Females of the wax moths Galleria mellonella and Achroia grisella, deposit its eggs in the comb cells of the beehives. After the eclosion, each caterpillar begins feeding of honey and later on the wax of the comb, building many tunnels of silk and feces in the whole beehive. The method of chemical control of the moths is unsatisfactory, basing on fumigation and the use of this method causes inevitable contamination in the products of the beehive. The biological agent used against the moths is the endoparasitoid Apanteles galleriae. In this work the preferential host species was determined to the activity of posture of Apanteles galleriae. The reproductive capacity of females of this endoparasitoid was evaluated in fifth instar caterpillars of Galleria mellonella and Achroia grisella fed with standard diet and diets enriched with protein; the effect of the development of Apunteles galleriae females in caterpillars of Galleria mellonella or Achroia grisella on its capacity to discriminate one of those hosts, and the reproductive capacity of females of Apanteles galleriae in fifth instar caterpillars of Galleria mellonella and Achroia grisella, with variable weight, were also evaluated. The parasitoids were maintained in flasks of 30 ml with bored caps covered with net, where the food was placed (diluted honey or diluted honey + pollen). The caterpillars and the adults of Galleria mellonella and Achroia grisella were maintained in metallic recipients with caps covered by very fine metallic mesh, containing food (comb and artificial diet). The tests were accomplished in clean and sterilized Petri dishes. Females of Apanteles galleriae preferred to parasitize caterpillars of Achroia grisella, on the average, in 67% of the accomplished tests, independently of the proportion of available caterpillars of the two hosts species. Females of the 5th generation of parasitoid developed in Galleria mellonella or Achroia grisella caterpillars preferred to parasitize caterpillars of Achroia grisella, and that preference didn't depend on the number of available caterpillars of the two lepidopterous species. The corporal weight of the host interfered in the sex ratio of the obtained parasitoids. In caterpillars of larger weight the investment in female descendants was larger than in males, and in caterpillars of smaller weight it happened the inverse.

[1698] DETERMINATION OF THE THERMAL LIMITS OF TRICHOGRAMMA PRETIOSUM (PIRASSUNUNGA STRAIN), ON THE EGGS OF ANTICARSIA GEMMATALIS

B.A. Zachrisson! & J.R.P. Parra², ¹Instituto de Investigación Agropecuaria de Panamá (IDIAP), P.O. Box 6782, Panamá 5, Panamá, E-mail bazsalam@sinfo.net; ²Dept. Of Entomology University of São Paulo, São Paulo, Brazil, E-mail jrpparra@carpa.ciagri.usp.br.

The object of this investigation was to define the inferior (Tb) and superior (Ts) thermal limits, also to establish the optimum temperature (To), for the development of Trichogramma pretiosum. This will allow the adaptation of the parasitoid at thermal variable conditions. In this way, the eggs of Anticarsia gemmatalis that were collected in the soybean fields of Pirassununga, São Paulo, Brazil; were transferred to the laboratory to wait the emergence of T. pretiosum strain. For the multiplication in the laboratory, it was used the alternative host Anagasta kuehniella, and latter at the emergence of the T. pretiosum were submitted to the parasitism on eggs of A. gemmatalis. For the massive rearing of the natural host it was used an artificial diet based on bean, wheat germ, soybean protein and casein. To reach the proposed objective, the A. gemmatalis were summited to the T. pretiosum for a five-hour period at 25°C. Then they were transferred to climate chambers at different temperatures (18, 20, 22, 25, 28, 30 and 32°C), with photo phase of 14 hours and relative humidity of 70 ± 10%. An evaluation of the duration period of the cycle egg-adult and the viability of the parasitoid were done. From these parameters it was determined the thermal inferior limits by the hyperbole method and the superior limit by a non-lineal model proposed by Sharpe and Demichelle in 1977 (modified by Shoofield and collaborates in 1980). The duration of the cycle egg-adult varied from 7 to 22 days for 32 and 18°C, respectively. The viability was high, finding between 86 and 96 %. The inferior thermal limit was of 11.7°C, presenting a thermal constant (K) of 123.12 degree-days, with a determination coefficient (\mathbb{R}^2) of 0.9532. The thermal superior limit (Ts) was of 31.7°C, observing a determination coefficient of 0.99. The optimum temperature (To) for the development of T. pretiosum (Pirassunanga Strain) was of 30°C. Index Terms: Trichogramma pretiosum, Anticarsia gemmatalis, biological control, sovbean.

