) Bahía Blanca, Argentina, e-mail: mjcariac@criba.edu.ar. ²Museo Cs. Nat. Bernardino Rivadavia, Av. A. Gallardo 470, (1405) Buenos Aires, Argentina. ³E.E.A.INTA Anguil, Ruta Nac. N°5 Km 580, C.C. 11, (6326) Anguil, La Pampa, Argentina.

Cydia pomonella is the most important pest that affects apple, pear, quince and walnut production in Argentina. Due to increasing number of insecticide resistant pest populations, it is neccessary to look for alternative control methods such as oil applications. Compared to syntethic insecticides, oils are cheaper and less toxic to mammals. In laboratory experiments, we determined the contact insecticide activity of crude cotton oil on C. pomonella adults. Insects were immobilized with CO2 and 1µl of crude oil was applied on the abdomen ventral part. Adult insects without oil treatment were used as checks. After treatment, insects were transfered to plastic containers and kept in rearing conditions. Mortality was determined at 24 h intervals. A nested design was used, and the data obtained were analized using ANOVA. Insects treated with cotton oil suffered a longevity reduction of 39% (n < 0.01) compared to untreated ones. In treated females and treated males longevity reduction was 27% (p<0.01) and 55% (p<0.01), respectively. These results suggest that determining subletal effects of cotton oil applications, such as fecundity and egg viability, should be neccesary to further evaluate the effectiveness of this technique.

Index terms: Cydia pomonella, longevity, cotton oil.

[0648] LOCAL DETERRENCE OF MULTIPLE ATTACKS BY THE COFFEE BERRY BORER

F. Cantor, O. DeSouza, E. F. Vilela, C. A. Faria & F. G. Costa, Depto. Biologia Animal, Univ. Fed. Viçosa, 36571-000 Viçosa MG, Brazil, Email: fcantor@alunos.ufv.br

Coffee berries (Coffea arabica) attacked by the borer Hypothenemus hampei (Coleoptera: Scolytidae) are known to be infested by a single individual, which builds its gallery into one of the fruit's seed, rarely attacking the second seed. Such a pattern of infestation differs markedly from other Scolytidae, which normally aggregate when attacking their hosts. We explore such a phenomenon, checking whether females seeking new oviposition sites are deterred by some clue produced by a female already attacking a berry. To do so, we carried out an experiment in which females of the coffee berry borer were allowed to choose between naturally infested berries and berries in which a borer attack was simulated. The attack by the borer was simulated by introducing a pin into the berry, thereby producing a hole and gallery of the same diameter as a borer would do. We arbitrarily call "resident" the borers already in the berry and "invaders" the borers to which the choice was presented. Three different tests were performed using the set up described above (natural x simulated infestations). Firstly, natural infested berries containing its borer were offered as an alternative to simulated infested berries. The second test ran similarly, with the exception that the resident borer was previously removed from the naturally infested berries. In the third test, the resident borer was killed and left inside the berry. Naturally infested berries were consistently more attacked by invading borers than berries on which the attack has been simulated (P<0.05). In lab conditions, when invading borers attacked infested berries, they avoided the fruit's end which had been already perforated, choosing instead the opposite end to build their galery. It seems, therefore, that either (i) our simulation of an attack actually deterred attacks by the invading borer, or (ii) the natural infestation acted as a clue for new borers, which are deterred only locally by some mark deposited by the female on its gallery. In natural conditions, the newcomers would then by able to depart to a nearby, noninfested, berry. This would allow borers to locate suitable hosts, without enhancing the risk of interindividual conflicts among their offspring.

Index terms: Hypothenemus hampei, aggregation, oviposition marks

[0650] SEX ATTRACTION OF MALES OF *COPITARSIA CONSUETA* (LEPIDOPTERA: NOCTUIDAE) UNDER CONDITIONS OF LABORATORY

V. R. Castreión¹, J. Cibrián², R. Osorio² & M. Camino¹, ¹ Centro de Desarrollo de Productos Bióticos del I.P.N. Carretera Yautepec-Jojutla km. 8.5, Yautepec, Morelos, México. C.P. 62730. A.P. 24. Tel. (739) 4-18-96. e-mail: vcastrej@hotmail.com.² Instituto de Fitosanidad, Colegio de Posgraduados. 56230 Montecillo, Estado de México, México. This research was supported by I.P.N. grant (CGPI 980052).

All laboratory studies were conducted between the 7-8 hr of the scotophase that coincided with the peak period of pheromone release by females. Test were conducted in a 1.8 X 0.7 X 0.7 m plexiglass flight tunnel housed in a room with the same photoperiod, temperatures and humidity maintained in rooms used to house adults. Air was pulled through the tunnel at 0.2 m/sec and expelled outside the building. For testing, a release cage with the male was placed on a cage older at the downwind end of the tunnel. Males were used once and those that were not activated within 120 sec of placing in the tunnel were discarded. The behavioral repertoire of males responding to calling females or abdominal glandular extracts included activation behaviors, random flight, guided flight, stopping on the wall, landing, reorientation and attempted copulation. Activation behaviors were identified by random walk before flying (orientation toward the stimulus), wing fanning and antennal grooming. Random flight involved upward and descending movements in any direction and crashes on the walls of the flight tunnel. The guided flight consisted of movements on zig-zag to the half height of the flight tunnel and the same level of the objective, these movements diminished in according width the insect came closer to the target, it was also observed the insect to be suspended in the air during some seconds and to fly short tracts. The landing was considered when the insect stopped in the wire cage and later walked vertical and horizontally looking for the female, besides shaking the wings vigorously. In the reorientation the insect flew against the wind toward the target after having oriented previously. Attempted copulation was a lateral curving of the abdomen to either left or right, besides touching the cage with the antennae.

[0651] FLOWER PREFERENCE AND FORAGING BEHAVIOR OF CENTRIS RODOPHTHALMA (HYMENOPTERA:ANTHOPHORIDAE)¹

<u>E. Chiappa</u>² & S. Rodríguez³, 1 Supported by FONDECYT Grant 1971141; 2 Fac. of Sciences. Univ. of Playa Ancha, 34-V, Valparaíso, Chile. 3 Lab. of Zoology, Catholic Univ., Valparaíso. boxmail 4059, Valpso., Chile. E-mail srodrigu@ucv.cl.

In 3 places of the IV Region of Chile (Varillar, Andacollito and Hurtado), a study was angle in Geoffroea decorticans, 3 species of Adesmia (Fabaceae) and Stachys albicaulis (Lamiaceae). In A. gluinosa and A. pedicellat the angle was 160° , making easy the access to the nectar of the tongue of C. rodophthalma, and did not for those plants with a smaller angle, 2.- To determine the foraging behavior of C. rodophthalma, the influence of 2 flower characters of 3 species of Adesmia, (a) the number of open flowers and (b) the nectar volume, was recorded and related on behavioral aspects of the bee: visitation frequency, the time spent at flowers and searching time (refers to the time spent outside of the bushes). To examine relations between those parameters, an analysis of multiple regression was performed. Results of the analysis shawn that in Varillar, the visitation frequency and the time spent at flowers are determined by nectar volume, through high quality and/or concentration of nectar in A. glutinosa. In Hurtado, distinctjy, is the number of flowers that are leading the foraging behavior of the bee, probably because this locality was in the peack of flowering. In the 3 places, the nectar volume and number of flowers did have not influence on searching time, supposedly, also used in other funtions like nesting, mating, resting, etc. The bee had foraging behavior alike in Varillar and Andacollito, probably because this localities have similar enviromental and geographical parameters and, with the strengthener of human disturbance of the habitat. Hurtado remain unchanged, is a natural habitat, there the foraging behavior of C. rodophthalma had greater values for each variable considered. This results suggest behavior variability of C. rodophthalma at populations level in this last locality.

[0653] CONTACT CHEMICAL CUES RELEASED BY ADULTS OF NEZARA VIRIDULA HAVE A KAROMONAL EFFECT ON THE EGG PARASITOID TRISSOLCUS BASALIS: A CHROMATOGRAPHIC INVESTIGATION

S. Colazza¹, E. Peri¹, G. Salerno², F. Saiano³, S. Ramirez³ & G. Alonzo³, ¹Inst. of Agricultural Entomology, Univ. of Palermo, Viale delle Scienze 13, 90128 Palermo, Italy, E-mail colazza@unipa.it; ²Dept. of Arboriculture and Plant Protection, Univ. of Perugia, Borgo XX Giugno, 06121 Perugia, Italy; ³ Dept. ITAF, Chemistry section, Viale delle Scienze 13, 90128 Palermo, Italy.

The host foraging behavior of insect parasitoids is generally mediated by chemical cues which may be detected both at long distance, where cues from the host-plant complex often play a major role, or at short distance, where host cues are frequently important for orientation. For insect parasitoids attacking the egg stage, short-range cues usually arise from sources associated with the adult host rather than from the egg stage itself, as for Trissolcus basalis, whose female shows an arrestment response when contacting traces left by adults of its host, Nezara viridula. Filter paper contaminated by males or females of N. viridula was extracted with solvents of increasing polarity: hexane, dichloromethane and acetone. The subsequent analysis by GC/MS revealed the presence of different contributing compounds in the various extracts (chemical identifications are currently underway). Laboratory bioassays were designed to determine the response of T. basalis females to the different extracts. The responses were scored as positive when the females, upon contacting the contaminated area, arrest locomotion and remain motionless for about 4-10 s, tapping the substrate intensively. Acetone filter paper extracts contaminated by Negara males or females were the most active; similar activity was also found in dichloromethane filter paper extracts contaminated by Nezara males alone. No activity was recorded with either hexane or dichloromethane extracts from Nezara females. Further analysis of the acetone extract has been done by HPLC producing five fractions of which only one shows evidence of some activity (chemical identifications in progress). Although the effectiveness of this kairomone for large-scale control has not been determined, the identification of the active compounds could provide an important tool to increase the biocontrol efficacy of T. basalis by stimulating host-seeking. Index terms: gas chromatography/mass spectrometry, solvent extracts, host location.

[0652] THE SOUTHERN PINE BEETLE INTERNET CONTROL CENTER: AN INTERACTIVE INTEGRATED PEST MANAGEMENT WEB-SITE

S. R. Clarke¹, S. M. Salon², N. D. Stone², B. R. Ward². & Q. C. McClellan², ¹Forest Health Protection, USDA Forest Service, 701 N. 1st St., Lufkin, TX 75901, USA, E-mail sclarke/r8_tx@fs.fed.us; ²Dept. of Entomology, Virginia Tech, Blacksburg, VA 24061-0319, USA.

The Southern Pine Beetle Internet Control Center is designed as an interactive web-site that provides current and historical information on the southern pine beetle (SPB), Dendroctonus frontalis, the most destructive forest insect pest in the southeastern United States. The SPBICC substantially increases the accessibility and utility of the vast amount of information available on SPB, and includes a searchable bibliographic database and a personnel directory of expertise. The search engines built into the site utilize state-of-theart technology developed at Virginia Tech, allowing experts and data collectors throughout the region to either access or update critical databases embedded in or linked to the site, minimizing the cost and effort that generally goes into site maintenance. Prediction models, decision keys, an IPM program, and training modules for SPB suppression techniques built into the site provide foresters or private landowners with a one-stop source for information on managing SPB on their lands. Maps illustrating the location of SPB infestations are presented, and users can point and click on individual spots to obtain spot data. Oracle 8 was selected as the database management system, with Livelink as the current search engine. A new, customizable Java servlet called StoneFission was created to link the databases to the web. Web-based, interactive training utilities are integrated into the site to provide opportunities for self-instruction. Currently, the front page and framework for the site are complete. The entity relationship diagram has been designed and the database built. SPB experts have been recruited to draft informative pages on SPB biological control, fungal associations, population dynamics, and IPM. The online bibliography is almost complete, and an integrated pest management program for SPB has been developed. A program demonstration will be run.

Index terms: Dendroctonus frontalis, website development, interactive training modules.

(0654) SEX PHEROMONE OF THE BRAZILIAN APPLE LEAFROLLER, BONAGOTACRANAODES (LEPIDOPTERA: TORTRICIDAE): EFFECT OF GEOMETRICISOMERS ON MALE ATTRACTION TO (E,Z)-3,5-DODECADIENYL ACETATE

M.D.A.Coracini¹, M.Bengtsson¹, J.L-fqvist¹, A.E. Eiras², E.F. Vilela³, A.Reckziegel⁴ & P.Witzgall¹, ¹Dept. of Plant Protection Sciences, Swedish Univ. ofAgricultural Sciences, P. O. Box 44, S-230 53 Alnarp, Sweden, E-mail:miryan.coracini@vsv.slu.se; ²UFMG, ICB, Dept.Parasitologia, Entomologia, Bloco L3, Campus da Pampulha,Belo Horizonte, MG, 31270-901, Brasil; ³UFV, DBA, Av. P.H.Holfs s/n, Vicosa, MG,36571-000, Brasil; ⁴Institut f.Organische Chemie & Biochemie der Universit"t Hamburg,Martin-Luther-King-Platz 6, D-20146 Hamburg 13, Germany.

The behavioural response of maleBrazilian apple leafroller, *Bonagota cranaodes*, to the main sexpheromone compound (E,Z)-3,5-dodecadienyl acetate (E3,Z5-12Ac) and tofemale extracts was studied in a wind tunnel. A field trapping test showedthat contamination of the main compound with the non-pheromonal isomersE,E; Z,E and Z,Z does not account for the discrepancy in male attraction toE3,Z5-12Ac and female extracts. Index terms: *Bonagotacranaodes*, geometric isomer, behavior, flighttunnel.
Symposium and Poster Session

[0655] DAMAGE-INDUCED CHANGES ON LEAF QUALITY OF BAUHINIA BREVIPES (LEGUMINOSAE) AND INSECT HERBIVORE ATTACK

T.G. Cornelissen¹ & G.W. Fernandes¹, ¹Univ. Federal de Minas Gerais, Lab. Ecologia Evolutiva de Herbívoros Tropicais, ICB, CP 486, 30161-970, Belo Horizonte, MG, Brazil, E-mail: tatiana@icb.ufmg.br.

Induced defenses to herbivory are physical, nutritional, and allelochemical traits that change in plants following damage or stress, and that reduce the performance and/or preference of herbivores. The aim of this study was to verify the occurrence and effect of induced responses in B. brevipes against herbivores through the manipulation of its leaves and its consequences to herbivore foraging behavior. We selected 15 planis, and 3 shoots per plant were designed for one of the three treatments: damaged shoots (simulation of the main types of foliar herbivory and insect exclusion), damaged control shoots (insect exclusion), and control shoots (not manipulated). Water and nitrogen content, tannin concentration, levels of herbivory, and shoot growth rates were compared among treatments through ANOVA. Leaf quality differed among treatments. Damaged leaves presented higher tannin concentration (df=2.0; F=8.57; P<0.05), and lower water (df=2.0; F=7.64; P<0.05) and nitrogen content (df=2.0; F=18.60; P<0.0001), but experienced higher rates of herbivory (df=2.0; F=12.82; P<0.0001) than leaves on control shoots. Moreover, shoots that were experimentally induced showed higher increment in final shoot length, a parameter that estimates fitness. These results suggest that simulated herbivory on B. brevipes reduced the nutritional quality of its leaves and increased the amount of secondary compounds, altering insect herbivore attack and increasing shoot performance.

Index terms: Induced defenses, plant quality, herbivory

[0656] CHEMICAL CONTROL OF THE "LEAF MINER", LEUCOPTERA COFFEELLA (LEPIDOPTERA: LYONETHDAE), WITH FURY 400 CE AND MARSHAL 400 SC IN COFFEE CROP, COFFEA ARABICA

L. E. A. Correa¹, A. C. Silva², L. O. Salgado² & R. S. de Mendonça³, ¹FMC do Brazil, Campinas, SP, Brazil, E-mail: luis_correa@fmc.com; ²Agroteste-Pesquisa e Consultoria, P.O.Box 201, Lavras, MG, Brazil, Zip Code 37.200-000, E-mail: agrotest@ufla.br, Instituto de Ciências Agrárias, Universidade de Alfenas/UNIFENAS, P.O. Box 23, Alfenas, MG, Brazil, Zip Code 37.130-000, E-mail: fileni@artefinal.com.br.

Leucoptera coffeella is responsible for a great damage on production and longevity of coffee plants in Brazil, being the chemical control the principal methods against this pest. The objective of the present work was to evaluate the efficiency of the commercial products Fury 400 CE (Zetacypermethrin) and Marshal 400 SC (Carbosulfan) to control the "leaf miner", *L. coffeella* In coffee crop. The treat was set up at the area Araguari, Minas Gerais State, Brazil, during December 1999 up to January 2000. The experimental design was the randomized blocks with 6 treatments and 4 replications. Each plot had 19.60 m² with seven plants. The efficiency of the treatment was evaluated according to the number of alive *L. coffeella* in damage leafs. It was used the Abbott formula as a measure of efficiency and means were separated by Ttukey test (p<0.05). As a whole of six evaluation were done during the observation period and the results are presents on the

According to the results the insecticides Fury 400 CE in all doses utilized and Marshal 400 were efficiency to control *L. coffeella* in coffee crop up to 30 days after application, reaching the top of 92,86 % of efficiency.

Index terms: Lepidoptera, Lyonetiidae, insecticides, coffee crop

[0657] ANTIFEEDANT EFFECTS OF ARGENTINE *MELIA AZEDARACH* FRUIT EXTRACT AND ITS ACTIVE COMPOUND MELIARTENIN

M. T. Defagó¹, <u>G. Valladares¹</u>, M. C. Carpinella², S. Palacios² & E. Banchio¹, ¹Centro de Investigaciones Entomológicas, F.C.E.F.Y.N., Univ. Nac, Córdoba, Av. Vélez Sársfield 299, (5000)-Córdoba, Argentina. ² CEPROCOR, Av. Arenales 230, (5000)-Córdoba, Argentina. E-mail: grv@onenet.com.ar.

Insect damage to plants results mainly from feeding, particularly in the case of chewing herbivores, therefore pest injury can be reduced by rendering plants unattractive or unpalatable. Antifeedants are chemicals which reduce or prevent insect feeding, and can be an important tool for pest management. One of the weak points of investigations into the occurrence of antifeedant substances is that in most cases only one test insect species is used. The objective of this study was to evaluate the antifeedant effects of Melia azedarach crude fruit extracts against a wide array of insects. Also, antifeedant and insecticide effects of Meliartenin (the extract's active compound) were assessed and compared with those of Azadirachtin. Insects from 17 mandibulate species (3 Orders, 8 Families), mostly folivores and seed eaters, were subject to laboratory Choice tests in order to evaluate the antifeedant properties of the extracts. A Feeding Inhibition Index was calculated which reflects the relative reduction in food consumption due to the extract being applied to the insect diet. Three extract concentrations were used (2%, 5%, 10%). Moreover, Choice and No-Choice tests were carried out to evaluate the antifeedant and lethal effects of Meliartenin and Azadirachtin (0.25, 0.5, 1, 4µg/cm²) using Epilachna paenulata (Coleoptera, Coccinellidae) larvae as insect test and Cucurbita sp. leaf disks as substrate. Data were analysed by Wilcoxon signed rank test, T test and ANOVA. All the species tested significantly preferred non treated food, at least for some extract concentrations. The extracts were strongly deterrent (reducing food consumption in more than 75% compared to non treated food) for 13 of those species. For 3 of the species, the extracts were tested on adults and larvae, being effective against both stages. Meliartenin completely inhibited feeding by E. paenulata at a concentration of 1µg/cm². When the insects were fed only on treated leaves, mortality rates of 80% or higher were reached after 4 to 8 days of treatment, depending on the concentration used. In both aspects, Meliartenin effects were similar or even slightly higher than those of Azadirachtin.

Index terms: Botanical pesticides, Epilachna paenulata, Meliaceae, Phytochemicals, Deterrents

[0658] PHYSIOLOGICAL REGULATION OF PHEROMONE PRODUCTION AND ITS INHIBITION FOLLOWING MATING IN *CHORISTONEURA FUMIFERANA AND C. ROSACEANA* (LEPIDOPTERA: TORTRICIDAE)

<u>J. Delisle¹</u>, J.-F. Picimbon² & J. Simard¹, ¹Natural Resources Canada, CFS, Laurentian Forestry Centre, P.O. Box 3800, 1055 du P.E.P.S., Sainte-Foy, QC G1V4C7, CA. E-mail: jdelisle@cfl.forestry.ca ²Inst. of Physiology, Hohenheim Univ., 70593 Stuttgart, GE. Email: jfp@uni-hohenheim.de.

In both *Choristoneura* species, the periodicity of calling and pheromone production is well synchronized, with maximal activity occurring during the early scotophase. Newlyemerged females decapitated prior to the onset of the scotophase produced no or very little pheromone, but the injection of PBAN or Br-SEG extracts restored normal pheromone production. Transection of the ventral nerve cord (VNC) did not affect pheromone production in controls females or in decapitated females injected with PBAN or Br-SEG extracts. These results clearly indicate that the regulation of pheromone production is not neurally mediated in either Choristoneura species. Furthermore, there was no evidence of PBAN-like factors in hemolymph collected during the calling period. However, while the presence of the bursa copulatrix (BC) was essential to produce pheromone, an extract of the BC injected into decapitated females did not elicit pheromone production. In both species, mating significantly depressed the pheromone titre 24 h later. However, on subsequent days, pheromone production increased in C. fumiferana but not in C. rosaceana. Male accessory gland extracts or hemolymph taken from mated females did not have pheromonostatic activity. However, pheromone production in mated females was not inhibited when the VNC was transected prior to mating, indicating that the integrity of the central nervous system is required to permanently switch off pheromone production. As suggested for other species, the presence of sperm in the spermatheca probably triggers the release of a signal, via the VNC, to inhibit pheromone production. Therefore, we speculate that in mated C. fumiferana females, the neural signal declines following the depletion of sperm in the spermatheca, and as it is less effective in preventing the release of PBAN there is a resumption of pheromone production. Mating induces a significant rise in the JH tire of both female moths, suggesting that the post-mating pheromone suppression may also be under hormonal regulation. Following injection of JH pheromone titres only declined in C. rosaceana virgins. This suggests that the significant post-mating rise in the hemolymph JH titre in this species plays a role in keeping the pheromone consistently low throughout reproductive life. These findings will be discussed in relation with the different life histories exhibited by the two Choristoneura species.

Index term: Choristoneura fumiferana, Choristoneura rosaceana, PBAN, bursa, JH

[0659] WHY METABOLITES PRESENT ON THE PLANT SURFACE HAVE TO BE CONSIDERED IN HOST SELECTION : APPLICATION TO TWO LEPIDOPTERA OVIPOSITION

<u>S. Derridi</u> & N. Lombarkin, INRA, Unité de phytopharmacie, Route de St Cyr, 78026 Versailles, France, E-mail derridj@versailles.inra.fr.

Till now the theory for dealing the factors determining insect-plant relationships and the strategies developed by plant and insect to evolve together remain obscure. The last step behaviour before feeding or ovipositing is the acceptation of the plant when the insect is in contact with the plant surface. There, there are metabolites which constitute a finger print and give also informations on plant state physiology. The plant cuticle which select the passing through of molecules from the tissue to the surface has a major role in the expression given by the surface. The balance between the expression of plant surface and the possibilities of insect to detect some of them is probably one of the alternative explanation for co-evolution. With rather few components for example five to six free amino acids, plant species can be discriminated. Furthermore a single component can give both informations on the plant specificity and the plant site nutritive value. Studies on the generalist Ostrinia nubilalis and the specialist Cydia pomonella oviposition showed clearly the incidence of the metabolites present on the plant surface (leaves, fruit) on the insect oviposition. Soluble carbohydrates (glucose, fructose, sucrose) have an influence for both insects on the site preference and the number of eggs laid per female. Fructose in both cases is highly involved. C. pomonella oviposition is also influenced by sugaralcohols which characterise its host plants (Rosaceae). In a combination of three sugars and three sugar-alcohols, sorbitol is as stimulant as fructose. On C. pomonella it was observed that according to time the influence of substances could be different. Both sugars and sugar-alcohols induced a rapid response of the females after 3 mn dark. After 25 mn of dark the oviposition stimulation was diminished only by the suppression of sugaralcohols by combinations of two. A deterrent effect of combinations of three sugars and three sugar-alcohols could be attributed to the concentration and was loss when diluted 100 times. Fructose and sucrose which elicit oviposition are also demonstrated to stimulate greatly feeding behaviour of O. nubilalis larvae. C. pomonella neonate larvae nibbling is stimulated by fructose, and sugar-alcohols. These subtances are also arrestant. Metabolites present on plant surface have a decisive role in host selection for lepidoptera oviposition and dispersion of neonate larvae. For the generalist as well as for the specialist, nutrients like sugars play a major role in these key steps of colonisation.

Index terms: Ostrinia nubilalis, Cydia pomonella, carbohyrate, sugar-alcohol

[0660] APHIS GROOSYPH MODEL WITH COMPLEX LIFE HISTORY

L. Dianmo & Ma Zufei, The State Key Lab of Integrated Management of Insect Pests & Rodents, Institute of zoology, Chinese Academy of Sciences, Box 70, E-mail Lidm@panda.ioz.ac.cn, Beijing, 100080, P. R. China.