[1699] RATES OF PARASITISM BY METEORUS RUBENS AND M. GYRATOR ON THEIR INSECT HOSTS

F. N. Zaki¹; K.T. Awadallah² and, M.A. Gesraha,¹. 1- Pests and Plant Protection Dept., National Research Centre, Cairo, Egypt. E-mail fnazir@frcu.eun.eg. Fax: (202) 3601877. 2- Biological Control Lab., Fac. of Agric., Cairo University.

Rates of parasitism by the two braconid parasitoids, *M.rubens* (gregarious parasitoid) and *M. gyrator* (solitary parasitoid) were estimated in association with certain lepidopterous pests in four governorates in Egypt, *i.e.*, Giza, Fayoum, El-Gharbia and El-Sharkia. *M.rubens* were most predominant and most effective than *M. gyrator*. Associating with *Agrotis ipsilon*, the main host of *M.rubens*; rates of parasitism in different localities were represented by a general mean of 14.5%. With the other two hosts, *Sesamia cretica* and *Spodoptera exigua*, the respective general means were 2.2 and 5.2%. As for *M. gyrator M. gyrator*, *S. exigua* and *Heliothis* spp., respectively.

[1700] BIOLOGICAL CONTROL OF THE CITRUS LEAFMINER (LEPIDOPTERA: GRACILLARIDAE) IN NORTHWEST ARGENTINA

M.P.Zamudio¹, <u>E.Willink¹</u>, D.Figueroa¹, G.Zaia¹, S.Toledo¹, & H.Salas¹, ¹Estación Experimental Agroindustrial Obispo Colombres, C.C.n^o 9, Las Talitas, (4101) Tucumán, Argentina. E-mail: sanceaoc@tucbbs.com.ar.

The presence of the citrus leafminer (CLM) Phyllocnistis citrella was first observed in citrus groves of northwest (NW) Argentina at the end of 1995, where it affected tender leaves and shoots of citrus plants. It spread very quickly throughout the citrus growing region and, after its establishment, chemical pesticides were used in excess, in an attempt to control the CLM. The need for a classical biological control programme was evident, and the encyrtid Ageniaspis citricola was selected because of its host specificity, dispersal capacity and high reproductive potential. The project was funded by the citric producers gathered in the Asociación Fitosanitaria del Noroeste Argentino (AFINOA). After a few attempts to bring A. citricola from the United States and Spain, the successful introduction was made from Perú at the beginning of 1998, and after a quarantine period, a massive breeding program was established at the Estación Experimental Agroindustrial Obispo Colombres (EEAOC) in Tucumán Province. The parasitoids were reared in an air conditioned glasshouse, using the technique developed by Hoy in Florida, USA. A. citricola was released into the natural environment both as adults and as pupae about to emerge, which had been placed in plastic bags containing leaves with the parasitoidized leafminer. In this way A. citricola was at first introduced into all citrus growing habitats in the northwest Argentina provinces of Jujuy, Salta, Tucumán and Catamarca. In many habitats the parasitoid flourished but in others it remained scarce or did not become established at all. For this reason, additional parasitoids were subsequently released into the less colonized areas. A total of 23,500 Ageniaspis were released between February and May 1998, and an additional 56.510 were liberated during the summer 1998/99. During March 1999 a survey was made throughout NW Argentina to evaluate the establishment of A.citricola. In Tucumán Province 75% of the CLM pupal chambers were parasitoidized, in Jujuy 44%, in Salta 43%, but in Catamarca only 5% of the pupal chambers were affected. Further studies are thus needed to ascertain whether the rate of parasitoidism by A.citricola is determined by climatic conditions.

[1701] HYMENOPTERAN NATURAL ENEMIES IN A EUCALYPTUS PLANTATION IN IPABA, STATE OF MINAS GERAIS, BRAZIL

T. V. Zanuncio¹, J. C. Zanuncio¹, J. II. Schoereder² & G. P. Santos³, ¹ Depto de Biologia Animal, Univ. Federal de Viçosa, 36.571-000, Viçosa, MG, BRAZIL. E-mail: zanuncio@mail.ufv.br; ² Depto de Biologia Geral, Univ. Federal de Viçosa, 36.571-000, Viçosa, MG, BRAZIL; ³ EMBRAPA-CTZM/DBA-Univ. Federal de Viçosa, 36.571-000, Viçosa, MG, BRAZIL.

Due to the increase in areas planted with Eucalyptus species in Brazil many harmful insects are now established in such plantations. The objective of this research was to study the hymenopteran natural enemies in a transect of *Eucalyptus*/native vegetation/*Eucalyptus* and to look at the effect of these native areas upon populations of such insects. This work was carried out at Ipaba in the State of Minas Gerais, with two samplings per month with Malaise traps, from April 1996 to March 1997. Sampling points were located 100 meters from each other in a transect starting in one Eucalyptus plot, crossing an area of native forest and reaching another Eucalyptus plot. Insects collected were separated, quantified and identified in the Laboratory of Forest Entomology, of the Federal University of Viçosa, in Viçosa, State of Minas Gerais, Brazil. A total of 3,636 individuals of Aculeata and Parasitica Hymenoptera, representing 85 morpho-species was collected and allocated to family. Of the Aculeata series, 68.2% of the individuals belong to the Formicidae, Mutilidae, Pompilidae, Sphecidae and Vespidae families, while the remaining 31.8% belong to species of Bethylidae, Braconidae, Chalcididae, Eulophidae, Evaniidae and Ichneumonidae within the Parasitica series. The number of species at each sampling point was higher at those located at the borders and inside the native forest. Larger numbers of individuals were collected at the sampling points Ea100 (Eucalyptus plot at 100m from the native forest), Mn1 (inside the native forest at 100m from the Eucalyptus plot), Tran1 (at the transition Eucalyptus/native forest) and Mn2 (inside the native forest at 200m from the Eucalyptus), with 587, 412, 390 and 382 individuals respectively.

Index terms: Diversity, fragmentation, remnants of native vegetation

[1702] EXPLORATION IN ARGENTINA FOR POTENTIAL BIOLOGICAL CONTROL AGENTS OF *HELIOTROPIUM AMPLEXICAULE*, AN INVASIVE WEED IN EASTERN AUSTRALIA

M.C. Zapnter¹, D.T. Briese², W. Pettit³, G. Perez-Camargo¹ & G. Serra⁴, ¹Facultad de Agronomía, Universidad de Buenos Aires, 1417 Buenos Aires, Argentina; ² CRC for Weed Management Systems and CSIRO Entomology, GPO Box 1700, Canberra 2601, Australia; ³CSIRO Entomology, CERZOS / CONICET, 8000 Bahía Blanca, Argentina; ⁴Facultad de Agronomía, Universidad de Córdoba, Córdoba, Argentina.