Cotton aphid is one of main cotton pest in the Yellow River valley between May and August. We have built a real model of *Aphis groosypii* Glover (cotton aphid) to test complexity dynamics in natural conditions. For this objection, we simulated a series of life cycle of this insect in field, and replaced the astronomic time with physiological time to counteract the effect of temperature on the model. Every parameters in the model in a wide parameter region. The model has complex structure (we considered the generations overlap, non-linear density feedback, wing aphid ratio and reproduction with age structure (as 100 k, means a series life history in a more complex aphid life cycle, per k is one quip and per quip is 7 dayx...) the output of model seems nearly chaotic. But in long term (as 10,000 k, means a simpler life cycle of aphid) the output appears as cyclic. This result proves that life history (in someway, its structure not only mortality and reproduction rates) is very important to population dynamics.

[0661] DETERMINING THE SUSCEPTIBILITY OF LESSER CORNTALK BORER IN RICE (*ELASMOPALPUS LIGNOSELLUS*) TO INSECTICIDES

<u>E Ferreira</u>¹ & J. A. F. Barrigossi¹, ¹National Rice and Bean Research Center (Embrapa Arroz e Feijão), Caixa Postal 179, Santo Antônio de Goiás, GO, Brazil, 75375-000, Email: evane@cnpaf.embrapa.br.

The lesser cornstalk borer, E. lignosellus, is a common pest of seedling upland rice in Brazil. Outbreaks are more likely under hot and dry conditions. Feeding by lesser cornstalk borer leads to the death of the shoot, resulting in the formation of 'dead heart'. Although control is difficult with soil applied insecticides due to the subterranean habit of this pest, seed dressing with insecticides have provided an efficient control. In this study, we evaluated the performance of three insecticides as seed treatments to control E. lignosellus larvae, under artificial and natural infestations. In addition, we tested and described field infestation techniques for the lesser cornstalk borer in rice. Three field experiments were conducted during the summer of 1998 at Embrapa Arroz e Feijão near Santo Antônio de Goiás, GO, Brazil. Rice plantings were made on November 6, November 26, and December 6, 1998. The experimental design was a Latin square 6x6. The experimental unit consisted of seven rows, 3 m long. Treatments consisted of the following insecticides and doses applied to the seeds: thiamethoxan (52.5, 70.0, and 105 g a.i./100 kg seeds), furathiocarb (320 g a.i./100kg seeds), and carbofuran (525 g a.i./100kg seeds). An untreated control was also included. At the end of the border rows of each plot, two groups of three randomly selected tillers were confined in a cylinder with 0.25 m and 0.20 m diameter. These cylinders were buried at 5 cm depth in the soil to prevent the escape of larvae from the cylinders after infestations. These plots were established 25, 33 and 44 days after planting. Then, 1, 7, and 14 days after plots were established, tillers were infested with the 2nd instar cornstalk borer larvae/cylinder. Immediately after infestation, each plot (cylinder containing three rice tillers) was covered with a transparent plastic bag (20 I capacity) to keep rain away from the larvae. Plots were evaluated 20 days after infestations, to determine the number of tillers exhibiting symptoms of 'dead heart'. Naturally infested plots were also evaluated to determine the number of injured-tillers by examining tillers located in the three center rows of each plot at 15, 44, 74, and 105 days after planting. All seed treatment insecticides reduced larval survival significantly for 60 days after planting compared to the untreated control. Thiamethoxan had a better efficiency in reducing injury from E. lignosellus larvae than furathiocarb and carbofuran at the doses used in this study. Artificial infestations, used in this study, increased the proportion of damage 30 fold, compared to plots without artificial infestation (untreated control).

Index terms: lesser cornstalk borer, Elasmopalpus lignosellus, insecticides

[0662] PHYSIOLOGICAL STATE AND ASSOCIATIVE LEARNING DETERMINE RESPONSE OF PREDATORY MITE TO FOOD-RELATED AND OVIPOSITION-RELATED VOLATILES

F. Faraii, A. Janssen & M. W. Sabelis, University of Amsterdam, Institute for Biodiversity and Ecosystem, Section Population Biology, Kruislaan 320, 1098 SM, Amsterdam, The Netherlands, E-mail: faraji@bio.uva.nl

Females of the predatory mite *Iphiseius degenerans* visit flowers for feeding but oviposit on leaves. We conducted Y-tube experiments to test the hypothesis that preference for cues related to these feeding and oviposition sites (flower and leaf odours) depends on the physiological state (hungry or fed) and experience of individuals. Females collected from pepper plants were either starved in the absence of any stimulus or were allowed to feed by placing them in pepper flowers, where flower odours are associated with the presence of food (pollen). When tested in a Y-tube olfactometer, fed females, that had thus been conditioned to flower odours, strongly preferred the odours of pepper leaves over flower odours, whereas starved females preferred flower odours. Females with no experience on pepper plants, by contrast, showed a weak preference to only leaf odours either when fed or starved. Our results can be explained by the fact that fed females mainly search for oviposition sites on leaves, whereas starved females try to localise food. These results suggest that the foraging behaviour of *L degenerans* is influenced by a combination of associative learning, innate response and the physiological state of individuals. Index terms: *Iphiseius degenerans*, experience, flower and leaf volatiles, olfaction.

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[0663] AN INTUITIVE APPROACH TO SELECTING UTILIZABLE ATTRACTANTS FOR A GENERAL FRUIT-FEEDING PEST: THE FRUITPIERCING MOTH EXPERIENCE

H. A. C. Fay & K. H. Halfpapp, Queensland Horticulture Institute, Department of Primary Industries, P O Box 1054, Mareeba, QLD 4880, AUSTRALIA, E-mail fayh@prose.dpi.qld.gov.au

Fruitpiercing moths (Lepidoptera:Noctuidae) are known to attack at least 50 different kinds of fruits, and can be significant pests of tree and vine crops in the Old World tropics and sub-tropics. They pierce fruit as it ripens, and when the odour composition is changing rapidly. Different fruits emit odours composed of hundreds of different chemical compounds, many of which are unique to a fruit and impart the characteristic smell. However, different fruits also have in common a range of general chemical volatiles which change in prominence through the ripening process. Such compounds were thought responsible for the attraction of moths to fruit at a specific stage of crop development. A number of these compounds were selected from the considerable literature on fruit volatiles, and the responses to them assessed by electroantennogram (EAG) in Eudocima fullonia and Eudocima materna. These responses were compared against those obtained for compounds specific to particular fruits. Of the individual synthetic fruit odours, the general fruity esters (such as n-butyl acetate and methyl butyrate) elicited the greatest response. However, combinations of volatiles, particularly where different chemical groups were involved, produced responses greater than expected from the observed responses to the same chemicals offered singly. This implied that combinations of general odours are probably involved in a moth's recognition of a crop with acceptable fruit. Flight cage tests with sugared-agar baits containing designated concentrations of particular fruit volatiles (esters, aldehydes and alcohols) suggested that moths seek out fruit of a certain level of ripeness based solely on the proportions of the volatile components produced. Ripe (58% esters) 'fruit', as opposed to mature (6%) or very ripe (92%), were preferred. Varying the type or proportions of the non-ester components appeared to influence bait selection. Trials in early maturing citrus through the susceptible life of the crop have shown that baits containing 3 esters, 3 aldehydes and an alcohol (totalling 25(1/25g bait) attracted 85% of moths on baited trees (with several hundred fruit/tree) through to the first week of harvest. This then fell to 75%, if the response of E. materna (the least responsive species) is ignored. Two severe pest species, E. fullonia and Eudocima salaminia, were particularly attracted to the baits, with 100% being attacked some nights. Recent studies have concentrated on prolonging bait life in the field and testing the technique in other crops.

Index terms: Eudocima fullonia, Eudocima materna, fruit, volatiles, EAG.

[0664] PLANT HYPERSENSITIVE RESPONSE TO GALL INDUCTION ACROSS HOST TAXA

<u>G. W. Fernandes¹</u> & D. Negreiros¹, ¹Ecologia Evolutiva de Herbívoros Tropicais, DBG/Universidade Federal de Minas Gerais, CP 486, 30161-970 Belo Horizonte, MG Brazil, Email gwilson@icb.ufmg.br

Hypersensitive reaction is an important type of induced defense by which the plant elicits a defense response to pathogens and insects. Hypersensitive reaction has been argued to be the most common plant resistance mechanism against insect herbivores that have intimate associations with their host plants. This study attempted to establish how important and widespread hypersensitive reaction might be against gall-forming species across host taxa. Hypersensitive reaction was the most important mortality factor against gall formation across host plant taxa in seven out of eight cases. The number of insect galls correlated with the size of the leaves but module (leaf) size was a weak factor influencing the incidence of plant hypersensitive reaction to galling. Insect galls and hypersensitive reactions occurred in genetically distant as well as geographically widespread host plant taxa.

Index terms: Hypersensitivity, Insect galls, Plant defenses, Plant induced defenses.

[0665] EFFICIENCY OF DIFFERENTS LURES AND THEIR PROBABLE INTERACTION IMPROVING RHYNCHOPHORUS PALMARUM ADULTS ATTRACTION TO THE TRAPS

J.M.S. Ferreira¹, R.P.C. Araujo² & <u>F.B. Sarro³</u>, ¹Lab. of Entomology, Embrapa/CPATC, P.O. Box 44, Aracaju, CEP 49025-040, Brazil;² Dept. of Biotecnology, Unesp, Araraquara, P.O. Box 355, CEP 14801-970, Brazil; ³ Dept. of Plant Protection, Unesp, Botucatu, P.O. Box 237, CEP 18603-970, Brasil, E-mail (bsarro@unesp.br.

Adults of Rhynchophorus palmarum are considered the main vector of the nematode Bursaphelenchus cocophilus, the causal agent of red ring, a lethal disease of coconut and other palms. Attractive lures and the male-produced aggregation pheromone are been used to monitor adult activities, to reduce pest population and to prevent red ring disease dissemination on palm plantations. The present work was carried out at Embrapa Coastal Tableland Research Center (CPATC) Sergipe, Brazil aiming to determine the efficiency of differents lures and to study their probable interaction in the capture of R.palmarum. Traps were randomly distributed around a coconut plantation, located at Itaporanga D'Ajuda County, Sergipe, Brazil, distant 200m from each other. The adults were captured for one year. The experimental design was completely randomized. The attractive lures sugar cane (C), aggregation pheromone (F), ethyl acetate (A), and molasses (M) were tested alone, combined 2 by 2 and 3 by 3, totalizing 12 treatments, namely: T1- C; T2 - F with change of the pheromone capsule every three month; T3 - F without change of the pheromone capsule; T4 - A; T5 - M; T6 - C+F with change of the pheromone capsule; T7-C+F without change of the pheromone capsule, T8 - C+A; T9- C+M; T10 - C+A+F with change of the pheromone capsule; T11 - C+A+F without change of the pheromone capsule; T11 - C+A+F without change of the pheromone capsule; T12 - C+A+M. "Plastic Buckets" (50 litres capacity) were used as traps to catch the adults. Every fifteen days, the traps were changed from site to site among themselves to avoid the spot effect on the weevil capture. A total of 5184 adults of *R.palmarum* was captured during the experimental period. The treatment T10 and T6 were the most efficient ones. They were able to attract 30,71% and 21,32% adults, respectively, totalizing 52,03% of the total adults captured. The lures tested alone shows an efficiency level of 4,38% of the total captures, showing the importance of the interaction of lures to promote a sinergistic effect by increasing attraction of adults of R. palmarum in the field. The number of adults attracted by each lures did not differ significantilly among the sites, showing no spot effect on the weevil capture. Index terms: palms, red ring, pheromone, coconut, trapping system

[0666] EVALUATION OF THE "PET" TRAP EFFICIENCY ON THE CAPTURE OF ADULTS OF RHYNCHOPHORUS PALMARUM AND THE COST/BENEFIT ANALISYS

J.M.S. Ferreira¹, R.P.C. Araujo² & <u>F.B. Sarro³</u>, ¹Lab. of Entomology, Embrapa/CPATC, P.O. Box 44, Aracaju, CEP 49025-040, Brazil;² Dept. of Biotecnology, Unesp, Araraquara, P.O. Box 355, CEP 14801-970, Brazil, E-mail coqueirat@mar.com.br; ³ Dept. of Plant Protection, Unesp, Botucatu, P.O. Box 237, CEP 18603-970, Brazil.

Several traps designs are being proposed to capture adults of Rhynchophorus palmarum on coconut and oil palm plantations using in most of them sugarcane and the aggregation pheromone (Rhynchophorol) as attractive baits. Nowadays, the "bucket" trap design is the one broadly recommended and adopted by brazilian farmers. The great disadvantage of using this design is related to factors like, trap container damage, cost and theft. This work was carried out by Embrapa Coastal Tableland Research Center - Aracaju, Sergipe State, Brazil (CPATC) aiming to evaluate the efficiency and feasibility of a "pet" design trap in capturing adults of R. palmarum and to evaluate the cost/benefit rate of use it as an alternative trap in a field control program. A number of five "pet" traps and five "bucket" traps were distributed around a coconut plantation, approximatelly 200m away from each other, in the County of São Cristovão/SE, Brazil. Each trap, does contain pieces of sugarcane (25 to 30cm long) and aggregation pheromone in it, as attractive source. The 'pet" trap is made with three plastic softdrinks bottles. The capture chamber of this trap measures approximatelly 0.151 m², that means, 3.73 times smaller than the capture chamber of the conventional "bucket" trap used on this experiment. The sugarcane pieces were weekly renovated from the "pet" trap and quartelly from the "bucket" trap, for a year period, and the number of captured adults recorded. The pheromone capsules were renovated every three months. The number of insects captured, transformed to m² of the capture chamber, was the parameter used to measure the traps efficiency. The net price of plastic containers and pheromone was the parameter used to evaluate the cost/benefit rate of both traps. The results showed a total of 2222 adults captured during the experimental period in the "pet" traps against 2836 adults in the "bucket" trap, which represents 43.9% and 56.1% of the total captures, respectivelly. However, by comparing these numbers of captures and the trap size (transformed in square meter of trap area) an efficiency level of 74,51% was obtained in the "pet" and 25,48% in the "bucket" trap. The "bucket" trap has an estimated cost of U\$12 while the "pet" trap U\$2,8. Considering all those parameters (adults captures, trap size and trap cost) it can be concluded that the "pet" trap is the most efficient ones. Besides to have a capture area 3,73 times smaller than the " balde" trap, it was able to capture 49,02% more adults than the former one and to give an economy level of U\$9,8 to the farmer which is equivalent to the cost of 3,5 pheromone capsules. Besides to be less attractive to thefts.

[0667] COPULATION PHEROMONE OF THE VECTOR OF CHAGAS DISEASE, TRIATOMA INFESTANS: IDENTIFICATION AND BIOASSAY

<u>A. Fontán</u>¹, P. González Audino¹, A. Martínez¹, R. Alzogaray¹, E. Zerba¹, F. Camps³ & A. Cork²; ¹Centro de Investigaciones de Plagas e Insecticidas (CIPEIN/CITEFA-CONICET), Zufriategui 4380, 1603 V. Martelli, Buenos Aires, Argentina. cipein@citefa.gov.ar. ²Natural Resources Institute, Central Avenue, Chatham Maritime, KENT 4TB, UK. a.cork@greenwich.ac.uk. ³Centro de Investigación y Desarrollo, Depto de Química Orgánica Biológica. Jordi Girona, 18-26, Barcelona, España. fcdqob@cid.es. Supported by INCO-DC EU Program, CONICET, Ag. Prom. Cient. de Argentina.

The haematophagous bug T. infestans is the major vector of Chagas Disease in South America. Behavioral and electrophysiological assays have demonstrated the existence of a copulatory pheromone emitted during copula, that is attractive to male T. infestans. This study was undertaken to identify the chemical components in the pheromone by studying the electrophysiological and behavioral responses elicited by chemicals collected from volatiles emitted by male and female before and during copula. Volatiles were collected on Porapak-Q from charcoal filtered air (100 ml/min) pass through a Pyrex glass entrainment apparatus containing 7 male and 7 female. The volatiles were desorbed into dichloromethane and analysed by GC and GC-MS after confirmation of its attractant effect in an arena bioassay. Studies carried out on polar and non polar GC columns demonstrated the presence of a complex mixture of compounds, identified as: 2- and 3-methyl-butan-1ol in a 2:1 ratio; short chain acids (ethanoic to nonanoic); long chain acids (decanoic to (Z)-9-octadecenoic acid); aliphatic aldehydes and other compounds such as benzaldehyde and propane,1,1-thios. EAG studies were carried out with a homologous series of aliphatic aldehydes on female and male. The results showed an increase in EAG response, for a given dose, with increase in chain length up to nonanal, after which the EAG-activity declined. The attractiveness of the major compounds identified in the volatiles formulated in polyethylene glycol 400 were tested on female and male in a 20 cm diam circular arena bioassay for 30 min using a video tracking method. No significant responses were obtained with mixtures of (S,R)2 and 3-methylbutan-1-ol in a 4:1 ratio. Aliphatic C7 to C10 aldehydes were tested: hexanal (1-100 µg) and heptanal (0.1 µg) elicited an attractant response from females that were equivalent to that elicited by benzaldeyde (5-10 ng). Nonanal (10 - 100 ng) elicited an attractive response from males. Blends of hexanal:benzaldehyde (20:1 and 40:1) showed an additive effect on attraction when tested on female. The study has demonstrated the presence of electrophysiologically and behaviorally-active compounds in the volatiles emitted by T. infestans in copula and it is hope that an optimised blend will be identified that can be used to form the basis of an attractant for a biocidal trapping system.

[0668] NITROGENOUS COMPOUNDS AS ATTRACTANTS OF TRIATOMA INFESTANS

<u>A. Fontán</u>¹, R. Alzoguray¹, P. Santo Orihuela¹ E. Zerba¹, D. Fernández⁴, F. Camps ³ & A. Cork², ¹Centro de Investigaciones de Plagas e Insecticidas (CIPEIN/CITEFA-CONICET), Zufriategui 4380, 1603 V. Martelli, Buenos Aires, Argentina. cipein@citefa.gov.ar. ²Natural Resources Institute, Central Avenue, Chatham Maritime, KENT 4TB, UK. a.cork@greenwich.ac.uk ³Centro de Investigación y Desarrollo, Depto de Química Orgánica Biológica. Jordi Girona, 18-26, Barcelona, España. fcdqob@cid.es. ⁴Inst de Investigaciones Químicas y Ambientales de Barcelona (CID-CSIC). Supported by INCO-DC EU Program, CONICET, Ag. Prom. Cient. de Argentina.

The haematophagous bug Triatoma infestans is the major vector of Chagas Disease in South America. The ability of its own feces to elicit aggregation in nymphs and adults is well known. The presence of nitrogenous compounds such as 4-methyl and 2,4 dimethyl quinazolines and the emission of NH3 were reported. Other authors could verify no attractant effect when doses of 0.1-100ng of quinazolines were tested in immature stadiums. Behavioral and electrophysiological assays have demonstrated the capability of NH3 to attract nymphs and the presence of NH3 antenna receptors. However, for practical purposes the finding of an active source of NH3 is indispensable. In this work, the activity of a number of hygroscopic ammonium salts with different NH3 release rates was tested. Ammonium chloride, ammonium acetate and ammonium carbonate were tested using a video tracking system on a circular arena, 20-cm diameter. After 30 minutes of acclimatization of the insect, 2 mg of the compound to be tested was introduced in the middle of the arena on thin glass. The approach of the insect around the compound source was recorded for 30 minutes. The attractant effect was quantified as the number of visits of the insect to the centeral zone during the assay. Ammonium carbonate or acetate did not elicit any response on nymph V. However, ammonium chloride proved to be attractive, increasing significantly the mean number of visit to the center zone (from 0.1 to 2.7). Aqueous solutions of methyl amine ranging from 10⁻³ to 10⁻¹ M significantly increased the mean number of visits of nymph V around the source from 0.1 to 1.3. No significant effect was observed when 2 mg of ethylammonium chloride was tested. A mixture of synthetic quinazolines obtained from 2-aminoacetophenone, in a ratio similar to that found in feces (1:1) was tested on females and males. Mixtures containing 50µg of each compound elicited a very significant attractive effect on females. Toxicological assays are now in progress to establish if placing quinazolines in a pyrethroid film would enhance the kill of T.infestans.

[0669] IDENTIFICATION OF HOSTPLANT VOLATILES ATTRACTIVE TO THE SPHINX MOTII, MANDUCA SEXTA

A. M. Fraser, W. L. Mechaber & J. G. Hildebrand, ARL Div. of Neurobiology and Center for Insect Science, Univ. of Arizona, Tucson, AZ 85721-0077, USA, E-mail: afraser@neurobio.arizona.edu

Female Manduca sexta moths (Lepidoptera: Sphingidae) exhibit upwind orientation and egg laying-related behavior when exposed to volatiles released by their hostplants. We collected headspace volatiles from three solanaceous hostplants (Lycopersicon esculentum, Capiscum annuum and Datura wrightii: Solanaceae) and one non-solanaceous host (Probiscidea louisianica: Martinyaceae) and used coupled gas chromatography-electroantennographic detection (GC-EAD) to determine what components stimulated olfactory receptors in the antennae of female moths. Antennae responded to an array of peaks in the GC traces of headspace volatile blends. A majority of the significant antennal responses corresponded with intermediate or minor GC peaks, suggesting that these less abundant components might be behaviorally important. Response-evoking GC peaks were identified by gas chromatography-mass spectrometry (GC-MS) and verified with synthetic standards. Electrophysiologically-active components included aliphatic, aromatic and terpenoid compounds. Data from GC-EAD studies were used to prepare a series of synthetic hostplant volatile blends for testing in wind tunnel behavioral bioassays. Index terms: electroantennography, GC-EAD, olfaction, plant volatiles, hostplant

[0670] MATING DISRUPTION PHEROMONES RELEASE IN PORTUGAL

C. Frescata, Biosani Lda., Casal Sto. Isidro, Serra do Louro, 2950-305 Palmela, Portugal, E-mail: biosani@mail.telepac.pt

In Portugal, during 1999, was done a study by Biosani company in co-operation with Shin-Etsu company about the release of the pheromones of the mating disruption dispensers of "Isomate-C Plus" for *Cydia pomonella*, "Isonet-L" for *Lobesia botrana* and "Isomate-OFM" for *Cydia molesta*. For each kind of dispenser was sampled 5 dispensers per month since the field application, done just before the start of the pest flight, till the harvest time. "Isomate-C Plus" applied in one pear orchard on 17/4/99 in "Oeste" region, after 156 days, on 20/9/99 still had 46 % of the active ingredient. "Isomet-L" applied in one vineyard on 15/3/99 in Settibal region, after 163 days, on 25/8/99 still had 6 % of the active ingredient. "Isomate-OFM" applied in one peach orchard on 12/4/99 in Terceira Island (Azores), after 143 days, on 2/9/99 still had 14 % of the active ingredient. So, in the places studied and for their usual weather conditions is possible to use the researched mating disruption dispensers doses over the years, due to the reduction of the pest population in the mating disruption fields, make this efficient pest control method an attractive alternative to the toxic insecticides.

Index terms: Cydia pomonella, Lobesia botrana, Cydia molesta.

[0671] VARIATION AND SPECIFICITY OF HERBIVORE-INDUCED PLANT ODORS AS FORAGING CUES FOR PARASITOIDS

<u>S. Gouinguené</u>, **T. Degen & T. Turlings**, Univ, Of Neuchâtel, Inst. of Zool., Lab. of Animal Ecology and Entomology, C. P. 2, Ch-2007 Neuchâtel, Switzerland. sandrine.gouinguene@zool.unine.ch

Many parasitoids that attack phytophageous insects make use of plant odors to locate the habitat of their host. In maize large amount of these odors are specifically emitted by a plant after it has been damaged by a herbivore, but not after mechanical damage. The odor emissions occur systematically throughout the plant. Factors in the oral secretion of the herbivores are the main elicitors of the plants' reaction. The induced maize odors are useful cues for the parasitoids and indicate the presence of a potential host. This odor is mainly composed of terpenoid compounds. We have studied different abiotic and biotic factors that determine the specificity and variation of the signal emitted by maize plants in response to caterpillar damage. Light intensity is the most important factor, but odor emissions were also affected by the soil and air humidity, temperature and the degree of fertilization. We found enormous quantitative and qualitative differences among maize genotypes. The absolute amount of volailes emitted was negatively correlated with the plant age, while larval instar appeared to have little or no effect. We discuss these results in the cortext of reliability of plant-induced signals as cues that allow parasitic wasps to find a suitable host.

[0673] ECONOMIC INJURY LEVEL AND SEQUENCIAL SAMPLING FOR BEMISIA TABACI IN TOMATO

M.R.Gusmão¹, M. Picanço¹, J.A.F. Barrigossi², A.L.B.Crespo¹ & T.L.Galvan¹, ¹ Dept. de Biol. Animal, Univ. Fed. de Viçosa, CEP 36571-000, Viçosa, MG, Brazil, ²EMBRAPA-CNPAF. E-mail picanco@mail.ufv.br.