Blue Heliotrope, Heliotropium amplexicaule Vahl, is a perennial, spreading broad-leaf weed of temperate South American origin. It was introduced into Australia in the late 19th century as a garden ornamental and now occurs in four states. In northern New South Wales and southern Queensland it has undergone rapid recent spread, in both cultivated pastures and areas of native vegetation. It is considered a serious weed in these areas because it competes with desirable summer pasture species and is toxic to stock. Conventional methods, including herbicide use have had limited success in reducing its impact and have not stopped its spread. In late 1998, a project was initiated in Argentina to survey for potential biological control agents in the native range of the H.amplexicaule, and evaluate their potential to control the weed. This poster outlines the results of field surveys and laboratory research on four candidate agents, including a preliminary openfield experiment to determine their host-range. Three study areas were selected and visited periodically to evaluate insect densities and damage to plants. Colonies from the four insects have been established on their natural host to study their biology. As a result of the studies, two insects, the defoliating chrysomelid beetle, Deuterocampta quadrjuga, and the flea-beetle, Longitarsus sp., have been selected for further study in quarantine in Australia. Index terms: Heliotropium amplexicaule, biological control

[1703] THE RELATIONSHIP OF STEM BORER COMPOSITION IN MAIZE TO PARASITOID DIVERSITY

G. Zhou & W. A. Overholt, International Center of Insect Physiology and Ecology, P.O. Bos 30772, Nairobi, Kenya

stemborers of maize were sampled in kenya in three different ecological zones; the humid lowland coastal zone, the semi-arid midaltitude eastern province, and the moist midaltitude lake victoria basin. several parasitoids of stemborers were collected, but two species, cotesia flavipes and cotesia sesamiae were dominant and accounted for about 85% of all parasitoids recovered. in the coastal area, three stem borer species were found. chilo partellus was the dominant species (63%), followed by chilo orichalcociliellus (25%), and sesamia calamistis (8%). a disproportionate number of c. flavipes were recovered from c. partellus compared to the other stemborer species, the parasitism of c. partellus by c. flavipes was 3.5% on average between 1992 and 1998; then the parasitism of c. orichalcociliellus was 1.1%, the parasitism OF S. CALAMISTIS was 0.4%. at sites where c. partellus are abundant and c. orichalcociliellus and s.calamistis are less abundant, the parasitism by c. flavipes reached a mean of 8.5%. in other areas, c. flaivpes caused only 1.6% parasitism, suggesting that the old association of c. flavipes/c. partellus was the optimal combination for population development of c. flavipes. the stemborer composition had little effect on c. sesamiae parasitism. average parasitism of both s. calamistis and c. partellus by c. sesaming was about 2.2% and the parasitism of c. orichalcociliellus was 1.5%. in the eastern province, the main stemborer species were c partellus (85%), s. calamistis (9%) and buseola fusca (2%). b. fusca was found at less than 50% of the sampling sites. in areas where b. fusca was found, parasitism by c. flavipes was as low as 4%, but in non-b. fusca areas, it reached a mean of 11.6%. additionally, in non-b. fusca infested areas, parasitism of total stemborers by c. sesamiae was 2.6%, whereas in b. fusca infested areas, parasitism was 6.5%. as the proportion of *b.fusca* increased, parasitism by *c. flavipes* decreased, but parasitism by *c. sesamiae* increased. in the lake victoria basin, *c. partellus* was the most abundant speices (72%), followed by b. fusca (12%), eldana saccharina (12%), and s. calamistis (3%). the b. fusca density was low, but it was found at all the sampling sites. average parasitism of c. partellus by c. flavipes was 1.4%. parasitism by c. sesamiae was 3.2% and b. fusca was the predominant host (85%) for this parasitiod. in areas where e. saccharina was abundant (>15%), parasitism by both c. sesamiae and c. flavipes was very low (<2% for both species). the higher the proportion of e.saccharina, the lower the parasitism by c.flavipes.

[1704] APPLIED TECHNOLOGY OF PEST CONTROLLING BY TRICHOGRAMMA FROM ARTIFICIAL HOST EGG IN SHANXI, CHINA

<u>Y. Zhou</u>, J. Ren, X. Zhang, M. Lian & T. Li, (Institute of Plant Protection, Shanxi Academy of Agricultural Sciences, ² Changfeng St., Taiyuan, Shanxi, 030006 P. R. China BSNY@public.ty.sx.cn)