This research aimed to determine the density of *Bemisia tabaci* (Homoptera: Alevrodidae) capable of causing economical damage in tomato and to determine a sequencial sampling for this species in this crop. Adults and nymphs densities of B. tabaci were evaluated in 14 squares of 9 commercial field of tomato in Coimbra, Guidoval and Viçosa, State of Minas Gerais, Brazil. The whitefly adults sample was accomplished through the beat of 2 medium leaves in white plastic tray, while the sampling of nymphs was accomplished by the direct count of the insects in 2 medium leaves. The relationship between densities of insects and crop productivity was determined by regression analysis. For the economic injury level determination, the cost of 1, 3 and 6 control applications of insecticides was considered. Variation on the commercialization price of tomato was also considered, from 181,82 R\$/ton. (low price), to 454,45 R\$/ton. (medium price) and 1136,36 R\$/ton. (high price). Stablished the economic injury level, the sequencial sampling for whitefly adults and nymphs was settled. Initially the densities of the insects data were adjusted using the model of binomial negative distribution. Later the degree of aggregation of the sampling data was calculated by the methods: reason variance-average, Green and K parameter of the binomial negative distribution. As the sampling data to the distribution model, was settler the limits of decision making in agreement to the methodology based on the test of the reason of sequencial probability of Wald. Were determined the critical densities of 1/3 and 2/3 of the economic injury level and a 10% mistake probability in the classification of the densities were considered. The economic injury level varied with the cost of control of the insects and the price of tomato commercialization, the smallest critical densities were verified in the situations of high price of the tomato and smaller control cost. For each critical density responsible for causing economical damage a plan of sequencial sampling characterized by a minimum and maximum size of samples was obtained for the decisions to be taken. An economy from 30% to 58% was verified in comparison with the conventional sampling plan.

Index terms: Whitefly, Integrated Pest Management, Decision making

[0672] ATTRACTIVITY OF PROTEIN HIDROLISATE AND SUGARCANE MOLASSES ON ADULT FRUIT FLIES ANASTREPHA SP. AND CERATITIS CAPITATA (DIPTERA: TEPHRITIDAE) ON CITRUS ORCHARD

<u>S. Gravena</u>¹, S.R. Benvenga¹, J.L. Silva¹, N. Araújo¹ & M.S. Linardi¹, ¹Gravena ManEcol Ltda, Rua Monteiro Lobato 856, 14870-000, Jaboticabal/SP, Brazil. E-mail gravena@asbyte.com.br

The fruit flies Anastrepha sp. and Ceratitis capitata still are important pests on productive citrus orchards due to the fruit injuries, resulting losses of commercial production of yield and dificulties to the Brazil's trade of fresh fruits. To estimate fruit fly densities properly for IPM purposes, a trial was carried out on an orange orchard (*Citrus sinensis*) variety Pera during a year. The substances tested were: 1- Corn protein hydrolisate at 0.3, 0.4 and 0.5%, 2-Sugarcane molasses at 10% and 3- Mixed of protein hydrolisate at 0.5% and molasses at 5%, conditioned in 2 types of traps: Serum Flask with 0.2 liters and Beverage Pet Plastic Bottle with 0.4 liters of attractive. The traps were installed at 1.5 meter high on alternated plants and rows, covering 140 square meters each one. The trial was carried out during a year with evaluations once a week and attractive replacement weekly. The Anastrepha sp. occurred on all the seasons and C. capitata mostly on winter and spring season. The later specie was more abundant. All the substances tested in its concentrations showed similar attractivity of both species.

[0674] CHEMICAL VARIATION AND ITS FUNCTIONAL SIGNIFICANCE IN GRASS-CUTTING ANT ALARM PHEROMONES

<u>W. O. H. Hughes</u>, P. E. Howse & D. Goulson, Biodiversity & Ecology Division, School of Biological Sciences, Bassett Crescent East, Univ. of Southampton, Southampton, SO16 7PX, UK

Leaf-cutting ants live in large colonies that are highly polymorphic and polyethic. They are adept at recognising non-nestmates and react to them, as well as to any other threats, with an aggressive alarm response. This reaction is governed by an alarm pheromone released from their mandibular glands. The compositions of the alarm pheromones of two grass-cutting species, Atta bisphaerica and A. capiguara, were examined, and caste and colony variations quantified. The pheromones of A. bisphaerica and A. capiguara were remarkably similar, and were composed of a complex mixture of volatiles in which 4-When the most abundant methyl-3-heptanone was one of the major components. compounds were tested in simple field bioassays, 4-methyl-3-heptanone was also found to be the compound that stimulated the greatest level of alarm behaviour in both species. The results support the view that alarm pheromones are rarely species specific. However, the ketone did not stimulate the same level of response as that resulting from a crushed ant head, suggesting that other compounds are also important. Small but consistent intraspecific differences were found between the worker castes and between individual colonies. The possible functional importance of intercolony variation is discussed. Key words: Atta; leaf-cutting ants; mandibular gland.

[0675] JUVENILE HORMONE – ITS EFFECT ON AGGREGATION BEHAVIOUR AND CENTRAL NERVOUS PROCESSING OF AGGREGATION PHEROMONES IN THE DESERT LOCUST

R. Ignell & S. Anton, Dept. of Ecology, Lund University, 22362 Lund, Sweden, E-mail Rickard.Ignell@ekol.lu.se

Juvenile hormone (JH) was shown to effect the central nervous processing of aggregation pheromones in the antennal lobe (AL) of the desert locust, Schistocerca gregaria resulting in changes in the aggregation behaviour. The aggregation behaviour of gregarious male and female desert locusts was monitored for individual control insects or insects subjected to either of three treatments; allatectomy, sham-operation and JH-injection. Two parameters were recorded to characterise aggregation behaviour (a) tendency to aggregate and (b) changes in behavioural activity, in a two-choice bioassay applying the main adult aggregation pheromone component phenylacetonitrile (PAN) in the treatment arena. Individual locusts were monitored at days 1, 8, 15, 22 and 29 after adult emergence in order to evaluate behavioural changes over time. Both male and female control and shamoperated locusts displayed behavioural changes coinciding with the naturally fluctuating JH-titre. Locusts generally displayed an increase in aggregation tendency and in behavioural activity up to days 8 and 15, which coincided with a low titre of JH. At days 15, 22 and 29, coinciding with a high JH titre, locusts displayed an initial (days 15 and 22) increase in behavioural activity and a tendency to avoid the treatment area followed by a low behavioural activity and no apparent attraction or repellency (at day 29). Locusts that were deprived of (allatectomised) or injected with JH either displayed a high behavioural activity and a high tendency to aggregate or did not show any specific behavioural response respectively. Intracellular recordings from projection neurons (PNs) in the antennal lobe of 8 and 29 days old control, allatectomised and JH-injected locusts revealed differences in the central olfactory processing; low JH-level (young and allatectomised) locusts displayed a fully functional olfactory system whereas high JH-level locusts displayed impairments in the olfactory system. In order to exclude the possibility of a diminished sensory input to the AL, electroantennograms (EAG) were performed. No significant differences in EAG amplitude between the three groups were observed. We conclude that the observed changes in aggregation behaviour may be regulated through a direct or an indirect effect of JH on the central nervous processing. We postulate that the observed behavioural indifference to PAN in high JH-level locusts arise due to a significant changes in the central nervous processing of aggregation pheromone components.

Index terms: Schistocerca gregaria, aggregation pheromone, electrophysiology

[0676] AREAWIDE MAPPING OF MAJOR PESTS ABUNDANCE WITH THE SEX PHEROMONE TRAPS AND MASS-TRAPPING IN HOT SPOTS ON VEGETABLES IN THE FORMER SOVIET UNION

<u>A. L. B'ichev</u>¹, Central Institute for Agrochemical Services, Moscow, former Soviet Union; ¹Present address: Inst. of Sustainable Irrigated Agriculture, P.O.Box 1, Tatura, Victoria 3616, Australia.

Integrated Pest Management (IPM) practices have been used for many years to control agricultural pests in the former Soviet Union. Areawide IPM has been applied not only in orchards as well-known, but also in vegetable crops. This abstract describes areawide monitoring, mapping and mass-trapping of major vegetable pests in 220 hectares (ha) of the Issyk-Kuhl Lake region of Kirghizia and in 110 ha of the Crimea region of Ukraine during 1987-1990. The pheromone traps "Attracon AA" with sticky base "Pestifix" (Flora Ltd., Tartu, Estonia) and sex pheromone dispensers for Noctuid moths Agrotis segetum Schiff., Agrotis exclamationis L., Amathes c-nigrum L., Autographa gamma L., Mamestra brassicae L., Scotogramma trifolii Hbn., were used for monitoring and control. The sex pheromone traps were distributed in the following way: 1 trap per 3-5 ha for each species for monitoring of initial pest population, I trap per ha for detailed mapping and identification of hot spots and 4 traps per ha for mass-trapping in hot spots. A daily average of 0.8 A. segetum, 1.7 A. exclamationis, 0.6 Am. c-nigrum, 0.8 S. trifolii per trap were recorded during mapping (880 traps in 220 ha) of the tomato fields in Issyk-Kuhl Lake. These levels of infestation were below the recommended economic threshold and regular insecticide applications were postponed. A daily average of 4.8 A. segetum, 6.2 A. exclamationis, 2.6 Au. gamma, 6.4 M. brassicae per trap were recorded during mapping (440 traps in 110 ha) of the tomato and cabbage fields in Crimea. These levels were above the recommended economic threshold and hot spots of each species were identified. Masstrapping in the identified hot spots with the use of 4 traps per ha for each pest resulted in the reduction of the infestation level and helped to avoid insecticide applications. The detailed mapping of species distribution and movement with pheromone traps indicated that such cutworms as A. segetum and A. exclamationis mostly concentrated on the edges of the vegetable fields, but armyworms M. brassicae, S. trifolii and Au. gamma distributed randomly and concentrated in hot spots throughout the field. The areawide application of mapping and mass-trapping for control of vegetable pests and reduction of regular insecticide application during 4 consecutive seasons will be discussed.

Index terms: areawide IPM, Noctuidae, sex pheromone trap, mapping, mass-trapping.

[0677] OLFACTORY RESPONSES BY MONOCHAMUS CLAMATOR, MONOCHAMUS SCUTELLATUS AND MONOCHAMUS OBTUSUS (COLEOPTERA: CERAMBYCIDAE) TO BARK BEETLE PHEROMONES

J. D. Allison¹, R. L. McIntosh² & J. H. Borden¹, ¹Simon Fraser Univ., Dept. of Biological Sciences, 8888 Univ. Drive, Burnaby BC, Canada, V5A 1S6; ² Saskatchewan Environment and Resource Management, Forest Ecosystems Branch, Box 3003 McIntosh Mall, Prince Albert, SK, Canada, S6V 6G1.

In the process of host selection, foraging woodboring beetles should exploit all information available to them including olfactory cues. Kairomonal responses by bark beetle predators to bark beetle pheromones are well documented, but only two examples occur in the literature of cerambycid beetles, *M. titillator* and *M. clamator*, responding to sympatric bark beetle pheromones. It appears that these species may have expanded their resource base through the development of a kairomonal response. We have demonstrated that multiple-funnel traps baited with a blend of bark beetle pheromones (ipsenol, ipsdienol, MCH and Frontalin) captured significant numbers of *M. clamator*, *M. scutellatus* and *M. obtusus*. Response to these bark beetle pheromones occurred whether or not they were offered with the host kairomones ethanol and α -pinene. Response by cerambycid beetles to the pheromones of sympatric bark beetles would be adaptive for two reasons: 1) the pheromones would indicate suitable host material; and 2) heterospecific cannibalism on bark beetle larvae may positively influence brood development. Index terms: kairomone, chemical ecology, host selection

[0678] CHEMICAL DEFENSE IN THE PLANT BUG LOPIDEA ROBINIAE

J. K Staples¹, R. J. Bartelt², & D. W. Whitman⁴, 4120 Biological Sciences Illinois State Univ. Normal, Illinois 61790, USA, E-mail jstapl@ilstu.edu; dwwhitm@ilstu.edu; ²USDA, ARS National Center for Agricultural Utilization Research, Bioactive Agents Research Unit, Peoria, IL 61604, USA, E-mail bartelrj@mail.ncaur.usda.gov.

Secretions from the metathoracic glands (MTG) of the black locust bug, Lopidea robiniae (Heteroptera: Miridae) contained six major compounds including: (E)-2-hexenal, (E)-2-hexenal, (E)-2-octenol (E)-2-Heptenal, and (?)-3-Octenol. Males and females did not differ significantly in the relative compositions of identified compounds. In feeding trials, six bird species demonstrated feeding aversions towards L. robiniae, implying that black locust bugs are chemically defended. Bugs discharged the liquid contents of their MTG's when attacked, thereby producing a strong and distinct odor. Some birds immediately ejected bugs out of their mouth after biting them, suggesting that the MTG secretion was a deterrent.

Index terms: Heteroptera, Miridae, allomone

[0679] USE OF MATING DISRUPTION IN COTTON IN NORTH AMERICA

J. W. Jenkins, Pacific Biocontrol Corporation, 620 E. Bird Lane, Litchfield Park, AZ, 85340, USA, E-mail jenkins@doitnow.com.

The pink bollworm, *Pectinophora gossypiella*, is one of the most serious pests of cotton worldwide causing losses in both yield and quality. Control with conventional insecticides is difficult because the pest is well protected within cotton squares and bolls. Furthermore insecticide costs are high and applications of broad-spectrum materials have contributed to outbreaks of secondary pests. Mating disruption has provided a viable alternative for pink bollworm control. Development of mating disruption for the pink bollworm began 25 years ago and the first Environmental Protection Agency registration of a pheromone formulation for mating disruption was issued for the pink bollworm in 1978. Since that time many formulations have been developed and commercialized. These materials represent various use methods and modes-of-action. The effectiveness of these formulations has been demonstrated in several areawide programs. These programs integrate pest management techniques conducive to mating disruption and avoid some of the factors detrimental to the technique.

Index terms: pink bollworm, Pectinophora gossypiella, mating disruption, pheromone, gossyplure

[680] OLFACTORY RESPONSES TO ISOAMYL ACETATE AND ADULTS OF THE LARGE MILKWEED BUGS (ONCOPELTUS FASCIATUS, HETEROPTERA:LYGAEIDAE) IN MALE AND FEMALE ANTENNAE OF THE SAME SPECIES

T. Jocys¹, O. Giannotti¹, A.Shpitz² & D. Fell¹, ¹.Instituto Biológico. Av. Conselheiro Rodrigues Alves, 1252. Vila Mariana. 04014-002. São Paulo, SP. Brasil. E-mail jocys@biologico.br; ². Consultant.

The interspecific communication among insects, with the exception of sexual attraction, has not been intensely investigated. Several authors identified pheromone presence with different functions of the *O*_i*fasciatus* Dallas. In the present paper the olfactory response of milkweed bug male and female antennae to odour source from live male and female adults, instead of insect extracts or dissected odour glands is investigated. We observed that recently emerged male adults, ten or more days old, as an odour source are capable of male and female antennae stimulation; while females, under the same conditions, did not produce any stimulation effect. The antennae stimulation response was measured by electroantennogram. The response to control (air) and female odour was in the order of 26.0 to 116.9 microvolts while the male odour response was 352.0 to 389.1 microvolts. As a standard a chemical stimulant: isoamyl acetate was used, resulting in a 413.9 to 463.4 microvolts response.

Index terms: Oncopeltus fasciatus, pheromone, electroantennogram.

[0681] PHEROMONE-BASED MANAGEMENT PROGRAM FOR SIMULTANEOUS CONTROL OF CODLING MOTH AND LEAFROLLERS IN BRITISH COLUMBIA'S COMMERCIAL ORGANIC APPLE PRODUCTION SYSTEM

<u>G.J.R. Judd</u>, Agriculture and Agri-Food Canada, Pacific Agri-Food Research Centre, 4200 Hwy 97S, Summerland, British Columbia, CANADA V0H 1Z0. E-mail juddg@em.agr.ca

A three-year study has demonstrated the utility of Isomate-CM/LR as an important management tool in simultaneously controlling codling moth, Cydia pomonella and four leafroller species (Lepidoptera: Tortricidae), Choristoneura rosaceana, Pandemis limitata, Archips argyrospilus and A. rosanus by mating disruption in an organic apple production system. Trapping with synthetic pheromone baits, mating of clipped-wing females in mating tables, and damage assessments at harvest, respectively, demonstrated that it is possible to significantly disrupt pheromone communication (89 - 100%) and mating (70 -100%) in each of these species and maintain overall crop damage below economic levels (2%) compared with conventionally-treated and untreated orchards, by releasing an incomplete mixture of these species individual pheromone components from the Shin-etsu rope-type dispensers applied at a rate of 500 dispensers / ha. To achieve these results organic orchards were treated once with Dipel[®] Bacillus thuringiensis in year 1 of the study to reduce initial populations of leafrollers to manageable levels. Over the three years trap catches and damage from leafrollers decreased in four of the five orchards treated with pheromone, but in one orchard catches and damage from leafrollers increased as a result of moth immigration into the test orchard from an adjacent organic cherry orchard. Levels of mating disruption among leafrollers was apparently density dependent and damage from leafrollers at harvest was positively correlated with seasonal total leafroller catches in pheromone traps placed at a density of 1 / ha. Catches of codling moth in synthetic pheromone traps deployed at a density of 1 / ha and baited with 10 mg of codlemone (E,E-8,10-dodecadien-1-ol) declined from a mean of 0.7 moths / trap / orchard in 1997 to 0 in 1999. Mean numbers of overwintering codling moth larvae caught in cardboard tree trunk bands declined from a mean of 4.7 larvae / ha / orchard in 1997 to 0 in 1999. Codling moth damage was undetectable in any of the orchards in any year of this study. This study has shown it is biologically and economically feasible to grow organic pome fruits in British Columbia by overlaying a pheromone-based management system for control of leafrollers and codling moth on top of the codling moth sterile insect release program that is ongoing in this tree-fruit production area.

Index terms: Tortricidae, Cydia pomonella, Choristoneura rosuccana, Pandemis limitata, Archips argyrospilus, A. rosanus, pheromones, mating disruption, organic apple production

[0682] CONTROL OF SCAPANES AUSTRALIS A MAJOR PEST OF COCONUT USING SEMIOCHEMICALS

T.K. Kakul¹, S. Laup¹, L. Ollivier^{1,2}, J-P. Morin² & D. Rochat³, ¹Dept. of Entomology, Cocoa and Coconut Research Institute, P. O. Box 1846, Rabaul, Papua New Guinea, ²CIRAD-CP, BP 5035 Montpellier, France; ³INRA, Unité de Phytopharmacie et Médiateurs Chimiques 78026 Versailles Cedex, France. Research with funding from the EU under INCO project No. RB-IC18CT970199

Scapanes australis Bsdy, (Colcoptera, Scarabaeidae) native to the Melanesian region is a major economic pest of coconuts in Papua New Guinea. Adults attack and kill young palms up to 2 years old and feeding sites left on older palms (2 to 7 years) are invaded by the secondary pest Black Palm Weevil, Rhynchophorus bilineatus (Coleoptera, Curculionidae), the larvae of which can kill the coconuts. S. australis is a very difficult pest to control because of its long life cycle (356 days) and can also attack palms for up to 7 years. There has been no effective method of controlling the pest in the past because of the poor knowledge of the insect's biology and ecology. New information on the biology and chemical ecology has recently enabled a mass trapping of the beetle. Various field experiments were carried out to evidence the existence of a long range active pheromone. Field collection of Scapanes during day and night observations had indicated that male Scapanes perform a calling behaviour and emit an aggregation pheromone. Traps were developed initially using cage with calling male as bait. After a year the pheromone was identified and synthetic pheromone became available and was used as attractant. Trapping S. australis first with calling males and latter with synthetic pheromone caused a decline of the population of Scapanes over a period of two years. Whereas trapped females cause the next generation to decline, removed males are prevented from attacking coconuts. Continuous trapping lowers the population of Scapanes overtime hence reduces the threat to coconuts to be attacked by the beetle. Preliminary data had indicated a reduction in the number of coconuts being damaged.

Index terms: Scapanes, communication Rhynchophorus, coconut, pheromone, trapping, live male.

[0683] EFFECT OF WHEAT INFESTED BY LARVAE OF THE HESSIAN FLY, MAYETIOLA DESTRUCTOR, ON OVIPOSITION BEHAVIOR OF THE HESSIAN FLY FEMALES

II. Kanno & M. Harris, Horticulture and Food Research Institute of New Zealand, Mt Albert Research Center, Pribate Bag 92169, Auckland New Zealand

The Hessian fly (HF) females lay less eggs on wheat leaves infested by HF larvae than uninfested ones. The wheat plant infested by HF larvae indicates particular symptoms,

th as stunting and color changing to more dark. It was confirmed that the both plant areght and leaf color are very important physical factors affecting the oviposition behavior of HF females. The chemical factors in the infested and uninfested wheat plants were also examined. The number of eggs laid on the paper models treated extracts of infested wheat leaves was significantly lower than that on the models treated extracts of infested wheat extracts. Recently, the two compounds, 1-octacosanal and 6-methoxy-2-benzoxazolinone (MBOA) , were identified from wheat leaves as the oviposition stimulants for HF females (Morris et. al., in press). Therefore, the chemical composition including these two stimulants in the both infested and uninfested wheat extracts are now analyzing to elucidate the differences on leaf surface chemicals between infested and uninfested wheat. The effect of volatile chemicals emitted by infested and uninfested wheat are also investigating using Y-tube olfactometer. The results of these analyzing and experiment will be discussed in a poster. [0685] AMINO ACID SECRETION IN DIGESTIVE JUICE: COUNTERADAPTATION OF HERBIVOROUS INSECTS AGAINST PROTEINDENATURING ACTIVITY OF PLANT IRIDOID GLYCOSIDES ACTIVATED BY PLANT \Box -GLUCOSIDASE

K. Konno, C. Hirayama, H. Yasui, S. Okada, F. Yukuhiro, H. Shinbo & M. Nakamura, Natl. Inst. of Sericultural and Entomological Sci., 1-2 Ohwashi, Tsukuba, Ibaraki 305-8634, Japan, E-mail: konno@nises.affrc.go.jp.

We found the existence of high concentrations (0.4-0.8 %) of free glycine in the digestive juice of several Lepidoptera and Hymenoptera larvae, particularly in the digestive juice of the species which feed on the privet tree, Ligustrum obtusifolium (Oleaceae) [1,2]. In one of such species, Brahmaea wallichii (Brahmaeidae), glycine was secreted in midgut lumen in an active and selective manner. Leaves of the privet tree Ligustrum obtusifolium contains oleuropein (3% per wet weight), a phenolic iridoid, probably as a defense chemical [3,4]. When the leaf cells are damaged, enzymes in organelles, □-glucosidase and polyphenol oxidase, activates oleuropein into a very strong protein-denaturant[4]. When, in particular, \Box -glucosidase deglucosidate the iridoid-glycoside moiety of oleuropein, this moiety is converted into glutaraldehyde-like structure and crosslinks protein molecules to form high molecular weight complexes [3,4] and makes protein nonnutritive by decreasing the lysine content[1,3,4]. Several other iridoid glycosides such as aucubin and geniposide are similarly activated by D-glucosidase. The fact that 1% glycinc could completely inhibit these activities [1,3] suggested that free glycine is secreted in the digestive juice as an adaptation mechanism to chemical defense of host plants. Our data indicate that amino residue in free glycine is responsible for the inhibition. We also found that, in some Lepidoptera species, high concentrations of other amino acids such as GABA and I-alanine exist in the digestive juice, which seem to play the same role as glycine does. Our results would be a good and clear example of coevolution of plants and herbivores mediated by chemicals.

Index terms: Ligustrum obtusifolium, Brahmaea wallichii, glycine, oleuropein, plantherbivore interactions

[0684] REPELLENT PROPERTIES OF CASSIA SOPHERA (CAESALPINIACEAE) AGAINST THE RICE WEEVIL SITOPHILUS ORYZAE (COLEOPTERA; CURCULIONIDAE); POTENTIAL AS A STORAGE PROTECTANT

C. Kestenholz & P.C. Stevenson, Natural Resources Institute, Univ. of Greenwich, Central Ave., Chatham Maritime, Kent ME4 4TB, United Kingdom.

Rice is one of the major staple crops world-wide and is gaining renewed importance in northern Ghana where it is traditionally grown by women. In particular, rice represents an additional source of income and thus improves the significance of women in their social groups. Post-harvest losses in small scale farming systems represent a serious problem for farmers and their families particularly since the introduction of exotic or high yielding rice varieties, which tend to be more susceptible to insect damage than the traditional but lower yielding varieties. The use of synthetic pesticides in food stores is still the major tool available to many farmers for managing insect damage but this is expensive for resource poor farmers and potentially dangerous. Moreover, inappropriate use has lead to the development of insecticide resistance. Small-scale farmers in the Northern Region of Ghana currently use different endemic plants as storage protectants. Cassia sophera is a widespread species, which occurs primarily on waste ground and is traditionally mixed to stored grain in form of powdered leaves. Preliminary investigations on this plant species confirmed its toxicity and F1 reduction against S. zeamais, Callosobruchus maculatus and Rhyzopertha dominica and consequently this plant has been selected for further investigation. In this study, S. oryzae was chosen because it is one of the main pests of tropical stored products not only in Ghana, but world-wide and therefore its control will be of great economic impact. Adults of S. oryzae were given the choice to feed on rice treated with the crude methanol extract of C. sophera at 1000 ppm or control rice (untreated) and were significantly repelled from the treated rice (p<0.001). The number of the F1 generation emerging on treated rice was also less than on untreated rice. Phytochemical analysis and bioassay of fractions of C. sophera, showed that the repellent activity was present in non-polar fractions of either 100% methanol, 100% acetone or 75/25 hexane/ethyl-acetate (p<0.005). The active fractions are currently being fractionated further and tested for their activity against adult S. oryzae and C. maculatus. The results of this study were reconfirmed by recent field trials with C. sophera in northern-Ghana, showing a reduced level of infestation in commodities treated with the plant powder. This study is particularly important since S. oryzae is tolerant of many control agents and pesticides and therefore difficult to control. Moreover chemicals with repellent properties to this species have the potential to be toxic or repellent to other stored products pests.

[0686] USE OF MICROENCAPSULATED PHEROMONE OF THE ORIENTAL FRUIT MOTH FOR MATING DISRUPTION IN BRAZIL

<u>A. Kovaleski</u> & J.F.S. Protas, Embrapa Uva e Vinho, Estação Experimental de Vacaria, CP 177, CEP 95.200-000, Vacaria, RS, adalecio@cnpuv.embrapa.br, Brazil.

The efficiency of a microencapsulated formulation of the sex pheromone (MEP) of Grapholita molesta as a mating disruptant under the conditions of Brazilian apple orchards was evaluated. The product was recently developed by 3M. Experiments were conducted in two commercial orchards in Fraiburgo, SC, each one containing blocks of 'Gala' and 'Fuji'. 10-ha blocks were used in each orchard, being half of the area treated with the MEP. The remaining 5 ha were treated with insecticides, according to adult population density. Sprays of the MEP (37.5 g.ha-1) were initiated during the period of emergence of the spring generation of the pest and then applied at 25-days intervals (range 17-42 days). Population was monitored in all areas, using three delta traps and synthetic sexual pheromone. Damage was evaluated five months after set up of the experiment, being 50 fruits and 50 shots checked from each of 20 randomly chosen trees. Adult population density was higher in areas treated with insecticides, surpassing 40 males.trap-1.week-1 in the beginning of the experiment (spring) and in one of the areas of the cultivar Fuji in January. Total damage was unexpressive in shots in all areas. Damage to fruits was higher in 'Fuji', as a result of higher adult population density. Results show that the damage in areas treated with the MEP occurs at acceptable levels, with the advantage of low or even no (Orchard 2, both cultivars) insecticide application. Sprays of the MEP at shorter intervals would probably lead to better control of the pest. Index terms: Apple pest, Grapholita molesta, IPM, Lepidoptera, Tortricidae

[0687] THE EFFECTS OF HOST PLANT ODOURS ON THE CALLING BEHAVIOUR, EGG MATURATION AND MATING SUCCESS OF THE COTTON BOLLWORM, *HELICOVERPA ARMIGERA* (LEPIDOPTERA: NOCTUIDAE)

O.L. Kvedaras¹, P.C. Gregg¹, A.P. Del Socorro¹, D. Alter¹ & C. Moore², ¹School of Rural Science and Nat. Res., Univ. of New England, Armidale, New South Wales, Australia 2351, E-mail okvedara@metz.une.edu.au; ² Queensland Dept. of Primary Industries, Yeerongpilly, Queensland, Australia 4105.

The influence of host plant odours on the calling behaviour and egg maturation of the female cotton bollworm, Helicoverpa armigera was investigated. Host plants included flowering cotton, maize and pigeon pea. Females were held in cages for a period of 6 days from the time of emergence and exposed to either no host (control) or a host plant. The time calling was initiated, time spent calling and the mean number of calling bouts were recorded. A selection of females that initiated calling for the first time 1-6 days after emergence were sacrificed to determine the stage of ovarian development at the onset of calling. In a separate experiment the sex pheromone released by individual calling females of H. armigera was trapped within the stem of Pasteur pipettes. Individual females were exposed to host plant odours and one female was exposed only to filtered air as a control. Host plants included, cotton, pidgeon pea and sunflower. The time spent calling was recorded and the amount of pheromone trapped quantified. Pheromone collection and behavioural observation commenced halfway into scotophase which is generally when female H. armigera start calling. Trapped pheromone was analysed by Gas Chromatography-Mass Spectrometry. Field studies were conducted in the Darling Downs, Queensland, Australia, during the 1996/97 and 1997/98 cotton growing seasons. Mating tables were used to determine the mating success of *H. armigera*. Moth abundance was assessed using light and pheromone traps. A series of comparisons of three or four crops were used. They included: mature corn; immature, flowering and mature cotton and soybeans; immature and flowering sunflower and sorghum. Fallow land was also included. Laboratory reared virgin females with their wings clipped were placed in mating tables in various crops where they remained until collection and dissection the following morning to determine whether they had been mated. These studies indicate that host plants did not significantly influence the chance of being mated, despite substantial variation in moth abundance between the crops.

Index terms: Helicoverpa annigera, host plants, mating tables, ovarian development, sex pheromone

[0688] JAVA GRASS (CYMBOPOGON WINTWRIANUS) ESSENTIAL OIL EFFECTS ON SPODOPTERA FRUGIPERDA BIOLOGY AND BEHAVIOR

<u>A.M. Labinas</u>¹ & W. B. Crocomo², ¹Dept. of Ciências Agrárias - Univ. of Taubaté - 432 Quatro de março St. Taubaté - SP - Brazil, 12020-270, E-mail <adianal@tecsat.com.br>; ² Dept. of Vegetable Production - FCA - UNESP - P. O. Box 237, Botucatu - SP - Brazil, 18603-970, E-mail <wcrocomo@fca.unesp.br >

This research, developed at the Entomology Laboratory of Vegetable Production Department, from FCA -UNESP (Botucatu, SP), in temperatures ranging from 23 to 27°C, 70% of relative humidity and 14 hour of photophase, was held to evaluated the effect of Java Grass (Cymbopogon winterianus) essential oil, in 0,001, 0,005, 0,01, 0,05, 0,1, 0,5 and 1,0% of concentration in Spodoptera frugiperda biology and behavior . The laboratory tests followed randomized experimental design, with 8 treatments including the check treatment. These dosage were added to the artificial diets to observe the larval and pupal periods, larval and pupal viability, 24 hours pupal weight, male and female adults longevity and the effects on laid eggs. The obtained data reveled the essential oil alters all S. frugiperda biology phases, without showing correspondence between dosage and effects. Corn leaves were deepen in solution containing those concentrations and were offered to recent hatched larvae, showing its repellency effect. Eggs were also deepen in those same solution to verify the essential oil effects on their viability, conforming its ovicide action. To estimate its possible insecticide use, a field test was conducted in a corn crop, following a randomized experimental design with the same treatments and 4 replications, permitted to conclude that the highest dosage (1,0 e 0,5%) showed the best control efficiency causing , however, phytotoxicity, in newer leaves

[0689] SCREENING GENOTYPES OF SESAME (SESAMUM INDICUM) FOR RESISTANCE TO WHITEFLY (BEMISIA TABACI)

H.E. Laurentin¹ & <u>C.J. Pereira</u>², ¹² Departamento de Ciencias Biológicas, Universidad Centroccidental Lisandro Alvarado, Apartado 400, Barquisimeto, Venezuela. helauren@yahoo.com entm96@hotmail.com

To evaluate incidence of whitefly in the genotypes 37-1, 37-3, 19x10, 43x32, UCV-3 (resulting from plant breeding for high yield before whitefly) and the cultivar Fonucla, field experiments were established in Turen, Portuguesa state, Venezuela, in 1998 and 1999, using ramdomized complete block design with four replications. Whitefly natural infestations appeared five weeks after establishment of experiments. Afterward, six consecutive weekly samples were taken each year from each plot. Samples consisted of five leaves from each third of the plant: apical, medium and basal. Leaf area, number of eggs(E), number of nymphs(N), E/cm² and N/cm² were estimated on each leaf. Log transformed data were analyzed as split plots in time. A combined analysis for years was conducted using the model AMMI (additive main effects and multiplicative interactions) for interactions. A genotype by week significant interaction (P<0.01) was detected for all variables measured (except leaf area) in both years. However, a trend to form two distinguishable groups was observed, with 37-1 and 43x32 genotypes in one group showing the lowest incidence and the rest in another group with the highest incidence. AMMI model confirms the potential value for resistance of these two genotypes, indicating 43x32 and 37-1 with both the lowest values and highest stability. Key words: *Sesanum indictum - Bemisia tabaci -* resistance – plant breeding

[0690] BIOCHEMICAL ADAPTATION OF BIRD CHERRY-OAT APHID TO PLANT PHENOLICS

<u>B. Leszczynski</u>¹, **B. Jozwiak**¹, **I. Lukasik**¹, **A. Urbanska**¹ & A.F. Dixon², ¹Dept of Biochemistry, Univ. of Podlasie, Prusa 12, PL-08110 Siedlee, Poland, E-mail leszczb@ap.siedlee.pl, ²School of Biol. Sci., Univ. of East Anglia, NR4 7IJ, Norwich, UK

Bird cherry-oat aphid, *Rhopalosiphum padi* L. belongs to host alternating species. It alternates between woody plants (*Prunus padus* L.) and herbaceous Gramineae. There are two migrations in the aphid life cycle. The spring migration, from primary (winter) host onto secondary (summer) hosts takes place in the middle of April. The autumn migration, from summer host onto bird cherry occurs in late September. Phenology of this phenomenon is quite well known, however chemistry of the host-plant alternation by the bird cherry-oat aphid was not extensively studied. The present paper reports on role of the plant phenolics in the aphid host plant interactions. While the aphid population developed on *P. padus*, an increase in content of phenolics in the bird cherry leaves was observed. During the spring migration, there was about 4-fold higher concentration of the phenolic compounds in the primary host than in the secondary ones. In addition, during the spring migration an increase in activity of the aphid enzymes involved in the phenolics metabolism was found. The obtained results suggest that content of the plant phenolics in factor that induces the spring migration of the bird cherry-oat aphid. Index terms: *Rhopalosiphum padi*, phenolics, host alternation

[0691] MONITORING MASSON PINE CATERPILLAR (DENDROLIMUS PUNCTATUS) WITH SYNTHETIC SEX PHEROMONE IN CHINA

⁴ <u>D. M. Li</u>, A. B. Zhang, The State Key Lab of Integrated Management of Insect Pests & Rodents, Institute of zoology, Chinese Academy of Sciences, Box 70, E-mail Lidm@panda.ioz.ac.cn, Beijing, 100080, P. R. China.

The distribution of the masson pine caterpillar (Lepidoptera: Lasiocamidae)lies in South China and SouthEast China. When the masson pine caterpillar breakout, needle leaves of masson pine were caten out. The traps baited with new resin pheromone lures, which can release sex pheromone at least 30d, were used to monitor masson pine caterpillar in this study, and field investigations were conducted at the same time in order to study the relationship between the number of male adult moths trapped and the trend of emergence of the larvae in the field. We found the number of male adult moths trapped was correlated with the number of larvae in the field. The average number of male adult moths trapped per town had the same trend as the percentage of pine trees that had larvae and the average insect population (the number of larvae per tree). In the present study, monitoring a field population with synthetic sex pheromone indicates that it is possible to predict the population dynamics in Qianshan, Anhui, China, especially in low-density population. Index terms: Dendrolinius punctatus (Walker) Monitoring Sex pheromone

[0693] MANAGING TEMPERATE FRUIT PESTS IN BRAZIL USING SEMIOCHEMICALS

A. Mafra-Neto⁶, A. Kovaleski¹, M. Botton¹, A. Eiras², E. Vilela³, R. Sugayama⁴ & L. Mafra⁵, ¹EMBRAPA/CNPUV, CP 177, CEP 95200-000, Vacaria, RS; ²Universidade Federal de Minas Gerais, Belo Horizonte, MG; ³Universidade Federal de Viçosa, Viçosa, MG; ⁴Universidade de São Paulo, SP; ⁵ISCA Tecnologias Ltda, Ijuí, RS, BRAZIL, ⁶ISCA Technologies, Inc., Riverside, CA USA.

There are four major pests identified in the apple growing region of the south of Brazil, which is comprised of 28,000 ha. Anastrepha fraterculus (Tephritidae), Bonagota cranaodes, and Grapholita molesta (both Tortricidae) are well known in commercial orchards. Cydia pomonella (Tortricidae) has never been detected in commercial orchards, but is present in urban areas. Semiochemicals have been used to manage these pest populations with good success. The best tool to monitor populations of *A. fraterculus* under our conditions are McPhail traps lured with 25% grape juice or turula yeast. Research on host fruit and food attractants of A. fraterculus is underway to improve this monitoring system. The sex pheromone of B. cranaodes was identified, synthesized, and formulated for use in monitoring and control techniques. Control of B. cranaodes was achieved using ISCACIDA formulation, an attract-and-kill technique. A single application of ISCACIDA-Bonagota at a density of 200 units/ha promotes monitoring trap shutdown for over two months and results in significant reduction of fruit damage at harvest. Two applications of ISCACIDA-Grapholita promoted monitoring trap shutdown and effective suppression of G. molesta in pome and stone fruit orchards throughout the fruit cycle. A single application of ISCACIDA-Cydia in urban host plants at a density of 45 units/ha resulted in monitoring trap shutdown that lasted for over 100 days. Monitoring pheromone traps have been widely accepted by apple growers and trap captures are used for management decision making. As pheromone tools to monitor the main apple pests became available, the frequency of cover applications of insecticide was reduced from 14 to 24 in 1996/97 to 4 to10 in 1998/99. As the number of cover sprays is reduced, opportunist pests currently kept under control by the insecticides may achieve the status of primary pests. We believe that the adoption of efficient monitoring systems coupled with the above mentioned environmentally sound pest managementtechniques will lead to an even more efficient and judicious use of insecticides in the apple growing regions of Brazil.

Index terms: Anastrepha fraterculus, Bonagota cranaodes, Grapholita molesta Cydia pomonella, managing

[0692] TIME-DEPENDENT VARIATIONS IN ESTERASE 9B FREQUENCY AND MALATHION-RESISTANCE OF THE DIAMONDBACK MOTH (*PLUTELLA XYLOSTELLA*) IN TAIWAN

C. J. W. Maa, Institute of Zoology, Academia Sinica, Taipei, Taiwan, 115, ROC.

EST 9b was recognized as an esterase allozyme associated with malathion resistance in the diamondback moth (DBM), Plutella xylostella L.. In 1987, Geou-Fang DBM population was significantly (P < 0.05) differentiated from other 14 local DBM populations in Taiwan based on EST 9b frequency. Meanwhile, Geou-Fang DBM was the most susceptible population found in Taiwan. Two years later Geou-Fang DBM was no longer being differentiated from other DBM populations based on the EST 9b frequency. In fact, EST 9b frequency of Geou-Fang DBM increased from 13% to 35% within the two years of 1987~1989; and no insecticide was applied in Geou-Fang area during that time period. A statistically significant (P < 0.02) linear regression was existed between the EST 9b frequency and malathion resistance of the 14 DBM populations, and this correlation lasted till 1991. Although the two regression lines of 1989 and 1991, respectively, showed different slopes, they shared the same interception point to the horizontal axis of EST 9b frequency. This phenomenon implicated that EST 9b frequency of Taiwan DBM might vary from year to year, and accordingly, resistance of DBM might also fluctuate from time to time. So the EST 9b frequency could be suggested as an indicator protein for monitoring malathion resistance in the DBM. However, by 1997 the regression line between EST 9b frequency and resistance of the DBM was neither statistically significant nor sharing the same interception point with that of 1991 and 1989. This might implicated some variations between the EST 9b frequency and the resistant mechanism from 1989 to 1997. In view of these consecutive accounts of the variation in EST 9b frequency and malathion resistance through the passed ten years, significance of the above-mentioned events was discussed. The adaptive phenomenon of the DBM to the changing circumstance in Taiwan was also discussed.

Index terms: Plutella xylostella L., esterase 9b, malathion-resistance, variation, adaptation

[0694] SEMIOCHEMICALS INDUCING DEFENSIVE BEHAVIOR OF APIS CERANA JAPONICA AGAINST VESPA MANDARINA

<u>S. Matsuyama¹</u>, T. Suzuki¹ & H. Sasagawa², ¹Inst. of Applied Biochem., Univ. of Tsukuba, 1-1-1, Ten-nou dai, Tsukuba, Ibaraki, 305-8572, JAPAN, E-mail honeybee@sakura.cc.tsukuba.ac.jp; ²Natl. Inst. of Seric. & Entomological Sci. (NISES), 1-2 Oowashi, Tsukuba, Ibaraki, 305-8634, JAPAN.

The Japanese honey bee, Apis cerana japonica Rad. (Acj), is known to perform a unique thermal defense against hornets such as Vespa mandarina (Vm) and V. simillima xanthoptera. The other interesting defensive behaviors of Acj are 1) cessation of foraging and hiding inside the hive and 2) shriving off the forage-site marking pheromone deposited from sternite gland (van der Vecht gland) by the hornet with mandibles. this study, we tried to identify semiochemicals inducing these defensive behaviors of Acj by using GC/EAD and GC/MS. a) Volatiles from live Vm worker were introduced into Super Q column and washed with ether. GC/MS analyses showed that the volatiles were composed of more than 30 components including hydrocarbons, 2-alkanones, alcohols, and esters. b) By using Acj worker antenna as a sensing element, etheral washings from Super Q were subjected into GC/EAD. At least four compounds elicited reproducible response by Acj antenna. c) From GC/MS analyses, a peak eliciting strongest antennal response was suggested as heptadecene, which was further identified as (Z)-8-heptadecene by GC/MS analysis of DMDS adduct and by GC comparison of geometric isomers. d) Sternite gland extract contained long chain hydrocarbons and fatty acids in the low volatile region. Main component in the high volatile region was (Z)-8-heptadecene. e) (Z)-8heptadecene, heptadecane, dehydromevalonic lactone were identified in both volatiles Behavioral studies using natural and from live Vm workers and sternite gland extract. synthetic compounds against both Acj and Vm are conducted in order to determine which compound(s) is necessary to induce defensive behavior in Acj, and/or to elicit aggregation of Vm.

Index terms: aggregation pheromone, forage-site marking pheromone, sternite gland, kairomone, GC/EAD.

[0695] SEX AND CRIME IN A BEETLE: FEMALE CHOICE AND DEADLY MALE - MALE AGGRESSION IN MALACHIUS BIPUSTULATUS

T. Meiners¹ & E. Strohm², ¹Institut für Biologie, Freie Universität Berlin, Haderslebener Str. 9, D-12169 Berlin, Germany, e-mail meito@zedat.fu-berlin.de; ²Zoologie III, Biozentrum, Am Hubland, D-97074 Würzburg, Germany.

Sexual selection has given rise to the evolution of unique and bizarre structures and behavioural traits. Male beetles of the coleopteran family Malachiidae are endowed with remarkable chitinous structures that are associated with complex glands (= exciter organ). The elaboration and location of these organs vary considerably among the Malachiidae. We hypothesised that these exciter organs play a role during courtship and might provide females either with valuable substances and/or with a signal of male quality. In M. bipustulatus the exciter organ is located on the forehead. Its structure allows females to insert their mouthparts in a fashion that looks like the female would bite into the male's head. Field observation of a total of 123 courtship interactions of this species revealed that interactions lasted 31 ± 36 min (range: 1-160min, n = 92). During courtship the female repeatedly bit into the exciter organ. The mean duration of single bites was 25 ± 17 s (range: 2-26s, n = 25). The total duration of female contact with the male exciter organ was 28 ± 28 min (range: 1-100 min, n = 26). In some cases the occurrence of droplets at the exciter organ or female's mouthparts suggested that actually some substance was transferred from the male to the female. After each biting the female turned around and the male touched the female's abdomen tip with its mouthparts. In 85 out of 123 cases the female left without copulation; only 10 interactions resulted in a final copulation (mean duration: 26 ± 9s, range: 17-39s, n = 9). In 21 cases, other males aggressively interfered with courting pairs and seemingly tried to take-over the females. Six M. bipustulatus males were found in the field feeding on other males (preferably on the head). Even direct attacks and killing of paired and unpaired males was observed in four cases. This was surprising since malachiids are actually pollen feeders. Our observations suggest that males offer valuable secretions during courtship to the female. Males try to attain these secretions even by killing and feeding on congenders. Whether female choice is based on qualitative or quantitative aspects of the secretion is not yet known.

Index terms: Malachiidae, courtship feeding, female choice, male competition, cannibalism

[0696] THE ROLE OF INDUCED PLANT VOLATILES FOR EGG PARASITOIDS AND THEIR POTENTIAL FOR SEMIOCHEMICAL CONTROL

T. Meiners & M. Hilker, Institut für Biologie, Freie Universität Berlin, Haderslebener Str. 9, D-12169 Berlin, Germany, e-mail meito@zedat.fu-berlin.de

Parasitoids of herbivorous hosts face the problem that they have to utilize reliable and detectable cues during host location. It has been shown that larval parasitoids can solve this problem by orientating towards plant odors that are released after herbivore feeding damage. The role of induced plant volatiles for egg parasitoids is almost unknown. Its elucidation, however, may contribute to the enhancement of performance of egg parasitoids utilized as biological control agents. The egg parasitoid Oomyzus gallerucae (Hymenoptera, Eulophidae) attacks eggs of the elm leaf beetle Xanthogaleruca luteola (Coleoptera, Chrysomelidae), which is a serious defoliator of different elm species in Southern Europe, North America and Australia. O. gallerucae has been repeatedly introduced into the United States for biological control of the elm leaf beetle. In Southern France 30 -70 % of elm leaf beetle egg masses sampled on different locations and during different years were parasitized by O. gallerucae. These high discovery efficiencies of female egg parasitoids might be mediated by volatile synomones. Our olfactory studies on host location of O. gallerucae proved that these egg parasitoids are attracted to the odor of field elm (Ulmus minor) leaves that are carrying eggs of the elm leaf beetle. Oviposition of X. luteola induces a change of the volatile pattern emitted by the field elm leaves resulting in the attraction of the egg parasitoids. The plant's reaction to oviposition is systemic; the leaves without eggs adjacent to those with eggs also emit attractants. Females O. gallerucae also react to odor of elm leaves treated with jasmonic acid. Jasmonic acid is known as mediator of plant responses induced by feeding of herbivorous arthropods. Plants that are able to respond to oviposition of herbivores may defend themselves by emission of volatiles which "call" for egg parasitoids. This potential might be used to enhance the performance of egg parasitoids for semiochemical control of herbivores. Index terms: Oomyzus gallerucae, elm leaf beetle, egg parasitoid, synomone induction,

Index terms: *Oomyzus gallerucae*, elm leaf bectle, egg parasitoid, synomone induction, biological control

[0697] CHEMICAL SIGNALLING BETWEEN HOST PLANT AND EGG PARASITOID OF A GALERUCINE LEAF BEETLE

T. Meiners & M. Hilker, Institut für Biologie, Freie Universität Berlin, Haderslebener Str. 9, D-12163 Berlin, Germany, e-mail meito@zedat.fu-berlin.de

Eggs of the elm leaf beetle Xanthogaleruca (Pyrrhalta) luteola (Colcoptera, Chrysomelidae) experience heavy parasitization by the egg parasitoid *Oomyzus gullerucue* (Hymenoptera, Eulophidae) in the field. We investigated the tritrophic interactions between the elm leaf beetle, its host plant, the field elm (Ulmus minor = U. campestris = U. procera), and its egg parasitoid. We found that oviposition of X. luteola induces the elm leaves to release volatiles that attract the egg parasitoid (induced symonones). Studies on the mechanism of this synomone induction revealed that neither intact elm leaves nor leaves damaged by feeding beetles released attractive volatiles. But oviduct secretion of X. luteola which glues the eggs onto the leaves was proved to elicit the emission of the attractive synomones. The eggs are always glued onto a small epidermal wound, which is inflicted to the lower leaf surface by the female prior to oviposition. The oviduct secretion only functions as synomone elicitor when applied onto such a wound. Scratching a leaf by a scalpel to mimic the wound and application of oviduct secretion results into the release of synomones. Our studies on the specificity of the synomone induction show that the attractiveness of induced volatiles was specific both for the Ulmus species and the herbivore species depositing eggs. Further steps in the egg parasitoid's host location process are mediated by kairomones from host faeces and egg masses. These kairomones were also shown to be host specific, since O. gallerucae clearly discriminates between host and non-host (e.g. *Galerucella lineola*) cues during host finding and host recognition. The tritrophic system studied here is characterized by oligophagous and monophagous relationships on the second and the third trophic level. These intrinsic characteristics of the tritrophic system might have been a prerequisite for the development of such selective responses of a parasitoid towards specific infochemicals and of the specific indirect defense reaction of the plant to oviposition of the chrysomelid host.

[0698] MASS TRAPPING EXPERIENCE OF CERATITIS CAPITATA (DIPTERA: TEPHRITIDAE) WITH SYNTHETIC FEMALE FOOD ATTRACTANTS IN A CITRUS ORCHARD (MALLORCA, SPAIN)

M.A. Miranda, R. Alonso, C. Blasco & A. Alemany, Univ. of Balearie Islands. Cra. Valldemossa km 7,5, CP: 07017, Palma de Mallorca, Spain, E- mail: analem@clust.uib.es

Mass trapping of *Ceratilis capitata* females has been carried out in an isolated plot of orange trees in Mallorca. 125 traps baited with synthetic food attractants (putrescine, ammonium acetate and trimethylamine), and 10 traps baited with Trimedlure for male monitoring, were used. This experience was begun with the first adult emergences at the beginning of summer (June '99) and ended with the disappearance of the Mediterranean fruit fly population, which occurred with the arrival of the first cold spells in November. Catches were monitored on a fortnightly basis. The aim was to check whether, with this method, it was possible to control the pest until harvest-time - due in the second fortnight of August. Results showed an adequate control of the pest up until that time, since the oranges were harvested without signs of being attacked. However, the presence of several of the host species Ficus carica, brought about a subsequent notable increase in the catches, as a consequence of the high infestation produced when the figs ripened at the end of August. Whereas mass selective female trapping may be a control strategy which brings about the elimination of or at least a reduction in insecticide treatment, in this experience it can be seen that figs cause the pest to multiply. In Mallorca, this is a very important fact as these fruit trees are scattered all over the island, and the figs are not usually collected, thus making them a considerable egg-laying source for C. Capitata. No differences were found between synthetic food attractants and Trimedlure as far as the detection capacity for first emergences are concerned. We discuss the causes determining a change in the sex ratio of flies captured with synthetic food attractants, as well as with Trimedlure, throughout the experience

Index terms: Ceratitis capitata, mass trapping, synthetic attractants

[0699] LUFENURON EFFICIENCY EVALUATION TO CONTROL THE MITE ACERIA GUERRERONIS THAT CAUSES NECROSIS IN THE COCONUT PALM

J.O.T. Moreira¹ & M. R. Lavorenti², ¹ Dept. de Tecnol. e Ciências Sociais/Univ. do Est. da Bahia, C. Postal 171, CEP 48900-000 Juazeiro-BA-Brasil, E-mail: osmateles@bolc.com.br; ² Dept. Among the mites associated to the coconut crop, one of the most important ones is Aceria guerreronis, because of the damage that it causes in young plants and fruits producing necrosis by its feed activity. The chemical control associated to other methods like better crop management, natural biologic control, can be adopted to keep this specie in an acceptible population level. This work evaluated the Lufenuron (MATCH CE) efficiency to control *A. guerreronis* in irrigated green dwarf coconut crop, *Cocos nucifera*, and was done from August to October 1999 in two farms in Nilo Coelho Senator Irrigated Perimeter, San Francisco Valley, Petrolina – Pernambuco – Brazil. The results showed that MATCH CE, 80 ml/100 I water, was efficient to control the mite at the time that the flower begin to open and compared with the standard MARSHAL 200 SC 50 ml/100 I water.