A number of Trichogramma from artificial host eggs have been transported from Guangdong to Shanxi since 1994. A controlling test of Helicoverpa armigera (Hubner) by Trichogramma chilonis Ishii and Trichogramma dendrolimi Matsumura from artificial host eggs was carried out in cotton fields in 1998. Trichogramma were gotten out into the field in the egg period of the 2nd and 3rd generations of *Helicoverpa armigera* in Bt transgenosis pest-resistant cotton field. The parasitic ratio of Trichogramma chilonis and Trichogramma dendrolimi were 56.8-565.9% and 36.8-38.2% respectively. Both Trichogramma had better effect than CK. After treatment, the residual larval population of Helicoverpa armigera was not higher than the controlling index of the residual larva for 100 plants. It meant that the technology is feasible. For the common field, similar results were gained when Trichogramma was gotten out in second generation of Helicoverpa armigera, but the controlling effect was not as good as expected for that of the third generation. A controlling experiment of Helicoverpa armigera in tomato field by Trichogramma chilonis from artificial host eggs was carried out in Taiyuan in 1997– 1998. The parasitic ratio got 52.0-71.1%. The decrease ratio of the corrected larval population was 95.0% if Bt preparation in 200 times was adopted. It is an effective method to combine Trichogramma chilonis from artificial host eggs with Bt preparation for Helicoverpa armigera in tomato fields. Some satisfying results were also obtained from the controlling test of Ostriniae furnacalis by Trichogramma chilonis from artificial host eggs in Taiyuan and Qinshui in 1998. It was going to be 1555 ha. of using Trichogramma from artificial host eggs for pest control from 1994 to 1998.

Keywords: Trichogramma chilonis Ishii, Trichogramma dendrolimi, Helicoverpa armigera, Ostriniae furnacalis, attificial host eggs

[1705] RISK-SENSITIVE FORAGING FOR MATES IN A PUPAL MATING BUTTERFLY, HELICONIUS HEWITSONI

E. I. Deinert¹, ¹ Organization for Tropical Studies, Duke University, 410 Swift Ave., Durham, N.C. 27705, U.S.A. E-mail: deinert@cro.ots.ac.cr.

A central theme in sexual selection theory is that there are costs associated with mate choice. Individual behavior, therefore, should reflect changes in the associated costs and benefits. For example, when response to predation risk alters male interactions with future potential mates, male response to such risk should depend on the relative value to the resource, for example the relative opportunity for obtaining a copulation. This study examines the mate locating and risk taking behavior of a pupal-mating butterfly, Heliconius hewitsoni, as a function of changing pupal maturity. Male H. hewitsoni locate female pupac, visit them repeatedly, and then 26-24 hours before female eclosion compete for access to the pupae and the teneral females. Males assess pupal maturity and adjust their searching and risk taking behavior according to changes in the opportunity for mate acquisition. Males visited pupae throughout the 9 day pupal phase and visits increased in frequency and duration as the pupae aged. Male response to simulated predation attempts at the pupal site depended on changing mating opportunity as reflected by changing pupal maturity. Captured males took significantly longer to return to pupae than uncaptured control males. However, time to return to site of capture was significantly less when pupae where close to eclosing than when pupae were days from eclosing. In response to constant predation risk males shift from a risk-averse to a risk-prone mate locating strategy as pupae increase in value.

Index terms: Heliconius hewitsoni, Lepidoptera, mate location, predation

[1707] PARASITE RESISTANCE AND SEXUAL SIGNAL TRAITS: DOES UNDERSTANDING INSECT IMMUNITY HELP US UNDERSTAND INSECT MATING SYSTEM?

M.Siva-Jothy, M.Siva-Jothy@sheffield.ac.uk

Hamilton & Zuk provided perhaps the best framework for understanding how intersexual selection for good utilitarian genes (in this case, genes for parasite resistance) might work. I will present results from long-term studies of calopterygid damselflies whichreveal (a) that male sexual signal traits are honest signals of parasite resistance (b) the signal and the immune system share a common physiological pathway, (c) aspects of immune regulation that are at odds with current ideas and (d) that time-constrained development and parasite-resistance may interact and influence many aspects of the mating system.