Index terms: Eriophyidae, coconut, Aceria guerreronis, lufenuron

Nacional de Colombia, A.A 27586, Santafé de Bogotá, DC 1, Colombia. ³ Centro Nacional de Investigaciones de Café CENICAFE, Chinchiná A. A. 2427 Manizales, Caldas, Colombia.

Tagetes zypaquirensis is a medicinal, perennial shrub, which occurs through temperate areas from the Colombian Andean region(1,2) From other Tagetes species, α -therthienyl derivatives with insecticide properties have been isolated, and today those compounds are commercialized in USA and Canada. Preliminary olfactometric assessment of the ethereal extract of the flowers, have shown notable attractive effects on the coffee borer adults females (Hypothenemus hampei Ferrari (Scolytidae:Coleoptera). The volatile fraction by HRCG and HRGC-MS was analyzed and the identification was made by comparative dihydrotagetone, cis-tagetone, fatty acids and their ethyl esters among other compounds. We are grateful to Colciencias and DIB–Universidad Nacional de Colombia for financial support and Cenicafé for their collaborative work.

In the family Piperaceae, the most important genus is Piper, whose species are especially diffused in tropical area, particularly the amazon area. Some of then are being cultivated until commercially for used like alimentary seasonings and to elaborate pharmochemicals products. Some studies indicate that the genus Piper has insecticidal and molluskcidal properties. Besides, the specie Piper tuberculatum Jacq, is known as " pepper-long" and, it has been used in Parafba State, Brazil, as sedative and antidote for snakes bites. In this way, the present work was carried out to evaluated the insecticide activity of the amide 4.5-diidropiperlongulina extract from P. tuberculatum, on Anticarsia gemmatalis Hueb. 1818 (Lepidoptera: Noctuidae). P. tuberculetum was collected in Manaus, Brazil, in July, 1998. The seed (24.33 g) were extracted (2x) in CH₂Cl₂:MeOH (2:1). The first extract (2.00 g) was submitted on CC of silica gel being used hexane: etil acetate in polarity gradient, supplying the fraction 13, that, after wash in CHCl3, it took to the isolation of the amide. The relationships dose-answer was compared by the Probit analysis to determine the susceptibility rate, measures in terms of the ia/insect mg. The trials consisted of topical applications in the following concentrations 0.0; 0.04mg; 0.06mg; 0.08mg; 0.10mg; 0.12mg and 0.14mg of i.a. /insect. In relation to dose-answer obtained by the analysis of Probit analyses, it could be observed that 4,5-diidropiperlongulina presents great insecticidal potential.

Index terms: amide, Anticarsia gemnunatalis, piper-long, insecticide.

[0705] INCREASE OF TRAP CATCHES BY A COMBINATION OF MALE SEX PHEROMONES AND FLORAL ATTRACTANT IN LONGHORN BEETLE, ANAGLYPTUS SUBFASCIATUS (COLEOPTERA: CERAMBYCIDAE)

K. Nakamuta¹, T. Gotoh², M. Tokoro¹ & T. Nakashima¹, ¹Forest Biol. Div., Forestry & Forest Prod. Res. Inst. (FFPRI), P. O. Box 16, Tsukuba Norin Kenkyu Danchi-nai, 305-8687, Tsukuba, Japan, E-mail: nakamuta@ffpri.affrc.go.jp; ²Tohoku Res. Center, FFPRI, Nabeyashiki 72, Shimokuriyagawa, Morioka, 020-0123, Japan

Anaglyptus subfasciatus (Coleoptera: Cerambycidae) is one of the most harmful insect pests of the Japanese cedar, Cryptomeria japonica, and the Japanese cypress, Chamaecyparis obtusa, the most abundant tree species of forest plantations in Japan, Females of the beetles lay their eggs on the dead twigs of the cedar or the cypress and the larvae bore into the twigs and migrate further into the tree trunk. Feeding by the larvae on sapwood followed by fungal infection causes discoloration and decay of the wood, resulting in a decrease of the commercial value of timbers. Since A. subfasciatus males and females were known to congregate on several species of flowers for feeding, floral scents and their structural similarities have been screened both in the laboratory and in the field. Methyl phenylacetate has been demonstrated as the most attractive and highly specific to A. subfasciatus and has been used as the most reliable floral attractant for A. subfasciatus in practice. A. subfasciatus females were attracted to males in a wind tunnel and that a male-specific cuticular structure in the pronotum seems to be an organ of pheromone excretion. Furthermore, the male-released sex pheromone constituents of the beetle are identified as a 7:1 blend of (R)-3-hydroxy-2-hexanone and (R)-3-hydroxy-2octanone. We have observed that the beetles were attracted to the trap baited with floral attractant alone, but they walked around the tree trunks or logs near the trap. Therefore we tested whether a combination of male sex pheromone constituents and the floral attractant improved pinpoint location of the beetles and increased the trap catches. In the present paper we report that the trap catches of the female beetles were increased by a combination of male sex pheromone constituents and the floral attractant.

Index terms: attraction, Methyl phenylacetate, (R)-3-hydroxy-2-hexanone, (R)-3-hydroxy-2-octanone

[0704] INFLUENCE OF EXPERIENCE ON THE OLFACTORY RESPONSES OF A PREDATORY BEETLE, *TROGOSSITA JAPONICA* (COLEPTERA: TROGOSSITIDAE) TO VOLATILES OF ITS PREY-HOST TREE COMPLEX

K. Nakamuta¹, P. Usha Rani. ^{1, 2}, M. Tokoro¹ & T. Nakashima¹, ¹Forest Biol. Div., Forestry & Forest Prod. Res. Inst., P. O. Box 16, Tsukuba Norin Kenkyu Danchi-nai, 305-8687, Tsukuba, Japan, E-mail nakamuta@ffpri.affrc.go.jp; ² Hort Res., Mt. Albert Res. Center, P. O. Box 92169, Auckland, New Zealand

The predatory beetle, Trogossita japonica (Coleoptera: Trogossita), feeds on wood boring insects in the forests. The Japanese pine sawyer, Monochamus alternatus, (Colcoptera: Cerambycidae), that transmits the pine wood nematode, Bursaphelenchus xylophilus, the pathogen of the pine wilt disease of Japanese red pines (Pinus densiflora) and black pines (Pinus thunbergii) is one of its prey species. M. alternatus utilizes monoterpenoids, especially alpha-pinene, which are emanated from nematode-infected pine trees, to orientate towards the host trees for oviposition. For T. japonica, it is advantageous to adopt a similar tactic as M. alternatus to locate the oviposition site, since the larvae of T. japonica feeds on the immature stages of M. alternatus in pine forests. We, therefore, analyzed the olfactory response of T. japonica to certain monoterpenoids in an open Ytrack olfactometer and also compared the responses between field-collected (experienced) beetles and artificially reared (inexperienced) beetles. Both experienced and inexperienced beetles showed strong responses to alpha-pinene, beta-pinene and a combination of alpha-pinene and EtOH. However, the time taken to locate an odor source by experienced beetles was much shorter than the inexperienced beetles. To delineate the role of pre-exposure to the prey-host tree odor complex by the predator, we further analyzed the responses of the artificially reared beetle, which have had an experience of feeding a prey with pine logs. This had a positive effect on the beetles and the preexposure to the pine volatiles certainly enhanced their attraction to the odors. These predators are faster in orienting towards the volatiles, as evident by the lesser time taken to locate an odor source than the inexperienced beetles, thus, demonstrating that the experience modifies the odor location in T. japonica.

Index terms: Terpenoids. Trogossita juponica, pine, predator, alpha-pinene.

[0706] SUITABILITY OF SEVERAL RUTACEOUS PLANTS FOR A PAPILIONID BUTTERFLY, PAPILIO POLYTES

T.Nakayama¹, T.Murakami², K.Honda², N.Hayashi² & K.Matsuda¹, ¹Laboratory of Insect Science and Bioregulation, Graduate School of Agriculture, Tohoku University, Sendai 981-8555, Japan, E-mail:tadanobu@bios.tohoku.ac.jp; ²Division of Environmental Sciences, Faculty of Integrated Arts and Sciences, Hiroshima University, Higashihiroshima 739-8521, Japan.

Papilio polytes is a rutaceae-feeding papilionid butterfly inhabiting Southeast Asia and Southwestern Islands of Japan. We have examined the affinity of the butterfly to two major host plants, Toddalia asiatica(TA) and Citrus deperessa(CD), and to other potential hosts: Murraya paniculata(MP), Evodia melifolia(EM), Fagara ailanthoides(FA), hosts: Murraya paniculata(MP), Evodia melifolia(EM), Fagara ailanthoides(FA), hellodendron amurense(PA), and Orixa japonica(OJ). [Latval performance and oviposition preference] Larval survivorships (1st and 5th instars) as an estimate of fitness on and oviposition responses to these plants were evaluated. While larvae performed well on TA, CD, FA, and PA, and all these plants were acceptable to ovipositing females, EM was found not to be very suitable for the larval growth and females showed much less preference for the plant. In contrast, both larvae and females almost completely rejected MP and OJ.[Oviposition deterrent in MP] Since preliminary experiments suggested the presence of oviposition deterrent(s) in MP, we attempted to identify active compound(s) from the MeOH extract(1) of MP, which, in the natural habitat of *P. polytes*, is abundant and grows sympatrically together with TA, the most important host plant. The extract(1) was separated by solvent partition into four fractions:CHCl3(2), i-BuOH(3) and water(4). Strong deterrent activity resided in Fr.4, from which one of active compounds was isolated by column chromatography and preparative TLC. The compound, identified as trigonelline by its FAB-MS and ¹³C-NMR spectra, showed noticeable deterrent effect on egg-laying. Index terms; Papilio polytes, Rutaccae, Murraya paniculata, trigonelline, oviposition deterrent

[0707] ODOUR-MEDIATED INDIRECT INTERACTIONS IN FOOD WEBS

<u>A. Pallini¹</u>, A. Janssen² & M. W. Sabelis², ¹Department of Animal Biology, Federal University of Viçosa, 36571-000, Viçosa MG, Brazil, E-mail pallini@mail.ufv.br; ²Section Population Biology, University of Amsterdam, Kruislaan 320, 1098 SM, Amsterdam, The Netherlands, E-mail janssen@bio.uva.nl.

Arthropods use odours associated with the presence of their food, enemies and competitors while searching for patches of food. Responses to these odours therefore determine the spatial distribution of animals, and are decisive for the occurrence and strength of interactions among species. We studied odour-mediated indirect interactions in an artificial arthropod food web that occurs on eucumber plants in greenhouses where biological control is applied. We investigated indirect effects in very simple subsets of this food web, considering (a) plant-mediated indirect interactions between two herbivores, the two-spotted spider mite Tetranychus urticae and the western flower thrips Frankliniella occidentalis, (b) responses of the two herbivores mediated by their predators (the phytoseiid mites Phytoseiulus persimilis, Neoseiulus cucumeris, and N. californicus) and (c) interactions between predators mediated by their prey. We found that odour-mediated indirect interactions are an important organising force in this arthropod food web. Spider nites and thrips can interact indirectly both through their common host plants and through predators, whilst predators may interact indirectly through prey. Indirect interactions as these may produce effects in food webs that are as important as those of direct predatorprey interactions, which may cause both positive and negative effects on biological control of herbivores. We will argue that the importance of odour-mediated indirect interactions in determining community-level interactions both in artificial and in natural food webs should not be underestimated.

Index terms: Frankliniella occidentalis, Tetranychus urticae, Phytoseiulus persimilis, Neoseiulus cucumeris, behavioural responses.

[0709] LABORATORY AND FIELD TEST OF SEX PHEROMONE OF SPODOPTERA EXIGUA (LEPIDOPTERA: NOCTUIDAE)

<u>A. D. Permana</u>¹ & Rostaman², ¹Department of Biology, Institut Teknologi Bandung, Ganesa 10, Bandung 40132, Indonesia. e-mail : agus@bi.itb.ac.id ; ²Polytheenic of Agriculture, Nusa Cendana University, Kupang. Indonesia.

Spodoptera exigua is one of the important pests in shallot. Test of sex pheromone of S. exigua was carried out at the laboratory and shallot field. The sex pheromone was extracted from abdominal tips of the virgin female moth 2-4 days old. Based on GC analysis, the crude extract at least contains Z-9 tetradecenol (Z9-14OH), Z-9 tetradecenyl acetate (Z9-14Ac) and Z9E12 tetradecadienyl acetate (Z9E12-14Ac). These components indicated as same as the commercial sex pheromone (Ugratas). The result of laboratory test using Y-olfactometer showed that the male moths give positive responses to the standard sex pheromone (blend of Z9-14OH : Z9E12-14Ac; 10:1), and statistically not different with the responses by the male moth to the virgin female. In field test, the male moth taraped by all sex pheromone tested, and Ugratas showed the best response. Index terms: Spodoptera exigua, Z-9 tetradecenol, Z-9 tetradecenyl acetate, Z9E12 tetradecadienyl acetate.

[0708] INFLUENCE OF PRE- AND POST- IMAGINAL EXPERIENCE ON HOST-FINDING BEHAVIOR OF *HYPOTHENEMUS HAMPE*I

<u>R.C. Pereira</u>, A. M. Viana Bailez & J. O. G. de Lima, Department of Plant Protection, Universidade Estadual do Norte Fluminense, Campos, RJ 28015-620, Brazil, E-mail rozimarcp@uol.com.br.

The Coffee Berry Borer (CBB), Hypothenemus hampei (Ferrari, 1867) (Coleoptera: Scolytidae), stands out as one of most the important pest of the coffee, representing a threat to for the viability coffee cultivation in many countries. CBB attacks the fruits in the several development al stages: green, mature or dry fruits. It is known that visual characteristics play an important role in host finding of CBB. At long distances, it is probably attracted by color and the characteristic shine of the coffee bean at short distances the color, the size and the appearance of the fruit could be the primary factors in selection of the host. This work evaluated the visual cues for locating fruit. These were investigated under laboratory conditions. The tests under takern between the months May and July 1999. Adult females were obtained from grains of coffee (Coffea arabica) in three different maturation stages (dry fruit - black color; fruit cherry - red color and green fruits - green color), collected in Viçosa - Minas Gerais. The preference of CBB originating from the three stages was evaluated (green, red and black colors) for natural and artificial fruits of coffee (green, yellow, red and black), that were suspended by means of pins and fastened in the bottom of an arena divided in four quadrants. After three hours the preference of CBB was evaluated by noting positon of the insect or penetration of the fruit. It was shown that there was a preference for boring into the same color as the original fruit for all the insects tested . In the natural fruits the percentage of females on the fruit, was superior to the percentage in the quadrant. Insect takem from green fruits, had a clear preference for green fruits which was also the case for insects from other colors, and natural fruits. The yellow color was, least attractive.

Index terms: Search behavior, visual incentives, Hypothenemus hampei, Coffee Berry Borer, Scolytidae

[0710] CONVENTIONAL SAMPLING PLAN FOR VECTORIAL INSECTS OF VIROSES, PREDATORS AND PARASITOIDS IN TOMATO

<u>M. Picanco¹</u>, M. R. Gusmão¹, D.J.H. da Silva² & R.N.C. Guedes¹, ¹ Dept. de Biol. Animal, ²Dept. de Fitoteenia, Univ. Fed. de Viçosa, CEP 36571-000, Viçosa, MG, Brazil, E-mail picanco@mail.ufv.br.

This research was accomplished from February to July, 1999 in Coimbra and Viçosa, State of Minas Gerais, Brazil and it aimed to determine a conventional sampling plan for vectorial insects of viroses, predators and parasitoids in tomato. The densities of the Mitelly Remisia tabaci (Homoptera: Aleyrodidae), greenbugs Myzus persicae and Macrosiphum euphorbiae (Homoptera: Aphididae), thrips Frankliniella spp. (Thysanoptera: Thripidae), predators and parasitoids in eight squares of four commercial fields of tornato were evaluated. The determination of the best sampling technique and sample size was made with basis in the variance and relative precision. After the best sampling technique and size of the sampling unit, were determined the numbers of samples to compose conventional sampling plans with precision of 5, 10 and 25%. The basal part of the canopy of the tomato plant was the most representative place for virose vectors, parasitoids and predators sampling, simultaneously, being the composed samples of two leaves the most precise sample size. For a the numbers of whitefly nymphs the direct count on the leaves was the most precise technique. However, in the whitefly adults sampling, greenbugs, thrips, predators and parasitoids the beat of leaves in tray was the most precise technique. In relationship to the number of samples necessary for sampling the populations of viroses vectors, predators and parasitoids, 65 samples were necessary. Index terms: Bemisia tabaci, Myzus persicae, Macrosiphum euphorbiae, Frankliniella

[0711] ROLE OF NEZARA VIRIDULA (HEMIPTERA:PENTATOMIDAE) ON INDUCING THE PRODUCTION OF FLAVONOID IN SOYBEAN GENOTYPES

G.C. Piubelli^{1,5}, LC Arruda², J.C. Franchini³, F. M. Lara¹ & C.B. Hoffmann-Campo^{2,4}, ¹ Dept. de Fitossanidade (FCAV/Unesp), Via de Acesso Prof. Paulo Donato Castellane, Km 05, 14870-000, Jaboticabal, SP, Brasil; ² Pronex (Núcleo Manejo Integrado de Pragas); ³ Bolisitat recém-doutor CNPq; ⁴ Embrapa Soja, C. Postal 231, CEP 86001- 970, Londrina, PR, Brasil. ⁵ Present address: Universidade Federal do Paraná, Departamento de Zoologia, Caixa Postal 19020, CEP 81531-900, Curitiba, PR, Brasil Email: giorla@enpso.embrapa.br

Induced response to insect damages can result in chemical alteration in plants. The ability of Nezara viridula to induce the production of flavonoids in seeds of soybean genotypes ('BR-16', 'IAC-100', PI 227687, PI 229358, PI 274454) was investigated at greenhouse conditions. Cages with four stink bugs were placed on soybean plants, during 18 hours. Soybean pods were collected 72 hours after stink bugs have been removed and the damaged parts were identified up ut and ground. A sample of 0,100 mg from each genotype was homogenised with 0,5 ml of 80% methanol (MeOH). After centrifugation, the supernatant was dried in N2, redissolved in 100 µL 80% MeOH and an aliquot of 20 µL were injected in HPLC (High Performance Liquid Chromatograph) for flavonoid analysis. The genotype PI 227687 damaged by N. viridula presented the highest concentration (0.35 mg/nl) of daidzin (daidzein 7-0-glucoside); the lowest concentration of isoflavone was observed in PI 229358 (0.03 mg/ml). The same tendency was observed with genistin (genistein 7-O-glucoside); PI 227687 presented 0.14 mg/ml, PI 274454, 0.03 mg/ml and PI 229358, 0.04 mg/ml of genistin. In general, genotypes damaged by stink bugs, produced higher isoflavones contents (daidzin and genistin), compared to controls (without stink bug damage). However, after being damaged by stink bug, PI 274454 and PI 229358 produced less genistin than the other genotypes and no difference in concentration between damaged plants and non-damaged was observed. N. viridula increased concentration or induced daidzin and genistin productions in PI 227687 seeds. Therefore, further studies must be carried out to elucidate their role on soybean defence against stink bugs.

Index terms: resistance, green stink bug, daidzin, genistin.

[0713] RESEARCH DIRECTIONS OF USING THE SYNTHETIC SEXUAL PHEROMONES ON FIELD CROPS IN ROMANIA

<u>C. Popov</u>¹ & I. Rosca², ¹Research Inst. for Cereals and Industrial Crops, 8264 Fundulea, N. Titulescu Str., 1, Calarasi District, Romania, E-mail:fundulea@cons.incerc.ro; ² Univ. Agricultural Sciences and Veterinary Medicine, Ave. Marasti 59, Bucharest, Romania.

The paper presents the results obtained in Romania during 1982-1998 in field trials with pheromone formulations, at Fundulea and different other agricultural research stations, for identifying of specificity and effectiveness of sexual pheromones synthesized in Romania. for species: Agrotis segetum, Agrotis exclamationi, Cnephasia pasiuana and Ostrinia nubilalis, (pests of wheat and corn), for Autographa gamma, Mamestra oleracea, Amathes c-nigrum, Discestra trifolii, for forage plants, Plutella maculipennis for rape, Etiella zinckenella for soybean. Methods. It was used pheromone traps type F-1 in 2-4 replicates, at 50-m distance between traps and a glue based on polyizobuthilen. Generally, pheromonal lures were changed once/month, and adhesive parts twice or once/month-Registrations were done with changing of adhesive parts, being noted number of captured target males and of others lepidopterous species. It was registered pheromone efficacy (number of target males species captured/trap) and specificity (percentage of target species and other different lepidopterous species, macrolepidopterous and microlepidoptererous). Results. Sexual synthesis pheromones for studied species were specific and efficient, captured number of target species has depended on year and locality and it is possible to use pheromones in establishing of pest spreading, flight curve and pest biology in generally. New spreading areas for *Cnephasia pasiuana* have been established. There is a relatively good enough formulation of Z and E sexual synthetic pheromone for Ostrinia nutrition good onlogin formation of D and D ortan of January photometer of mutual of mutual and it was stated that in Romania Z pherotype is predominant. Control of European Corn Borer by mass trapping of males or male disorientation has failed in small cornfield surrounded by forest, but pheromones are helpfulness in a future integrated control system of this pest by determination of releasing Trichogramma spp., or males with inherited sterility. Conclusions. Sexual synthesis pheromones for studied species were specific and efficient. Pheromones traps gave essential information for Insect Pest Management, referring to the pest area, level of pest population and dynamic of pest on area and during the year. These make possible reducing, in the future, using of pesticide, minimal effects on useful organisms, reducing of chemical treatments which will reduce risk of developing of pesticide resistant pest populations and especially a better timing for chemical control, which mean time and money economy.

Index terms. Lepidoptera, synthetic sexual pheromones, field trials.

[0712] BEHAVIOURAL AND ELECTROPHYSIOLOGICAL RESPONSES OF SILVER Y MOTH, AUTOGRAPHA GAMMA (LEPIDOPTERA: NOCTUIDAE), TO FLORAL VOLATILES

<u>D. Plepys</u>¹, F. Ibarra², C. Löfstedt¹, B. Hansson¹ & W. Francke², ¹Department of Ecology, Lund Univ., S-223 62 Lund, Sweden; ²Institute of Organic Chemistry, Univ. of Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany.

Flowers produce volatile chemical compounds that attract pollinators. Silver Y moth Autographa gamma in nature is observed to be attracted to a variety of flowers. Attractivity of flowers from five different families, *Platanthera bifolia* (Orchidaceae), *Trifolium pratense* (Fabaceae), *Cirsium arvense and Centaurea scubiosa* (Asteraceae), Saponaria officinalis (Caryophyllaceae), Nepeta faasseni (Labiatae), and their headspace extracts to Autographa gamma was tested in a wind tunnel bioassay. Headspace samples from flowers were collected and analysed by GC-EAD. Both female and male moths were attracted to plant species, listed above, except Nepeta faasseni, and respective headspace extracts. Antennae responded to 6-15 compounds from each extract. Both male and female antennae responded to the same conpounds. There was no a single electrophysiologically active compound found in all the plant species. Benzyl benzoate was found in four of five attracted to genese. *Platanthera bifolia, Trifolium pratense, Cirsium arvense* and *Saponaria officinalis*, Methyl salicylate was present in *Platanthera bifolia* and *Cirsium arvense*. The rest of compounds were unique for each species. Attractivity of electrophysiologically active compounds was tested in a wind tunnel both individually and in mixtures. Single cell recordings of the EAD active compounds are in progress. Results will be presented. Index terus: floral volatiles, nectar foraging

0714] HABITUATION OF JAPANESE BEETLES (COLEOPTERA: SCARABAEIDAE) TO AZADIRACHTIN APPLIED AS A FEEDING DETERRENT

D. A. Potter¹, D. W. Held¹ & T. Eaton¹, Dept. of Entomology, Univ. of Kentucky, S-225 Agric. Sci. Bldg. N., Lexington, KY 40546-0091, USA, E-mail dapotter@ca.uky.edu.