[1708] SINGING AND SCALES: VARIATION IN SEXUAL SIGNALS OF CRICKETS SUBJECT TO PHONOTACTIC PARASITOIDS

<u>R. J. Knell</u>, School of Biological Sciences, Queen Mary and Westfield College, Mile End Road, London E1 4NS, UK, E-mail R.Knell@qmw.ac.

[1706] SEXUALLY TRANSMITTED DISEASES AND THE EVOLUTION OF

INSECT MATING SYSTEMS

Sexually transmitted diseases (STDs) are common in the animal kingdom, and are capable of causing considerable pathology. Reports are now beginning to appear describing a variety of such parasites from insects, including nematode worms, mites, microsporidia and fungi. Hosts reported include coleoptera, lepidoptera and diptera. One possible reason for the small numbers of reported cases is that STDs are less likely to occur in temperate insects because an element of vertical transmission will be necessary in many potential hosts to ensure transmission between generations, and this vertical transmission will lead to strong selection for reduced virulence. STDs may prove to be common in tropical insects, and I will discuss the possible role of STDs in the evolution of insect mating systems, with particular reference to parasite mediated sexual selection and the evolution of polygamy.

Index terms: Sexually transmitted disease, mate choice, evolution, sexual selection

<u>M. Zuk¹</u>, J.T. Rotenberry¹, & L.W. Simmons², ¹Dept. of Biology, Univ. of California, Riverside CA 92521 USA; ²Dept. of Zoology, Univ. of Western Australia, Nedlands 6009 W.A. Australia.

Signals used to attract mates are also often conspicuous to predators and parasites, and their evolution via sexual selection is expected to be checked by natural selection. The calling song of the field cricket *Teleogryllus oceanicus* has been influenced by the presence of acoustically-orienting parasitoid flies in part of the crickets' range. We examined this song variation at a variety of scales; in the Hawaiian Islands, where the parasitoid occurs, the song differs from that in either the continent of Australia or the island of Moorea in French Polynesia. Song differences between two islands of Fiji are not as distinct as those among the three Hawaiian islands where the parasitoid accurs. Within the Hawaiian chain, a significant portion of variation of song can be attributed to differences in prevalence of infestation with the fly, and in any one parasitized population, individual crickets are more likely to harbor larvae if their song contains a longer series of continuous pulses. Variation is also greater between parasitized groups are more widely geographically separated. These countervailing effects of sexual and natural selection have numerous implications for the maintenance of variation in sexually selected traits

Index terms: phonotactic parasitoid, sexual selection, Teleogryllus oceanicus

[1709] FIGHT OR FLIGHT? - ALTERNATIVE REPRODUCTIVE TACTICS IN CARDIOCONDYLA ANTS

S. Cremer & J. Heinze, LS Biologie I, Univ. Regensburg, Universitätsstrasse 31, D-93040 Regensburg, Germany

In many species of animals, alternative reproductive phenotypes co-occur, which show different behavior and occasionally even different morphology. Proximately, alternative phenotypes may be either based on a genetic polymorphism or on different environmental conditions acting on the same genotype. In the ant genus Cardiocondyla, two different male morphs exist which differ strikingly in behavior, morphology, and physiology. Winged Cardiocondyla males leave the colony several days after their eclosion and mate outside the nest with alien virgin queens. Before dispersal, however, they may also attempt to mate with virgin queens in their natal colonies. Wingless, "ergatoid" males, on the other hand, stay in their natal nests and only there mate with virgin queens. In contrast to the docile winged males, ergatoid males are highly aggressive towards each other and use their strong mandibles to fight for access to the virgin queens. Freshly eclosing rivals are typically killed by adult ergatoid males and therefore most colonies contain only as single ergatoid male at any time. Whereas spermatogenesis is completed and testes have degenerated in winged males when they reach sexual maturity (as is generally the case in male Hymenoptera), spermatogenesis continues throughout the whole life span of ergatoid males (Heinze & Hölldobler 1993; Heinze et al. 1998). Proximately, the production of winged males can be induced in the laboratory by different manipulations, all related to environmental stress. Male morph thus is not genetically determined but depends on propagated by winged males and dispersing queens under unfavorable conditions, the under favorable conditions the colony can grow quickly due to ergatoid males and nondispersing queens.