The Japanese beetle, Popillia japonica, is an polyphagous scarab whose grubs feed on roots of turf and pasture grasses, and whose adults are serious pests of shade trees, ornamental shrubs, flowers, tree and small fruits, and garden crops in the eastern United States. Concern about hazards of pesticide use has stimulated interest in less-toxic alternatives, including botanical repellents, for managing this introduced pest. Azadirachtin is a bitter and biologically-active limonoid derived from seeds of the neem tree, Azadirachta indica. Several azadirachtin-based products are labeled as repellents for use against Japanese beetles attacking shade and ornamental plants. We tested the potential for the beetles to become desensitized to one such product following intermittent or prolonged exposure to residues on linden, Tilia cordata, a preferred host plant. Linden leaves were spraved with 3% azadirachtin (Azatin XL) at label rate (1.25 ml/liter) or 0.25 label rate and allowed to dry. Leaf discs from treated or control leaves were exposed to beetles in no-choice or choice tests. Particular beetles were tested for 4 h per day, over 4 consecutive days, and relative consumption of treated or untreated foliage was measured. Potentially confounding effects of hunger were mitigated by allowing beetles to feed on untreated foliage between each 4-h trial. In another experiment, groups of beetles were conditioned by confining them for 24 h with either treated foliage, untreated foliage, or a mixture of both types of leaves. Relative sensitivity to azadirachtin was then tested as before. Both rates of azadirachtin significantly deterred feeding by naïve beetles, but deterrence declined upon successive exposures. In no-choice tests, beetles became desensitized to the lower rate, but not to the higher rate. Beetles conditioned for 24 h with untreated foliage, or the mixed treatment, were repelled by azadirachtin, whereas those conditioned with treated leaves were not. This study suggests that Japanese beetles may habituate to azadirachtin-based repellents used for plant protection.

Index terms: Popillia japonica, neem, desensitization, feeding repellent

Session 04 – CHEMICAL AND PHYSIOLOGICAL ECOLOGY

[0715] AZADIRACTA INDICA AND BOUGAINVILLEA SPECTABILIS EXTRACTS TO CONTROL VELVETBEAN CATERPILLAR

E. L. V. Primiano¹, H.V. Vescove², P. Fortes², L. Vieira², G. Bissoli², S. A. De Bortoli², J. E. Miranda⁴ & A. T. Murata⁴, ¹CREUPI, Fund. Pinhalense de Ensino, Av. Helio vergueiro Leite s/n, 13990-000 Espírito Santo do Pinhal, SP, ²Dept. de Fitossanidade, Univ. Estadual Paulista, 14884-900, Jaboticabal, SP, Brasil; ³Dept. de Biologia, Fac. Filosofia, Ciências e Letras de Ribeirão Preto, Univ. de São Paulo, 14040-901, Ribeirão Preto, SP, Brasil (FAPESP fellowship), E-mail: murataat@asbyte.com.br.

The tetranortripenoid Azadirachtin is the principal constituent from the neem tree Azadiracta indica (A. Juss), and it is the main biologically active compound of neem seed insecticides. This semiochemical has strong antifeedant activity against many insects, which is supplemented also by marked insect growth regulatory and sterilizing effects. The objective of this work was comparing the use of the aqueous extracts of A. indica and Bougainvillea spectabilis to the chemical control of Anticarsia gemmatalis larvae. This work was conducted in the Laboratory of insect Biology located at University of São Paulo State, Jaboticabal, and the neem and B. spectabilis leaves were collected from trees in the field. The leaves were triturated in blender in the proportion of 5 L/water: 0.5 Kg/leaves. Was used caterpillars of third instar and 8 treatments (control water; control with pyrethroid insecticide; neem; B. spectabilis) sprayed on the leaves and insects. It was made 10 repetitions with 5 insects each, and verified mortality, larvae and pupae development and pupae weight. It was observed that the extracts of neem sprayed on the leaves (30%) and B. spectabilis (38%) sprayed on insects caused larger mortality: neem sprayed on the leaves showed the largest larvae and pupae period and smallest pupae weight. It can be concluded that neem and B. spectabilis have insecticide potential to A. gemmatalis.

Index terms: Anticarsia gemmatalis, neem, insect control

[0717] FEMALE SEX PHEROMONE OF CASTNIA LICUS (LEPIDOPTERA:CASTNIIDEA): IDENTIFICATION AND FIELD APPLICATION

L.M.C. Reboucas^{*1}, M. Socorro Caraciolo¹, F.A.C. Griepink², A. S. De Bruin², F.A.O. Paulino¹, C.A. Monte¹, G. C. Santos Jr. ¹ & A. E. G. Sant'Ana¹, 1-Depto. Quimica-CCEN-UFAL-Tabuleiro dos Martins-57072-970 - Maceió - AL-Brasil 2-Research Institute for Plant Protection IPO-DLO-Binnenhaven 5 - 6700 GW-Wageningen The Nerthelands. Finacial support: Cooperativa dos Usineiros do Estado de Alagoas-NATT e ASSUCAL

The giant moth borer, Castnia licus Drury, 1770 (Lepidoptera: Castniidae) is considered one of the most important pest of sugarcane in Northeast of Brazil, especially in the State of Alagoas and Pernambuco. The larvae of this moth enter the cane from the bottom, close to the root, and then working upward through and gradually excavates a long vertical tunnel (30 to 100 cm). It spends the rest of they life in this tunnel and can survive from some days to 8 months. Hexane extracts of Castnia licus abdominal gland show activity by EAG and GC/EAD. The GC/EAD shows that the compound with the same retention time and mass spectrum of the diunsaturated alcohol 3,13-LEF was active. The four geometric isomers (Z,Z)-3,13; (Z,E)-3,13; (E,E)-3,13 and (E,Z)-3,13 LEF were tested separately by EAG and only (E,Z)-3,13 and (E,E)-3,13 LEF show activity. These compounds are sex pheromone components for many other lepidopteran species. Field experiments so far show fewer attraction of the male adults to the (E,Z) 3,13 LEF isomer. Besides the alcohol 3,13-LEF other compounds were identified in the hexane extract of the C. licus abdominal glands. The total ion chromatogram show by comparison with standards the presence of saturated fatty acids as hexadecanoic and octadecanoic; saturated and unsaturated fatty acids esters as methyl hexadecanoate, methyl 9,12-octadecadienoate, methyl 9-octadecenoate, methyl octadecanoate, ethyl hexadecanoate and n-butyl hexadecanoate. This paper will discuss the identification and the field results. Index terms: EAG, GC-EAD, mass spectrum, giant moth, and sugarcane.

[0716] EFFECT OF ORYCTES RHINOCEROS PHEROMONE (ETHYL 4–METHYLOCTANOATE) DIFFUSION RATE ON THE SIZE OF PEST CATCHES*

R. Purba¹, R. Desmier de chenon^{1,2}, S. Prawirosukarto¹, <u>I-P. Morin²</u> & D. Rochat³, ¹IOPRI, P.O. Box 1103, Medan 20158, Indonesia; ² CIRAD-CP, TA 80 / PS3 Boulevard de la Lironde, 34398 Montpellier Cedex 5, France, e-mail : jean-paul.morin@cirad.fr: ³ INRA, 78026 Versailles Cedex, France. *Research with funding from the EU under INCO project No. RB-IC18CT970199.

Oryctes rhinoceros (Coleoptera, Scarabaeidae, Dynastinae) is one of the most important pests to be considered when replanting coconut and oil palm. Mass trapping with the insect's pheromone (ethyl 4-methyloctanoate or E 4-MO) as an attractant offers new prospects for control. We describe the results of a trial comparing catches obtained with different dispensers in an oil palm plantation (in North Sumatra, Indonesia). The trial covered 163 ha and took place over 15 weeks. Total catches over 14 weeks (week 2 was not considered due to trap thefts) amounted to 11,482 insects (33% males and 67% females). The higher the pheromone dose, the greater were the catches. There was a very good linear relation between log(dose) and the catches: figure 1. Given the current cost of E 4-MO, the highest 2 doses are too expensive to consider their use in plantations. Nevertheless, it can be hoped that synergistic compounds will make it possible to reduce the doses required and consequently the cost price. Mass trapping of O. rhinoceros with synthetic attractants is a very promising control method to reduce pest populations and prevent damage in the early years after planting

Index terms : Replanting, oil palm, rhinoceros beetle, mass trapping, Indonesia

[0718] INTERACTION BETWEEN VISUAL AND OLFACTORY CUES IN THE ASSEMBLING BEHAVIOUR OF THE HAEMATOPHAGOUS BUG TRIATOMA INFESTANS

C. E. Reisenman¹, A. N. Lorenzo Figueiras¹, M. Giurfa² & C. R. Lazzari¹, ¹Lab. de Fisiología de Insectos, Fac. de Cs. Exactas y Naturales, Univ. de Buenos Aires, Ciudad Universitaria, (1428) Buenos Aires, Argentina, E-mail: carolina@bg.fcen.uba.ar; ²Inst. für Neurobiologie, Freie Universität Berlin, Königin-Luise-Str. 28/30, 14195 Berlin, Germany. Supported by Univ. Buenos Aires, CONICET (Argentina) and WHO (TDR)

The aggregation behaviour of triatomines is mediated by thigmotaxis, chemical signals and negative phototaxis. The present work analyses how the aggregation behaviour of the haematophagous bug Triatoma infestans is modulated by the convergence of chemical factors and the spectral composition of the light associated to potential refuges. Secondinstar larvae were presented with two refuges of filter paper disposed in a two-sector circular arena. In each trial, each refuge presented a chemical cue (presence or absence of a piece of paper impregnated with dry facces) and a visual cue (a dark vs. a coloured spot, both on a white background). Coloured lights used were blue, green and red to humans. Results show that: 1) in absence of facces bugs assembled in the dark sector, 2) bugs rejected refuges associated with green light regardless of the presence or absence of faeces; 3) orientation towards chemical cues was more relevant than negative phototaxis to red light. Such a light was avoided in the absence of faeces but was irrelevant in their presence; 4) negative phototaxis towards blue light can be counteracted by orientation to chemical cues: insects distributed randomly between a blue-light refuge with faeces and a clean dark refuge. We conclude that: 1) in the absence of olfactory signals, a photonegative reaction guides the assembling behaviour of T. infestans, 2) in the presence of visual and olfactory signals, both inputs can interact and control the aggregation behaviour; 3) this interaction depends on the colour of the light (e.g., green light induces a stronger photonegative response than blue or red light).

Index terms: triatomines, colour, faeces.

[0719] DEVELOPMENTS IN SPRAYABLE PHEROMONE DELIVERY SYSTEMS FOR MATING DISRUPTION

<u>R. E. Rice</u>¹, ¹Univ. of California, Dept. of Entomology, One Shields Ave., Davis, CA 95616, USA.

Mating disruption (MD) for control of pests in agricultural, urban, and forestry environments has become a major component of pest management programs throughout the world. In addition to the known advantages over conventional insecticides, MD is becoming an increasingly preferred strategy for control of pests on food crops destined for international markets. Over the past 15 years the majority of successful control programs using MD for various pests have required application of synthetic pheromones in a variety of plastic or polymer reservoirs applied by hand. In spite of these successes, however, growers, pest control advisors, and suppliers of pheromone products have all recognized that a preferred method of applying pheromones would be with some form of reservoir or dispenser that would not require hand application. Improving technologies of polymer synthesis and dispenser design have led to several types of pheromone formulations that can be applied mechanically. This paper presents formulation, application, and efficacy data on three relatively new sprayable pheromone delivery systems. Products developed by Cousep, Inc., Oregon, USA; 3M Corporation, Minnesota, USA; and the University of California, will be presented. Sprayable products from Consep and 3M are essentially sprayable polymer bead reservoirs in micron diameters, while the University of California system was designed around water soluble paraffin emulsions with the pheromones incorporated into the paraffin base. As with any new technology, there are both advantages and disadvantages to using sprayable formulations for MD pheromones. Advantages of sprayable pheromone delivery systems over conventional hand-applied pheromone reservoirs include more timely application over large acreages requiring less labor, and providing better coverage. The polymer bead formulations can also be tank mixed with other agricultural pesticides, particularly fungicides, that are applied throughout the season. In many cases grower equipment can be used, which reduces the cost of application. A major disadvantage of polymer bead formulations is a shorter residual, requiring more frequent application of the pheromones in comparison to handapplied dispensers. However, the consensus among all users and pheromone formulators is that sprayable pheromone technology has now reached the stage of development that will encourage increased grower acceptance and use of mating disruption pheromones. Index terms: pheromones, mating disruption

[0720] DESIGNING EFFECTIVE MULTIMEDIA TEACHING PACKAGES FOR ENTOMOLOGY

D. J. Robinson, Dept. of Biological Sciences, Open University, Milton Keynes, MK7 6AA, U.K. Email d.j.robinson@open.ac.uk

Educational multimedia is a relatively new field and fully evaluated examples of good design are not yet widely recorded in the literature. However, there are a number of rules that can guide the designer of teaching and learning packages and arguably the key rule to the design of effective multimedia teaching packages is to provide a substantial level of interactivity. In designing teaching and learning material for distance education in biology, it has been necessary to simulate on the computer, some of the exercises that students would undertake in laboratory or field situations. No simulation can recreate the real experience perfectly, but a simulation can teach a range of skills necessary for the entomologist in the laboratory or field. As part of the investigation of a section of woodland, students are required to collect data on insects that could form food for predators. By analysis of the energy content derived from the food, the students can build up a picture of the ecological relationships between the animals in the food chain and quantify the energy levels between one trophic level and the next. In addition to teaching ecological methods, the students learn about the use of field guides, insect life cycles and the distribution of insects within a woodland, at different seasons. The entire exercise is carried out by students learning in their own homes, using a computer. They receive the exercise on a CDROM that has been sent to them through the post. The taxonomy of the insects is also taught using a CDROM. A hierarchical browser is provided, which allows students to see the relationships between different groups and the characters that are used to distinguish between taxa. The browser is well illustrated with still pictures, video and sound. While these CDROMs were produced for use in distance education, they have a wider utility for biological education since the skills they teach are generally applicable and they have interactivity as the basis of their design.

[0721] MALE EMITTED SEX PHEROMONES IN CONFUSED FLOUR BEETLE-BEHAVIOUR AND POSSIBLE PRODUCTION SITE

C. Rvne, C. Olsson & C. Löfstedt, Dept. of Chemical ecology, Lund University, Sölveg. 37, SE-223 62, Lund, Sweden, E-mail camilla.ryne@ekol.lu.se

Behavioural studies show that confused flour beetle, Tribolium confusum (Coleontera: Tenebrionidae) males emit a substance that is highly attractive to conspecific females (p<0.001). Males, however, are not attracted to conspecific males. The studies were conducted in a four-choice olfactometer, and the females and males were tested individually. It has been stated that the species specificity in the aggregation pheromones emitted by the males in *Tribelium* depend on the ratios of the stereoisometric configurations of the substance 4,8-dimethyldecanal. The emitted pheromones are called aggregation pheromones, since they appear to attract both males and females. Racemic 4,8-dimethyldecanal was tested in the olfactometer as a dose-response assay and showed no significantly attraction to the females. The contradicting data from the olfactometer tests imply that T. confusum males emit another active substance, which gives rise to the female attraction. Different tests in the olfactometer conclude that the sex pheromone is emitted actively by the live male. Leg extracts were significantly (p<0.01) attractive to females, but not legs from taken from live males, suggesting that the substance is not present as soon as the male is dead. Scanning electron microscopic pictures show that T. confusum males differ from the closely related species T. castaneum in that T. castaneum males have production sites only on the prothoracic femurs, whereas they are present on all three pairs of femurs in T. confusum males. GC-analyses of whole body-, leg-, or headspace extracts show no peak corresponding to 4,8-dimethyldecanal. A re-occurring peak in all extracts, including female extracts, is identified as 1-pentadecene, which is previously reported as being a surfactant that is facilitating absorption of odour molecules. 1pentadecene may not be the active substance since it is present in the female extracts as well as in the male extracts. The results point to the fact that aggregation pheromones may not exist in T. confusum, but instead a system based on sexual pheromones emitted by the male attracting the female.

Index terms: Tribolium confusum, pheromones, behaviour, SEM.

[0722] VIRTUAL REALITY IN A WALKING MALE SILK WORM MOTH ON A SERVO-SPHERE

M. Sakuma, Lab. of Insect Physiology, the Graduate School of Agriculture, Kyoto Univ., 606-8502, Kyoto, Japan, E-mail sakuma@kais.kyoto-u.ac.jp.

The pheromonal orientation of a male silkworm moth (Bombyx mori) towards a female was analyzed on 'Servo-sphere' apparatus (or Kramer's treadmill). The sphere is driven by a pair of AC-servo motors controlled by a computer, which provides negative feedback to the positional shift of a test insect transmitted regularly from a high-speed video tracker. A built-in encoder on each motor reports periodically an actual position of a motor-axis, and this conversely indicates the track of the insect traveling on the sphere. When a calling female moth on a perch was placed beside the sphere in still air conditions, the male being tethered dynamically on the sphere beat his wings and walked straight towards the female 7 - 28 cm away from him. Moreover, he oriented not only towards a pheromone plume passing by, but also towards its downwind side as the airflow rate increased. Although a unilaterally antennectomized and pterectomized (wing-amputated) males oriented towards a female in the still air condition, bilaterally amputated ones never exhibited directed movements. These results support the idea that his wing-fanning introduced pheromonally odoured air onto his antennae only when he directed towards the pheromone source and/or plume, and this precise timing could be a crucial behavioural component for him to set direction towards the source: the resulting consecutive pheromonal odour pulses may change his circling into a straight walk by resetting frequently the 'flip-flopping' activity in the CNS. This idea was demonstrated by virtual reality experiments in terms of odour pulses. The experiments were conducted in a small wind tunnel covering the servo-sphere, and a three-way solenoid valve attached to the tunnel generated the pulses. A driver program of the sphere enabled to switch the valve to a bombykol-impregnated reservoir when a male directed towards a virtual odour source. Under the control of this program, both intact and bilaterally pterectomized males reached the source irrespective of the wind direction. These results strongly suggest that timing odour pulses during circling, by drawing odourous air through the antennae with fanning wings, is essential to the orientation of a walking male silkworm moth towards the odour source. Index Terms: Bombyx mori, flip-flop, orientation, pheromone, treadmill

[0723] EFFECT OF BUCCAL CAVITY SECRETIONS OF PARASITISED AND UNPARASITISED CHILO INFUSCATELLUS LARVAE ON THE SYNOMONAL ACTIVITY OF SUGRACANE PLANT

K. P. Salin, N. Mukunthan, R. Nirmala & Y. S. Goud, Sugarcane Breeding Institute, Coimbatore - 641 007, India, E-mail: sugaris@md3.vsnl.net.in

Seven sets of experiments were conducted to understand the role of parasitisation of the herbivore in the production of synomone which acts as kairomone to the parasitoid, Cotesia flavipes. Our earlier studies have shown that the sugarcane shoots damaged by the shoot borer, Chilo infuscatellus attracts the parasitoid C. flavipes, an oligoparasitoid adapted to sugarcane ecosystem. The experiments were conducted in 'Y' tube olfactometer with freshly emerged mated females of C. flavipes reared on C. infuscatellus over ten generations. The experiments included (1) Mechanically injured (MI) shoots and normal shoots, (2) MI shoots and MI shoots smeared with buccal cavity secretion (BCS) of normal larva, (3) MI shoots and MI shoots smeared with BCS of parasitised larva. (4) shoots with normal larva feeding inside and normal shoot, (5) shoot with normal larva feeding inside and MI shoot smeared with BCS of normal larva, (6) shoot with normal larva feeding inside and MI shoot smeared with BCS secretion of parasitised larva and (7) shoot with parasitised larva feeding inside and MI shoot smeared with BCS of parasitised larva. Seventy female parasitoids were subjected to observation in each experiment. The parasitoid exhibited significant (p=0.025) preference for shoot damaged by normal larva and the MI plant smeared with the BCS of normal larva. No distinct preferences were shown by the parasitoids to the shoots damaged by the parasitised larva or the MI shoot smeared with BCS of parasitised larva. The physiological state of the herbivore is known to be altered by parasitisation which affect the food consumption. The salivary secretions of the feeding larvae contains chemicals which trigger the production of the synomones. It could be possible that the altered physiological state of the larva due to parasitisation alter the quantity / quality of the synomone of the plants through the modified salivary secretions which the foraging parasitoid could discriminate between. However further detailed studies on the chemical composition of the volatiles produced by the different set of plants used in the present experiments and the electroantennogram studies would establish conclusively the differences in plant reaction to the differential physiological state of the herbivore.

Index terms: Cotesia flavipes, Chilo infuscatellus, Chilo sacchariphagus indicus, Chilo partellus.

[0724] BIOLOGICAL ACTIVITY OF WORKER MANDIBULAR ACIDS IN APIS CERANA AND APIS MELLIFERA

II. Sasagawa¹ & S. Matuysma², ¹PRESTO, JST; Natl. Inst. of Seric. & Entomological Sci. (NISES), 1-2 Oowashi, Tsukuba, Ibaraki, 305-8634, JAPAN, E-mail sasagawa@nises.affrc.go.jp; ²Inst. of Applied Biochem., Univ. of Tsukuba, 1-1-1, Tennou dai, Tsukuba, Ibaraki, 305-8572, JAPAN.

The Oriental honey bee, Apis cerana (Ac), is tolerant against diseases, does not collect propolis, and highly tolerant against parasitic mite, Varroa jacobsoni especially in the case of the Japanese honey bee, Apis cerana japonica (Acj). In the course of our study on chemical ecology in honey bees in Asia, (R)-(-)-3-hydroxyoctanoic acid (3-HOA) was identified as forager specific mandibular gland components in Ac. By using Acj, age and task related changes in worker mandibular acids were demonstrated. Workers younger than 18 days old produced 10-hydroxydecaoic acid (10-HDAA) and (2E)-10hydroxydecenoic acid (10-HDA) as major manbubular gland components (<5 micro g/bce). On the other hand, 21 days old workers and foragers were found to posses more than 10 micro g of 3-HOA as a main component. In this study, biological activity of forager mandibular acids was tested. By using a conventional pollen germination test (10% sucrose-agar), ether extracts of both Acj and Am mandibular glands surpressed pollen germination completely at 1.0 head equivalent /ml and 0.5 head equivalent /ml and above respectively. Synthetic 3-HOA showed 100% surpression of pollen germination at 50 ppm (50ng/ml) and above. GC analyses after methylation by diazomethane showed that Acj foragers had an average of 28 micro g of 3-HOA/bee, while Am foragers possessed averages of 43 and 187 micro g of 10-HDAA and 10-HDA respectively. 3-Hydroxydecanoic acid (3-HDA, major) and 3-HOA (minor) were first identified form the Hydroxydecatiol act (FIDA, hajo) and 3-HOA (innor) where this manufacture action and in a manufacture action A is a standard s several Bombus species in Japan. So far, 3-HOA was identified in forager mandibular gland of Apis cerana collected in Japan, Korea, Taiwan, Vietnam, China, Nepal and Thailand. Other Apis species do not produce this acid. Distribution and biological function of these 3-hydroxy fatty acids among hymenopteran insects will be discussed.

Index terms: antifungal activity, pollen germination, 3-hydroxyoctanoic acid (3-HOA), 10-HDAA, 10-HDA

[0725] POLLINATOR ATTRACTION BY PHEROMONE-MIMICKING VOLATILES IN AUSTRALIAN AND EUROPEAN ORCHIDS

F. P. Schiestl¹, R. Peakall¹, F. Ibarra² & W. Francke², ¹Division of Botany and Zoology, The Australian National University, Canberra, ACT, 0200, Australia; Email: florian.schiestl@anu.edu.au; ² Institute of Organic Chemistry, University of Hamburg, Germany

Flowers of sexually deceptive orchids mimic the sex pheromones of their pollinator species. Pollination occurs when the male pseudocopulates with the flowers. We investigated the "pseudopheromones" of orchids as well as the sex pheromones and mating behavior of their respective pollinator species in the Australian orchid genus Chiloglottis, which is pollinated by thynnine wasps (Hymenoptera: Tiphiidae), and the European genus Ophrys, pollinated by solitary bees (Hymenoptera: Apoidea). We examined semiochemicals and their detection by the males using gas chromatography with electroantennographic detection (GC-EAD). Gas chromatography - mass spectrometry was used to identify odor compounds and behavioral tests to investigate reactions of males to natural and synthetic odor compounds. Behavioral tests with flowers of Chiloglottis trapeziformis showed that males of its pollinator species, Neozeleboria cryptoides, are attracted over long distances, which relates to their mating behavior. Female thynnines are flightless and call for males by releasing sex pheromones from a low perch. They are rapidly located by the males and transported to a feeding site. In GC-EAD experiments with C. trapeziformis volatiles, only one peak elicited electroantennographic reactions in male antennae. This peak was found in the labella as well as in the sepals of the flowers. C. valida, which occasionally share the same pollinator species, produces the same compound(s), in labella and sepals. Although identifications and field tests remain to be done, this suggests that the mimicry of the sex pheromone requires only a few compounds. In Ophrys sphegodes, on the contrary, 14 alkanes and alkenes have been found to clicit electroantennographic responses and were shown to elicit copulation behavior in the pollinator bee species, Andrena nigrouenea (Schiestl et al. 1999, Nature 399: 421-422). These compounds also constitute the sex pheromone. The low volatility of these compounds suggest them to act primarily at close distance, which is in accordance to the mating behavior of the bee species. Andrena nigroaenea males search for females in aggregations on odor marked trails. Females are thought to fly in an aggregation where mating occurs. Differences between the mating behavior in thynnine wasps and solitary bees appears to have led to the evolution of different pheromone communication systems. Thus Australian and European sexually deceptive orchids, have recruited male pollinators with contrasting chemical communication systems.

Index terms: Neozeleboria cryptoides, Chiloglottis, Andrena nigroacnea, Ophrys sphegodes, orchid pollination

[0726] SAPONINS IN THREE ALFALFA (*MEDICAGO SATIVA*) VARIETIES AND THEIR RELATION TO APHID RESISTANCE

<u>A. A. Silva¹</u>, E. M. Varanda¹ & N. P. Lopes². ¹Dept. de Biologia, FFCLRP – USP, Av. Bandeirantes, 3900, Ribeirão Preto – SP - Brasil, CEP 14050 901, E-mail alealsil@usp.br; ²Dept. de Física e Química, FCFRP – USP, Via do Café, SN, Ribeirão Preto – SP – Brasil, CEP 14040 903.

Several studies concerning the secondary compounds of plants and their relation to herbivory suggest that they may play an important role in host selection by herbivores. Qualitative and quantitative variation are present in different species varieties, and therefore, are supposed to be related to resistance to herbivores. It is known that saponins are responsible for the antinutritional effects related to deterrency as a result of their bitter taste to monogastric animals. They can also make complexes with cholesterol thus decreasing its availability in the diet and causing non-specific inhibition of several enzymes, such as proteases. Three alfalfa (Medicago sativa) varieties, P30 (susceptible), CUF 101 (resistant) and Crioula (most frequently cultivated in Brazil), with different levels of resistance to aphids were cultivated at Fazenda Canchim\CPPSE\EMBRAPA -Brazil and the number of aphids were counted monthly from September/97 to August/98. The average number of Therioaphis trifolii and Aphis craccivora aphids in the CUF 101 variety was significantly smaller than that presented by the two other varieties, which indicates a possible resistance to these species. Although CUF 101 had been previouly described as resistant to Acyrthosiphon spp aphids, that is A. pisum and A. kondoe, there were no significant differences in the number of such aphids among the three varieties. The saponin profile of the three varieties, obtained by using HPLC, was determined and a correlation between such profile and the resistance in the CUF 101 variety to the *T. trifoli* and A. craccivora aphids was observed. However, the results suggest few differences in the saponin profile and in the concentration of major components among the three studied varieties, which seems to indicate that they may not be related to resistance to T. trifolii and A. craccivora aphids.

Index terms: aphids, resistance, herbivory, chromatography, saponins

[0727] CHARACTERIZATION OF *TRICHOGRAMMA* FEMALE VOLATILES LIKELY INVOLVED IN COURTSHIP BEHAVIOUR AND THEIR POTENTIAL USE IN TAXONOMY

I.M.M.S.Silva¹, M. A. Posthumus², R. Stouthamer¹ & T. A. van Beek², ¹ Laboratory of Entomology, Wageningen Univ. and Research Centre, P.O Box 8031, 6700 EH Wageningen, The Netherlands. ² Laboratory of Organic Chemistry, Wageningen Univ. and Research Centre. Dreijenplein 8, 6703 HB Wageningen, The Netherlands.

Egg parasitoids of the genus *Trichogramma* (Hymenoptera, Trichogrammatidae) are widely used in biological control against lepidopterous pests. In order to find taxonomic tools for this group of natural enemies, we characterized volatiles produced by virgin females of several *Trichogramma* species. These compounds are possibly involved in sexual communication of *Trichogramma* wasps. Collection of volatiles was done by Solid Phase Micro-Extraction (SPME). Chemical analyses were performed by means of Gas Chromatography and Mass Spectrometry (GC and GC-MS). For *Trichogramma turkestanica*, volatiles were identified that had not been previously recorded for insects. Index terms: *T. turkestanica*, *T. cordubensis*, *T. pintoi*, *T. evanescens*, *T. bourarchue*

[0729] BIOLOGICAL ACTIVITIES OF PLANT SECONDARY METABOLITES TOWARD INSECTS

<u>M. E. Sosa¹</u>, C. E.Tonn² & O. S. Giordano², ¹ Area de Zoología; ² Química Orgánica INTEQUI-CONICET- Fac. de Química, Bioquímica y Farmacia, Univ. Nac. de San Luis, Chacabuco y Pedernera, 5700, San Luis, Argentina. E-mail:molitor@unsl.edu.ar.

Nowadays the study of allelochemical interactions between insects and plant-secondary metabolites is an important subject in chemical ecology. Plants have developed highly elaborated chemical defences against insect attacks, and that provides a rich source of biologically active compounds. The need to protect our food supply from predatory attack using more ecologically acceptable methods has led to a rapidly growing interest in behaviour-modifying chemicals from natural sources. As a part of our research on plant natural products we started a systematic investigation about the bioactivities of secondary metabolites and chemical derivatives from Compositae and Labiatae families toward Tenebrio molitor L.(Coleoptera: Tenebrionidae) larvae. The structure-antifeedant activity relationship of several clerodane type diterpenoids as well as the role that the hydrophobicity plays in the bioactivity, have been studied. Results suggest that among the furanditerpenes tested , the possession of an α,β -unsaturated - γ -lactone moiety or a C-4 epoxy with C-5-methylacetoxy or C-12 acyloxy substitution are essential for imparting antifeedant and repellent activities in the test system used. On the other hand, the toxicity of sesquiterpene lactones has been determined. The comparison showed that both conjugated a-methylen-y-butyrolactone system and a, B-cyclopentenone ring, were important for the bioactivity. Growth-inhibitory activities of selected natural benzofurans, trans-cinnamic acid derivatives, chromene compounds, and some semi-synthetic derivatives, were determined in last instar larvae via topical administration in acetone. The most inhibitory of the tested compounds, were 3-00-dimethylallyl-p-coumaric acid and the benzofuran derivative 12-(p-cumaroyloxy)-tremetone, the former compound acting on the pupae and the latter on the last instar larvae. Several developmental deficiencies were observed, and some structure-activity relationships were discussed. Finally, nineteen flavonoids were evaluated, in this group of secondary metabolites quercetin reduced significantly the growth of larvae. This report extends that T. molitor is an sensitive insect to plant natural products. These data also identify potential or alternative sources for synthesis of compounds that mimics the aforementioned bioactivities.

Index terms: Tenebrio molitor L.; allelochemicals; antifeedants; growth-regulators

[0728] POLYSACCHARIDASES IN NESTS OF THE LEAF-CUITING ANT ATTA SEXDENS

C. G. Siqueira, M. Bacci jr., F. C. Pagnocca, O. C. Bueno & M. J. A. Hebling, Centro de Estudos de Insetos Sociais, Universidade Estadual Paulista, Rio Claro, SP. CEP.13506-900, Brazil. Supported by FAPESP 97/13383-0, 95/04229-2, and 97-05358-6.

The nests of leaf cutting ant Atta sexdens harbor great amounts of a symbiotic fungus called Leucoagaricus gongylophorus. The fungus is a food source for the ants, especially for larvae, and is likely to provide the insects with proteases. A fundamental question concerning the symbiosis is whether the fungus can efficiently degrade the structural polysaccharides of plant material inside ants' nests, and thus support ants utilization of these compounds. In the present investigation we found that isolated cultures of the symbiotic fungus are able to produce great amounts of pectinase, intermediate levels of amylase and xylanase and few amounts of cellulase. The faecal fluid of ants also contained high activity of pectinase followed by amylase, xylanase and cellulase. The same activities were also detected in the sponge inside ants' nest. These results suggest that the symbiotic fungus is the major producer of depolymerases found in the ants faecal fluid as well as in the sponge, where polysaccharide degradation efficiently occurs. The high amount of pectinases detected indicate that the symbionts need the enzyme to macerate plant tissue and then access nutrients from cut leaves. To better characterize the pectinolytic system acting in ants nests, we have determined pectin esterase (PE), endopolygalacturonase (endo-PG) and exopolygalacturonase (exo-PG) activities of the sponge, fungal cultures, and the faecal fluid of ants. All sources of enzymes presented greate amounts of exo-PG, compared to those of endo-PG or PE. This reinforce the concept that the symbiotic fungus is the main responsible for pectinase production inside ants' nests. In addition the fungus was able to produce pectinases on a variety of carbon sources, including pectin from apple, citric pectin, sodium polypectate, starch, cellulose and xylan. This indicates that the pectinolytic system of the symbiotic fungus is not repressed by carbon sources and thus it is able to generate the greate amounts of enzymes seen in ants' nests.

[0730] PHEROMONES SYSTEM OF LEPTOGLOSSUS ZONATUS (HETEROPTERA:COREIDAE)

C. E. P. Souza^{1, 2}, J. Millar², S. Mc Elfresh², B. F. Amaral-Filho³, R. T. Cardé² & A. Mafra-Neto², 1-Fac. Filos. Ciênc. Letras de Ribeirão Preto, Univ. de São Paulo, Av. Bandeirantes, 3900, Ribeirão Preto São Paulo, Brazil, 14040-901; 2-100 A Chapman Hall Univ. of California - Riverside, Riverside, United States, 92521. 3-Univ. Est. de Campinas- Depto. de Zoologia, caixa postal:6109, Campinas, São Paulo, Brazil.

Leptoglossus zonatus is a coreid bug that occurs in Southwestern of United States, Central America and Northern of South America. In recent years I. zonatus has reached new areas of the South American Continent, mainly in Brazil, where it became widely distributed. L zonatus feeds on several economically important plants such as citrus, soybean, sorghum, cotton, among others. The attack due to feeding can cause losses of more than 15% of the corn production. Feeding on the corn seeds cause them to wither, thus facilitating penetration of microorganisms which increases losses. Behavioral and chemical studies were conducted to identify the chemicals involved in the sexual/aggregation communication of L. zonatus. Bioassays in y-tubes and four-arm arenas indicated that adult males were attractive to other adults, whereas females were not. Chemical analysis of airborne collection from immature and adult L. zonatus showed that males emit sexspecific volatile compounds. Further laboratory arena bioassays with the several synthetic male-specific volatile components indicate that these chemicals attract adults of both sexes. Field traps containing individual synthetic male-specific chemicals or their blend captured nymphs and adults, suggesting that the chemical functions as an aggregation pheromone. Our data suggests that L. zonatus has a long distance chemical communication system mediated by pheromone volatiles emitted by the males.

Index terms: Leptoglossus zonatus, leaf-footed bug, coreid, pheromones. corn

[0731] A COMPARATIVE STUDY OF PHEROMONE DISSEMINATING STRUCTURES IN TERGITES OF SOME *LUTZOMYIA* SPP. (DIPTERA: PSYCHODIDAE)

C. N. Spiegel¹, R. P. Brazil² & M. J. Soares¹, 1. Lab. Biologia Celular de Microrganismos, Departamento de Ultra-estrutura e Biologia Celular, Instituto Oswaldo Cruz / FIOCRUZ, 21045-900 Rio de Janeiro, RJ; 2. Lab. de Leishmanioses, Centro de Pesquisas Reneé Rachou / FIOCRUZ, 30190-000 Belo Horizonte, MG, Brazil. This work has been supported by CAPES and FIOCRUZ.

Sex pheromones are widespread in insects and appear as an option for biological control to vectors of some human diseases, such as Leshmaniosis. Pheromone glands are invariably related with cuticular pores, which allow transport of the pheromone granular are invariably gland to the cuticle surface. The cuticle may be adorned with a variety of architectural modification, allowing a greater surface area for pheromone evaporation. Several Lutzomyia species, the insect vectors of Leishmaniosis, have been described to possess sex pheromone disseminating structures (Ward et al. Bull. Entomol. Res., 83:437-445, 1993), associated to pale tergal spots on some abdominal segments. In this study males of four different species of the Lutzomyia genus were analyzed by scanning electron microscopy. Two species belong to the same species complex: L. longipalpis (vector of Leishmania chagasi, the causative agent of visceral leishmaniosis in the New World) and L. cruzi (a related species incriminated as a vector of leishmaniosis in Mato Grosso state, Brazil). Two species of another complex were also analyzed: L. carmelinoi and L. lenti. New observations could be recorded on the presence of pheromone disseminating structures on the tergites of male sandflies. In L. cruzi and L. longipalpis the pheromone glands were present only on abdominal tergites bearing pale spots, characterized as regions where macrotrichia are absent. The glands were morphologically identical and were present either on tergal segments III-IV or only on segment IV. The glands appeared as small round elevations, 2.3-2.8 μm in diameter, presenting a central pore. On the other hand, in L. lenti and L. carmelinoi the pheromone glands were present on tergal segments V and VI. Furthermore, pale spots could not be observed. The round shape was more pronounced in L. lenti and L. carmelinoi, the glands appearing as small papules containing a central pore. In L. carmelinoi the structures were 2.0-2.9 µm in diameter. Further studies are being conducted by transmission electron microscopy to analyze the pheromone gland organization and the gland cells fine structure.

Index terms: Lutzomyia, pheromone glands, ultrastructure.

[0732] LIFE TABLES OF THE CULTURES APPLIED TO PESTS OF MAIZE UNDER INTERCROPPED CULTIVATION

F.A. Suinaga¹, M. Picanço², C.S. Bastos¹ & J.C.C. Galvão¹, ¹Dept. de Fitotecnia, ²Dept. de Biol. Animal, Univ. Fed. de Viçosa, CEP 36571-000, Viçosa, MG, Brazil, E-mail fsuinaga@alunos.ufv.br.

The objective of this work was to study the losses in yield components of maize (Zea mays) intercropped with common beans (Phaseolus vulgaris) under different doses of mineral fertilizer (0, 250 Kg of 4-14-8 + 100 Kg of ammonium sulfate - AS/ha and 500 Kg of 4-14-8 + 200 Kg of AS/ha) and organic fertilizer (0 and 40 m³ of organic matter/ha). The experimental design was in randomized blocks with four replications and it was conducted in the agricultural year of 1996/97. Plant mortality and losses in each of these yield components: ovules, ears and grains were evaluated, as well as their causes. After that, life tables of the cultures were developed. The highest damage level being responsible for 79% of the total losses was ovules abortion. Besides this cause, the attack of *Helicoverpa zea* and *Spodoptera* spp. (Lepidoptera: Noctuidae) to the ovules was the other cause of losses in this yielding component. This loss was positively correlated with the adults of Diabrotica speciosa (Coleoptera: Chrysomelidae) (r = 0.48; p = 0.0084; n = 24) and Spodoptera frugiperda (r = 0.34; p = 0.0538; n = 24) to the leaves. The main causes of losses in plant component were the attack of S. frugiperda (9.31% of losses) and the perforation of seeds by neonate Coleoptera: Elateridae (2.08% of losses). The highest damage level in ears component was "empty ears" (without grain or ovules). In the grains component, the main pests related to these losses were: Sitophilus zeamais (Coleoptera: Curculionidae) (22.82%), H. zea and Spodoptera spp. (5.79%). Mineral and organic fertilization increased pests attack in maize intercropped with common beans. Higher adult populations of D. speciosa and S. frugiperda were verified with organic fertilization. Larger attack of S. frugiperda was also observed with the increase of mineral fertilization. Index terms: Life table, Diabrotica speciosa, Spodoptera frugiperda, Sitophilus zeamais, Helicoverpa zea

[0733] IDENTIFICATION OF *CAMERARIA OHRIDELLA* SEX PHEROMONE AND ITS POSSIBLE USE IN HORSE CHESTNUT PROTECTION

A. Svatos, B. Kalinova, M. Hoskovec, J. Kindl, O. Hovorka & <u>I. Hrdy</u>, Department of Natural Products, Institute of Organic Chemistry and Biochemistry, Academy of Sciences of the Czech Republic, 166 10 Prague 6, Czech Republic. E-mail: svatos@uochb.cas.cz.

The horse-chestnut leafminer Cameraria ohridella Deschka & Dimic (Lepidoptera: Gracillariidae) is presently the most dangerous pest of horse-chestnut, Aesculus hippocastanum L in Southern and Central Europe. At present, the possibilities to control this pest are rather limited (raking of the damaged leaves, spraying with insecticides). Sex pheromone can represent a basis for an alternative - designing an integrated pest management (IPM) program. The major component of a sex attractant released by virgin females of the horse-chestnut leafminer was identified in picogram quantities as (8E,10Z)-tetradeca-8,10-dienal. The spectral methods were not used, the identification relied entirely on alternative analytical methods like (1) gas chromatography with electroantennographic detection (GC-EAD), (2) calculation of Kovats' retention indices of the active principle on different GC phases, and (3) construction of EAG response profiles to C_{12} and C_{14} saturated and unsaturated standards with different functional groups. The synthetic pheromone was prepared by a stereospecific synthesis and shown to be highly active for conspecific males and was proved to be fully comparable to the natural substance in all respects. The potential use of the pheromone to protect horse chestnut trees in Europe is discussed.

Index terms: horse-chestnut leafminer, Lepidoptera, Gracillariidae, EAG, GC-EAD, wind tunnel, field test, delta-traps

[0734] PHEROMONE-BASED MATING DISRUPTION OF THE INDIAN MEAL MOTH *PLODIA INTERPUNCTELLA* (LEPIDOPTERA: PYRALIDAE) USING SINGLE- AND MULTI-COMPONENT BLENDS

G. P. Svensson, C. Ryne & C. Löfstedt, Dept. of Ecology, Lund Univ., Solvegatan 37, SE 223 62 Lund, Sweden.

The Indian meal moth, Plodia interpunctella (Lepidoptera: Pyralidae), is a serious indoor pest on stored products (grains, seeds, dried fruit etc). As populations have developed multi-resistance towards insecticide treatments, there is a need for new methods to control this species. Pheromone-based mating disruption may be an effective alternative to traditional management. The first identified sex pheromone component of P. interpunctella, Z9,E12-14:OAc, was reported in 1971. Recently, a reidentification revealed three additional components as part of the sex pheromone blend, namely Z9-14:OAc, Z9,E12-14:Ald and Z9,E12-14:OH. We performed small-scale mating disruption experiments in a green-house to evaluate the potential to control this species by means of sex pheromones. Male and female moths were introduced into 2.5 x 2.5 x 2.5 m transparent plastic tents under a natural dark-light regime. Insects were recaptured after 24 hrs and mating success was determined as presence or absence of spermatophores in females. Pheromone was emitted from controlled-release devices (MSTRS™). Two disruption blends were used: Z9,E12-14:OAc alone or the complex, four-component, blend. Mating frequencies at different doses (5, 50 or 250 □g of Z9,E12-14:OAc emitted per minute) were estimated. Mating disruption was significantly lower at the lowest dose compared to the two higher doses. However, no difference in mating frequency was observed between blends at similar doses. In addition, the disruption effect at different moth densities (10, 20 or 30 individuals per tent) was investigated. At the lowest and highest densities, surppression of matings was lower compared to the intermediate density. No difference was observed between blends at similar densities. EAG recordings were performed using a portable device in combination with air-sampling to determine the concentrations of pheromone in control and treatment tents. Although the tents were provided with ventilation, a significant increase in EAG responses in the treatment tents during the experiments was observed, indicating ackumulation of pheromone. However, this increase in pheromone concentration was not paralelled with increased surppression of matings. No increase in EAG responses was observed in control tents. Aerial concentrations of Z9,E12-14:OAc and Z9-14:OAc in treatment tents ranged from 52 to 433 ng per m³ and from 29 to 121 ng per m³, respectively. In summary, our results indicate that pheromone-based mating disruption can be an effective way to control populations of P. interpunctella. Surprisingly, Z9,E12-14:OAc alone is as effective as disruptant as a complex blend.

Index terms: sex pheromone, pest control, electroantennogram, MSTRSTM

[0735] FEEDING BEHAVIOUR OF PEA APHID ON ALFALFA

S. Szynkarczyk, <u>B. Leszczvnski</u>, J. Markowski & H. Matok, Dept. of Biochemistry, Univ. of Podlasie, Prusa 12, PL-08110 Siedlee, Poland, E-mail leszczb@ap.siedlee.pl

Pea aphid, Acyrthosiphon pisum Harris is one of the most important insect pests on alfalfa (Medicago sativa L.). Preliminary evidences suggest that the aphid feeding cause foliar damage and increase in cournestrol content in the infested alfalfa plants. On the other hand, it is well documented that alfalfa contains saponins with a variety of biological activities. The present paper reports on feeding behaviour of the pea aphid on alfalfa lines containing different level of saponins. Alfalfa selected lines with high and low content of saponins were used in the experiment. EPG (electrical penetration graphs) recordings of the pea aphid feeding behaviour on thigh and low- saponin lines were performed. There was no clear difference in duration of total tissue probing of the alfalfa. The aphids fed on low-saponin lines showed slightly shorter pathways phase (penetration of epidermis and mesophyll). Phloem phase (salivation into sieve elements and phloem sap ingestion) was prolonged on such lines, and no clear difference was observed during ingestion of xylem sap. Importance of the retaliations between saponin concentration and the pea aphid performance on the alfalfa is discussed.

Index terms: Acyrthosiphon pisum, alfalfa, saponins, EPG

Symposium and Poster Session

[0737] APHID ENZYMES INVOLVED IN DETOXICATION OF CEREAL ALLELOCHEMICALS

A. Urbanska, <u>B. Leszczynski</u> & H. Matok, Department of Biochemistry, University of Podlasie, B. Prusa 12, PL-08110 Siedlee, Poland, E-mail leszczb@ap.siedlee.pl

Cereal xenobiotics e.g. hydroxamic acids, phenolics and flavonoids are involved in resistance to aphids. However, aphids are able to survive on cultivars with relatively high concentrations of these allelochemicals, since they developed specific adaptive enzymes that enable them to detoxify the toxic plant allelochemicals. Present paper reports on participation of several oxidoreductases and transferases of the grain aphid *Sitobion avenae* (Fabr.) and bird cherry-oat aphid *Rhopalosiphum pndi* (L.) in detoxication of the cereal allelochemicals. Activity of polyphenol oxidases, peroxidases, UDP-glucosyl transferases, glutathione-S-aryltransferases, aryl sulphotransferases and phosphotransferases has been found in the aphid tissues. The studied oxidoreductases act both in host-plant tissues, due to the action of secreted aphids' saliva and within their alimentary track. Activity of the second phase transferases is located mostly in the aphids' midgut. Studied enzymes are specific to: monophenolics, *o*-dihydroxyphenolics, methoxyphenolics and flavonoids, naturally occurring in the cereals. However, not always relatively high concentrations of the allelochemicals within the creat issues, induced the activity of the aphid enzymes. Importance of oxidation of the plant phenolics and their conjugation with glucose, glutathione, sulfate and phosphate for chemical interactions between cereal aphids and their host plants is discussed.

Index terms: Sitobion avenae, Rhopalosiphum padi, cereal allelochemicals, detoxifying enzymes.

[0736] A NEW AUTOMATIC BIOASSAY TO TEST THE ATTRACTION OF HOST STIMULI IN CRAWLING INSECTS

S. Trenner, M.Hofmann, H. Bleckmann & H. Schmitz, Institut für Zoologie, Poppelsdorfer Schloß, D – 53115 Bonn. EMAIL: uzsjvm@uni-bonn.de

A semi- automatic setup was designed to test the attraction of various sensory stimuli on crawling insects. Especially in long lasting experiments in which many animals must be tested, our approach has a considerable advantage. The setup consists of a starting box (35 x 20 cm, height 20 cm) with two openings at opposite sides. Each opening leads to a "downfall module" (PCV, 3 x 5 cm, height 13 cm). Inside each module, a turnable plastic cylinder is installed. If an insect crawls into a downfall module, it steps onto the cylinder, which starts to turn. Consequently the insect falls into a corresponding collecting box. In the wall of the downfall module, opposite to the opening in the starting box quadrangular hole (3 x 3 cm) was made. The hole can be closed either by a piece of PVC or a stimulus can be presented through it. All downfall modules are equipped with a photoelectric barrier. With aid of a computer, single downfall events and the time of their occurrence can be registered. To demonstrate the suitability of our setup we tested starved 3^{rd} instars of the Chagas bug Triatoma infestans (N = 12). We offered a natural host stimulus (living mouse) and single components of it (warmed mouse skin, cold mouse skin, warm air gradients). In control experiments no stimulus was presented. In controls 8% and 10% of the bugs were found in the collecting boxes, respectively. When a living mouse was presented, 58% of the bugs were trapped in the corresponding collecting box and 19% in the control collecting box. A warmed mouse skin attracted 45% of the bugs (control: 19%), whereas warm air generated by a Peltierelement (38° C) trapped 42% (control: 13%). All differences were significant (χ^2 -test, p < 0.01). A mouse skin at room temperature was not attractive (7%/7%). With aid of our setup we were able to show with a minimum effort that a living mouse offers all necessary stimuli for the bloodsucking bug Triatoma infestans to approach the host. A thermal stimulus alone was effective as well, but not as effective as a combined thermal/olfactory stimulus (warmed mouse skin). A cold mouse skin did not attract the Chagas bugs. Time profiles of the downfall events showed that the bugs were most active in the first two hours after a 30 min dusk (lasting from 6:30 - 7:00 p.m.). In single cases the activity lasted past midnight. A second smaller peak was observed two hours before dawn (which was set from 6:30 to 7:00 a.m.).

[0738] NEW TOOLS TO CONTROL APHID PESTS: REPELLENT ODOURS

<u>J.H. Visser</u> & W.J. de Kogel, Plant Research International, Business Unit Biointeractions & Plant Health, Wageningen UR, P.O. Box 16, 6700 AA Wageningen, The Netherlands, E-mail j.h.visser@plant.wag-ur.nl

In temperate regions aphids are important pest insects on a large variety of crops, such as potatoes, sugar beets, lettuce, cucumbers, sweet peppers, tulips, lilies and roses. Since aphids transmit plant viruses, current insecticides do not prevent crop damage by non- and semi-persistent viruses. In order to develop new tools to control aphid pests and subsequent virus infections, a programme on plant-odour derived aphid repellents was started at Plant Research International in cooperation with TNO Industry and Dutch experiment stations. The programme addressed a sequence of questions: (a) what do aphids smell, (b) which of the components perceived by aphids are repellent, (c) how do particular repellents affect aphid colonisation and reproduction, and (d) can particular repellents control aphid pests. By means of electroantennogram recordings of aphids, a large collection of plant odour components was tested on Myzus persicae, Aphis fabae, Megoura viciae and Brevicoryne brassicae. The odour response profiles were differentiating for species-specific traits as well as general aphid response characteristics. In special designed olfactometers the behavioural responses of aphids were tested to a range of components selected from the previous electroantennogram screening. A number of volatiles were very repellent to aphids and their repellency was consistent for a number of aphid species including Aphis gossypii. The effect of these repellents on aphid colonisation was tested in dual-choice leaf disk bioassays: one leaf disk sprayed with just the formulation compared to another leaf disk sprayed with the formulation containing the repellent. Aphids avoided the leaf disk sprayed with the repellent formulation, and at a range of concentrations the repellency was consistent over a two-weeks period. One repellent component in a particular formulation showed, in addition, strong effects on mortality and reproduction of sphids: it acted as an insecticide. This repellent formulation was tested in greenhouses in comparisons of treated and untreated plants for Aphis gossypii on cucumbers and Myzus persicne on Chinese cabbage. In both aphid-plant combinations the repellent formulation controlled aphid populations very well. Further field evaluations of this repellent formulation will be performed this summer. Index terms: insecticides, Aphis gossypii, Myzus persicae, Myzus nicotianae

[0739] PRELIMINARY STUDY ON THE BEHAVIOR OF SELECTING HOST OF LONGHORNED BEETLES AND THE ROLE OF THEIR SENSE ORGANS IN THIS PROCESS

F.G. Waug¹, J. X. Zhou² & X. Y. Yaug², ¹ P.O. Box 11, Res. Inst. Of Forest Ecol., Environ. and Protec., Chinese acad. Of Forestry, Beijing 100091, P. R. China, E-mail fugui@prot.forestry.ac.cn, ²Northwest Forestry College, Yangling 712100, Shaanxi, P. R. China.

Longhorned beetles (Anoplophora nobilis) cause serious damage and loss on poplar, willow in north China. Planting mixed forest was thought a better measure to control them, replenish the loss of forest and gradually replace pure forest according to previous research. But how to afforest mixed forest is a mystery which need to be exposed. Hence, the selecting-host behavior of longhorned beetles should he studied as a basis for making a strategic decision. In 1994, the behavior of selecting host of longhorned beetles was observed in a mixed forest consisted of 30 species of trees. The results showed: for different species of trees, the longhorned beetles had different selecting-host behavior respectively. The susceptive host trees in mixed forest, such as acer oliverianum, could finally be selected by a complex, time-consuming and gradual sense behavior. After a few longhorned beetles fed, mated on them, it was sure that more longhorned beetles would be attracted to them, and finally the susceptive trees were damaged seriously. It was obvious that longhorned beetles were attracted by the odor of hosts firstly, then by intraspecific sex attraction. However, for some species of trees, such as platycladus orientalis and robinia pseudoacacia, longhorned beetles loved to approach to them, selected them and sometimes inhabited on them for a long time, but they didn't feed on them and had no mating behavior. It was thought that the odor of host trees apparently influenced this behavior of longhorned beetles. So, mixed forest could only delay the time that longhorned beetles reached susceptive hosts, but it couldn't effectively prevent their invasion. When afforested, many trees, like platycladus orientalis, should be planted and a few susceptive trees, like acer oliverianum or poplar, should be planted as trap trees in mixed forest. Generally, longhorned beetles probed which species of trees they liked by swinging antenna, rubbing tarsus besides vision before they reached them. Beetles' compound eyes or visual sense was the most important sense organ, and the next is antenna and tarsus. If losing vision, longhorned beetles would not know where they should head for, often went around at one place, and lost their most flying ability. Labial palpi and maxillary palp functioned only when longhorned beetles probed which food was flavorful or delicious. Tarsus was useful and indispensable in the whole selecting-host procedure because, together with other sense organs, it often supplied information for longhorned beetles to affirm hosts.

Index terms: Anoplophora nobilis, behavior, selecting host, sense organs, forest.

[0740] LOOKING AT PESTS THROUGH THE ANTENNAE OF THEIR PARASITES: HOST PHEROMONES AND BIOCONTROL

A. Zhang & J. R. Aldrich, USDA-ARS Insect Chemical Ecology Laboratory, Agricultural Research Center-West, B-007, Beltsville, MD 20705, USA, E-mail: azhang@asrr.arsusda.gov.

The southern green stink bug (SGSB), Nezara viridula (Heteroptera: Pentatomidae), is a serious agricultural pest worldwide. Its host range includes soybean and other field crops, a variety of fruits and nuts, and many vegetables. The parasitoid fly, Trichopoda pennipes (Diptera: Tachinidae), is the only native tachinid fly that has naturally adopted the SGSB as a host since its accidental establishment in the southeastern U.S. some 200 years ago. However, T. pennipes introduced into Hawaii from Florida failed to parasitize N. viridula, and *T. pennipes* fails to attack the squash bug, *Anasa tristis* (Coreidae), in California although *A. tristis* is the most common host of this parasitoid in the northeastern U.S. These observations suggest that different strains of T. pennipes exist in the U.S. Sexually mature males of N. viridula release a sex pheromone containing isomers of the sesquiterpenoid, 1,2-epoxy-(Z)-D-bisabolene, and females of T. pennipes use the pheromone as a signal (a "kairomone") to find this host. We report here that geographically isolated populations of T. pennipes gave dramatically different antennal responses to pheromone extracts of N. viridula and certain native host species. This is the first experimental verification that kairomone-strains of T. pennipes exist, and demonstrates that electro-physiological screening of parasitioids prior to classical biological control introductions could avoid inevitable failures. In addition, we have found that the antennae of tachinid parasitoids are commonly 5-10 times more sensitive to the pheromone of their hosts than are the antennae of the host species themselves. Therefore, we plan to try to use the antennae of the T. pennipes strain that prefers to parasitize squash bugs as a means to identify the sex pheromone of this pest.

Index terms: Kairomone, Nezara, Trichopoda, Anasa, bisabolene.

[0741] ANTENNAL AND BEHAVIORAL RESPONSES TO NONHOST ANGIOSPERM LEAF AND BARK VOLATILES BY CONIFER INSECT

O. II. Zhang¹, G.T. Liu², F. Schlyter¹, G. Birgersson³, P. Anderson¹ & P. Valeur⁴, ¹Dept. of Plant Protection Sciences, Swedish Univ. of Agricultural Sciences, P. O. Box 44, S-230–53 Alnap, Sweden, E-mail: qing-he.zhang@vsv.slu.se; ²Baiyinaobao Natural Preserve, 025375 Inner Mongolia, P. R. China; ³Chemical Ecology, Dept. of Botany, Göteborg Univ., Box 461, S-405 30 Göteborg, Sweden; ⁴Dept. of Ecology, Lund Univ., S-223 62 Lund, Sweden.

Leaf and bark volatiles from non-host angiosperm trees were tested on the conifer bark beetle, lps duplicatus by gas chromatographic-electroantennographic detection (GC-EAD) and by pheromone-baited traps in Sweden and Inner Mongolia, China, respectively, GC-EAD analysis of the headspace volatiles from fresh bark chips of Betula pubescens revealed trans-conophthorin, two green leaf volatiles (GLVs): 1-hexanol and (Z)-3-hexen-1-ol, and two C8-alcohols: 3-octanol and 1-octen-3-ol, that consistently elicited antennal responses by I. duplicatus. The identification of these antennally-active compounds was confirmed in further GC-EAD recodrings with synthetic mixtures. Antennal responses were also found to synthetic (E)-2-hexen-1-ol, that has been identifed from the leaves of non-host birch and aspen species. In field trapping experiments, blends of antennally active, GLV alcohols or C8-alcohols, or trans-conophthorin alone resulted in significant reductions (27-60%) in the number of I. duplicatus captured compared with the pheromone-baited trap. The unsuitable host compound, verbenone, also significantly reduced the trap catches up to 60% in both experiments. The strongest disruptive effect resulted from the addition of the combination of GLV-alcohols, Cg-alcohols and Vn to the pheromone trap, which caused 84% of trap catch teduction. The blend of two GLV aldehydes plus the acetate increased the trap catches in 1998 and had no negative or positive effects in 1999. Our results suggest that these nonhost leaf and bark volatiles are important olfactory signals used by *I. duplicatus* in descriminating between host and nonhost species. They may have great significance in developing semiochemical-based management program against the outbreaks of I. Juplicatus by reducing attacks on suitable hosts and thereby decreasing population levels and damage.

Index terms: *Ips duplicatus*, host selection, nonhost volatiles, NHVs, Green leaf volatiles, GLVs,

[0742] INFLUENCES OF PLANT-DERIVED SEMIOCHEMICALS ON BEHAVIOR OF APHIDS

Z. N. Zhang & F. Zhang, State Key Lab. of Integrated Management of Pest Insects & Rodents, Inst. of Zoology, The Chinese Academy of Sciences, Beijing 100080, China, E-mail: zhangzn@panda.ioz.ac.en.

Some plant-derived semiochemicals were found with activity to aphids. A compound extracted from radish, Raphanus sativus L., was identified its' structure as 4isothiocyanato-1-methylthio-1-butene by GC-MS. Myzus persicae and Macrosiphum avenae showed EAG response to the compound in electrophysiological experiment (n=9, P=0.001) and the compound showed high attraction activity to aphids in field test (n=8, P=0,001). A compound extracted from catmint, Nepeta cataria L.- (+)-(4as,7s,7aR)nepetalactone — as one of the pheromone of many aphid species. The contents of nepetalactone in flower, leaves, tender stem were 0.237%, 0.052% and 0.033% respectively. The compound showed high attractive activity in field: M. persicae were caught in large numbers in water traps baited with plant-derived nepetalactone in peach orchard and cabbage garden; Aphis sp. and Schizaphis graminum males were attracted in wheat field. Alate virginoparae were also attracted by plant-derived nepetalactone in the field. The numbers of aphid overwintering eggs of M. persicae were reduced 47.6% as mass trap male aphids by the two synthetic components: nepetalactone plus nepetalactol (1:1) in peach orchard. Benzaldehyde, a major component of the volatile from the Prunus persica extract, enhanced the attractancy of aphid sex pheromone. M. persicae males and gynoparae respond to peach leaf volatiles in the field, but not to benzaldehyde alone. (E)β-farnesene as aphid alarm pheromone existed in some plants. It was found in barley leaves. Host plants influence on alarm pheromone behavior of aphids. The dispersive response of Aphis gossypii Glover to (E)-\beta-farnesenc on Lagenaria siceraria and Gossypisum hirsutum was more sensitive than that on Cucumis sativus. Index terms: Myzus persicae, Aphis gossypii, semiochemicals, behavior

Session 05 – COMPUTER SCIENCE APPLIED TO ENTOMOLOGY

Symposium and Poster Session

[0743] STUDIES OF FORAGING FLIGHTS WITH HARMONIC RADAR.

J. R. Riley, A. D. Smith & D. R. Reynolds, Natural Resources Institute Radar Unit, Univ. of Greenwich, North Site, Leigh Sinton Road, Malvern, Worcestershire WR14 1LL, UK. Email: jriley@nriradar.demon.co.uk.

Most of our current knowledge about the high-altitude flight behaviour of insect migrants has been derived directly from observations made with conventional entomological radars. Until recently, however, it has not been possible to use this very powerful technique to study the foraging behaviour of insects flying close to the ground. This is because the strong echoes reflected from ground features and from vegetation ("clutter"), usually mask the very tiny signals returned from insects. We have overcome this constraint by attaching small transponders to the insects we wish to track. The transponders send back signals at the second harmonic of the radar frequency, and these signals can be detected even in the presence of very strong clutter. The range of detection (900 m) vastly exceeds that of human vision, and the radar also provides dynamic and geometrically accurate records of the insects' flight paths. By presenting some examples of the radar flight trajectories of bumble bees, honey bees and moths, we show that harmonic radar has introduced a new era into the study of insect flight, bees, moths

[0745] TRACKING ALPINE BUTTERFLY MOVEMENT USING HARMONIC 'RADAR'

<u>J. Roland</u>, Department of Biological Sciences, University of Alberta, Edmonton, Alberta, Canada, T6G 2E9., S. Matter, Department of Biological Sciences, University of Alberta, Edmonton, Alberta, Canada, T6G 2E9, and C. Backhouse, Department of Electrical and Computer Engineering, University of Alberta, Edmonton, Alberta, Canada. T6G 2E9.

Dispersal of alpine *Parnassius* butterflies is well estimated for males by the use of markrecapture techniques, but because females are relatively secretive, other methods must be used to adequately estimate their movement. We have developed extremely small (0.4mg) harmonic 'radar' tags which flying butterflies can carry. We use these tags to estimate daily dispersal of female *Parnassius smintheus* butterflies in the Rocky Mountains of Alberta, Canada, by repeated location of tagged females over the period of the study. Data are used to help estimate the effects of changing landscape structure on dispersal and colonizing ability.

Index terms: dispersal, direction finder, alpine, butterfly

[0744] AUTOMATICALLY OPERATING RADARS FOR MONITORING INSECT PEST MIGRATIONS

V.A. Drake, I.T. Harman & II.K. Wang, School of Physics, University College, The University of New South Wales, Australian Defence Force Academy, Canberra, ACT 2600, Australia. E-mail: a.drake@adfa.edu.au.

The Insect Monitoring Radar (IMR) allows insect migration to be observed automatically at remote sites, so that long data series can be accumulated without incurring the high costs associated with maintaining an observer in the field for an extended period. The IMR employs a vertical beam and combines a conical scan with linear polarization, to produce a complex echo signal containing information about the trajectory of an overflying target, and the target's orientation, size, and shape. A second operating mode provides information on target wingbeat frequencies and amplitudes. The IMR operates under computer control, and alternates periods of data acquisition with periods of processing during which the target parameters are retrieved from the recorded signals. The results of these analyses can be downloaded daily to the base laboratory via a telephone link. Summary statistics and graphical representations of the data can then be produced for interpretation by pest forecasters and incorporation into a database. Summaries can also be placed on a server for dissemination to users via the internet. A network of two IMRs connected to a central communications node and server has been operating in eastern Australia since mid-1999. The IMRs are sited in the semiarid zone ~1000 km from the communications node and base laboratory in Canberra. The capabilities of this network will be illustrated with data from the two IMRs, and related to the requirements of operational forecasting of Australian plague locusts *Chortoicetes terminifera* and native budworm Helicoverpa punctigera - two important migratory pests that frequently build up populations within the region where the IMRs are located.

Index terms: Chortoicetes, Helicoverpa, locust, forecast, internet-

[0746] COMPUTERIZED VIDEO TRACKING, MOVEMENT ANALYSIS AND BEHAVIOR RECOGNITION IN INSECTS

L.P.J.J. Noldus, M.O.S. Buma, R. Lievaart, F.J.F.W. van Rijswijk & R.A.J. Tegelenbosch, Noldus Information Technology b.v., Costerweg 5, P.O. Box 268, 6700 AG Wageningen, The Netherlands. E-mail: info@noldus.nl.

During the past decade, video tracking technology has evolved dramatically. Early systems, based on analog video and hard-wired electronics, were only able to track a single animal under very stringent light conditions and in highly artificial environments, Modern systems, based on full-color video frame grabbers and flexible software, can track multiple animals simultaneously against a variety of complex backgrounds. In 1993, we introduced EthoVision[®] as a general-purpose video tracking, movement analysis and behavior recognition system. Based on feedback from users around the world, the system has undergone numerous updates over the years, which has resulted in a very comprehensive package for studies of movement and behavior. The software has recently been redesigned from the ground up for 32-bit Windows platforms, with a highly interactive graphical user interface for display of experiment design, experimental arena and movement tracks. In the talk, we will outline the basics of digital image processing, movement tracking, path analysis and behavior recognition. Special attention will be given to the hardware and software components of a video tracking system. A comparison will be made between video tracking and other detection techniques such as radar, radio tracking and infrared beam activity measurement. Next, the design and operation of EthoVision for Windows will be presented. The focus will be on experiment design, arena definition, data acquisition, visualization and analysis. We will review various quantitative parameters with which insect movement can be described. Finally, we will report on our research into new methods of multi-object tracking and behavior recognition. Algorithms have been developed that allow an objective quantification of interactions between individuals. Examples will be taken from studies of foraging behavior, chemo-orientation. host-parasitoid interaction and social behavior.

Index terms: video tracking, movement analysis, behavior recognition, computer software. EthoVision

[0747] DEVELOPMENT OF AN OPTICAL FLYING INSECT DETECTION AND IDENTIFICATION SYSTEM (OFIDIS)

A. Moore, 57 Belmont Ave., Ottawa, Ontario, K1S 0V2, Canada, E-mail AubreyMoore@home.com.

The Optical Flying Insect Detection & Identification System (OFIDIS) has three components: light source, photosensor, and data logger. The photosensor produces a modulated voltage signal whenever it detects light reflected off the wings and body of a flying insect. This signal is digitized, stored, and analyzed by the data logger. When a typical insect wingbeat waveform recorded by OFIDIS is converted into a frequency spectrum using the fast Fourier transform, several frequency components are revealed: the insect's wingbeat frequency, plus harmonics that occur at integer multiples of the wingbeat frequency. Recent research indicates that wingbeat spectra contain species-specific information, in addition to the wingbeat frequency, that can be used for automated identification of individual flying insects. A prototype system is being evaluated in a variety of laboratory and field studies. This system uses either the sun or an infrared LED array as a light source. The photosensor signal is digitized by the sound card of a personal computer. Wingbeat waveforms are detected and logged by a transient waveform recorder program. Potential applications for OFIDIS are: 1- Automated monitoring of pests and biocontrol agents in integrated pest management programs. 2- Automated monitoring of mosquitoes and other insects of importance to public health. 3- Automated monitoring of pollinator and forager activity. 4- As a research tool for studying insect movement and effects of attractants and repellents. 5- As a taxonomic aid

Index terms: wingbeat waveform, wingbeat spectrum, fast Fourier transform.

[0748] VIDEO ANALYSIS OF APHID FLIGHT BEHAVIOUR

J. Hardie & G. Powell, Aphid Biology Group, Dept. of Biology, Imperial College at Silwood Park, Ascot, Berks SL5 7PY, UK, E-mail j.hardie@ic.ac.uk.

We have used video techniques to study the flight behaviour of aphids over a number of years. Experimental approaches include: 1) assessment of behaviour prior to, and of time to, take-off under defined conditions; 2) two-dimensional analysis of responses to visual stimuli in a video-computer automated vertical wind tunnel; 3) three-dimensional analysis of flight tracks in the laboratory and field. This presentation will concentrate on studies of the host-alternating black bean aphid, Aphis fabac. When young adult winged aphids are placed on host or non-host plant material they may stay and settle or fly off. The use of close-up video has allowed us to show that the autumn winged females of A. fabae (gynoparae) can discriminated between a summer (broad bean, Vicia faba) host and the winter, relevant (spindle tree, Euonymus europaeus) host within a 5-min period. Plant factors detected during brief (epidermal) stylet penetration appear to be responsible for this discrimination. Individual winged A. fabae can be flown for many hours in a vertical wind tunnel when changes in the rate of climb are countered by corresponding changes in air flow. Such control may be automated by coupling the video signal of the flying aphid, through a computer, to air flow control, The flight track of the insect can be saved for later analysis and responses to visual stimuli presented during flight can be observed. Studies have revealed major differences in initial flight behaviour between summer and auturn forms as well as a maximum response to a visual target illuminated with green monochromatic light at *cai* 550 nm. To obtain a more accurate analysis of flight we developed a video technique to examine three-dimensional aspects of aphid flight tracks. By mixing the signals from two cameras with overlapping fields of view, two images of the insect appear on the monitor and the distance between them is proportional to the distance from the cameras. The xyz co-ordinates during flight can then be calculated at up to 50 Hz and flight track parameters computed. We have used this technique for aphids flying in a horizontal wind tunnel in the laboratory and, when coupled to an ultrasonic anemometer, in the field. Studies show that aphids tend to land into the wind Index terms: Aphis fabae take-oft, visual stimuli, three-dimensional

[0749] TRANSMISSION OF MUSCLE POTENTIALS DURING FREE FLIGHT OF LOCUSTS

W. Kutsch, Fakultät für Biologie, Universität, 78457 Konstanz, Germany

One of the most conspicuous features in evolution is the flight capability in insects. For over 40 years scientists have being trying to understand the evolution and ontogeny of flight, and the aerodynamics, morphology and physiology underpinning it. Earlier studies had to be carried out on tethered animals, but recent achievements made it possible to investigate the muscle potentials of insects flying freely within laboratory arenas. We have developed a radio system that transmits muscle potentials during the free flight of the large locust, Schistocerca gregaria. The device, which is mounted to the insect's prothorax weighs only about 10 % of its body's mass, and so does not restrict the animal's ability to fly normally. When combined with video-monitoring the system allows to record the electrical activity of certain muscles (EMG), and then to investigate how this activity is associated with several flight parameters, e.g. flight speed, wing-beat frequency, ascent and body angle. Careful interpretation of the EMG records yields information on the recruitment of muscles at the level of individual motor units and, therefore, reflects the activity of identified motoneurones. Our results corroborated several earlier findings derived from tethered animals, but also produced data that could not be obtained previously. The recordings reveal a basic flight motor pattern that permits free flight, and show how it becomes modified to allow deviation from a straight horizontal flight path. Recent studies supplemented by high-speed video recordings show muscle recruitment correlated to fine movements of the wings. The effects on the motor pattern produced by interfering with peripheral sensory systems were also studied. It is expected that further technical achievements will facilitate the construction of multi-channel devices allowing the transmission of several synchronous events, e.g. several EMGs, EMG and receptor activity, EMG and specific aspects of the wing movement. Index terms: telemetry, video-monitoring, flight parameters

[0750] SIMULATION OF INSECT MOVEMENT WITH RESPECT TO PLANT ARCHITECTURE AND MORPHOGENESIS

J. S. Hauan¹, **P. W. Prusinkiewicz²**, **M. P. Zalucki³**, **S. Dorosh² & D. J. Skirvin⁴**, ¹Centre for Plant Architecture Informatics, The University of Queensland, Australia 4072, Fax: +617-3365-1477, E-mail: jim@cpai.uq.edu.au; ²Dept of Computer Science, University of Calgary, Alberta, Canada T2N 1N4; ³Dept. of Zoology and Entomology, The University of Queensland, Australia, 4072; ⁴ Horticulture Research International, Wellesbourne, UK, CV35 9EF.

A plant represents a highly heterogeneous habitat to an insect moving around or over its surface. Properties of plant parts vary within a complex canopy architecture, and insect damage can induce further changes that affect an animal's movements, development and likelihood of survival. Up to now, however, entomologists, evolutionary biologists and ecologists interested in insect-plant interactions have usually abstracted from the threedimensional (3D) architecture of plants because of the lack of an appropriate methodology for expressing the movements of insects over the plant surface or among plants, and for capturing interaction between the insects and the plants at the scale of individual organs. We present an approach to simulation of insect behaviour around and on growing plants. Models of plant architectural development based on Lindenmayer systems serve as dynamic platforms for the simulations, providing an explicit model of the developing 3D structure of a plant, as well as allowing physiological processes associated with plant growth to be simulated. Movement of phytophagous insects on the plant can be modelled, along with associated behaviours such as feeding. Once feeding has occurred, the plant model can explicitly describe responses to damage, such as release of apical dominance when a meristem is removed, or induction of defences. We extend such models to tritrophic interactions by modelling predators searching for prey on arrays of virtual plants, as well as oviposition behaviour by adult butterflies moving between host plants growing in a virtual field. The latter step closes the loop. Eggs laid on virtual plants hatch to become virtual caterpillars damaging the plants and being subject to predation by virtual predators. We present simple examples of this approach operating at different spatial scales, from caterpillars foraging on an individual plant to interactions of adult male and female butterflies around a patchy distribution of plants in a field. Such models can be used to explore questions about the consequences of changes in environmental architecture and configuration on host finding, exploitation and its population consequences. We have in effect created a "virtual ecosystem" laboratory to address local as well as landscape level questions perlinent to plant-insect interactions, taking plant architecture into account Index terms: insect behaviour model, plant architecture model, Lindenmayer systems

[0751] SPATIAL ANALYSIS OF HELIOTHIS DISTRIBUTION AND ABUNDANCE FOR MEASURING THE EFFECTS OF MOTH MOVEMENT AT THE REGIONAL SCALE

W. A. Rochester¹, M. P. Zalucki¹, A. Ward², M. Miles² & D. A. H. Murray², Department of Zoology and Entomology, The University of Queensland, Brisbane Qld 4072, Australia, E-mail: w.rochester@epitt.uq.edu.au; ². Queensland Department of Primary Industries, PO Box 102, Toowoomba Qld 4350.