Index terms: Cardiocondyla wroughtonii, male dimorphism, morph determination Heinze, J. and B. Hölldobler. 1993. Fighting for a harem of queens: physiology of reproduction in Cardiocondyla male ants. Proc Natl Acad Sci USA 90: 8412-8414 Heinze, J., B. Hölldobler and K. Yamauchi. 1998. Male competition in Cardiocondyla ants. Behav Ecol Sociobiol 42: 239-246

[1710] SCALING RELATIONSHIPS AS 'REACTION NORMS': INSIGHTS FOR THE EVOLUTION OF BEETLE HORNS

D.J. Emlen, Division of Biological Sciences, Univ. Montana, Missoula MT, 59812-1002, U.S.A.

I discuss a framework for studying the evolution of morphology in insects, based on the concepts of "phenotypic plasticity" and "reaction norms". I illustrate this approach with the evolution of exaggerated horns in beetles. Most morphological traits scale with body size (large individuals have larger traits than smaller individuals), and I propose that scaling relationships in insects are best viewed as reaction norms. I present data from three independent origins of beetle horns and suggest that the evolution of horns has resulted from genetic changes in the slope and shape of the scaling relationships. In each case, the evolutionary enlargement of horns resulted in non-linear (sigmoid) scaling relationships. I use the "reaction norm" perspective of scaling relationship evolution to suggest why this might be.

[1711] THE INHERITANCE OF FEMALE PREFERENCE FUNCTIONS IN A MATE RECOGNITION SYSTEM

M. G. Ritchie, Environmental & Evolutionary Biology, Bute Medical Building, University of St Andrews, St Andrews, Fife, KY16 9TS Scotland. E-mail: mgr@stand.ac.uk.

Mate Recognition Systems play a major role in sexual selection and speciation, yet few studies have analysed both male and female components in detail. Here female preference functions have been characterised for the tettigoniid bushcricket *Ephippiger ephippiger*, and the inheritance of male song and female preference functions followed in crosses between subspecies. Songs are disproportionately determined by sex-linked genes, as has been predicted by some recent reviews. However, in contrast to other studies, there is no evidence for a role of maternally derived sex-linked genes in female preference, or of maternal effects. Reasons for disproportionate linkage of sexually selected traits will be discussed. At the genetic level, there is a mis-match between peak preferences and male song, consistent with an evolutionary history of persistent directional preferences. The pattern of inheritance described could contribute to the process of speciation via the evolution of new Mate Recognition Systems, as hybrid hemizygous males could be discriminated against by heterozygous females.

Index terms: Ephippiger ephippiger, mate recognition system, sex-linkage, female preference, speciation

[1712] DIET-DEPENDENT FEMALE CHOICE FOR MALES WITH iGOOD GENESI

I. Lesna & M. W. Sabelis, Section Population Biology, University of Amsterdam, Kruislaan 320, 1098 SM Amsterdam, The Netherlands, E-mail: lesna@bio.uva.nl.

We showed previously (Nature 401: 581-584, 1999) that a local population of the soil predatory mite, Hypoaspis aculeifer, harbours genetic variation in preference for two prey species: the bulb mite, Rhizoglyphus robini, and the copra mite, Tyrophagus putrescentiae. Here, we show that in terms of population growth rate the bulb-mite-preferring line outperforms the copra-mite-preferring line irrespective of whether it is reared on copra mites or bulb mites alone. Hence, there is no evidence for a trade-off in reproductive performance. However, hybrids outperform the selected lines when fed on copra mites, but have intermediate reproductive success when fed on bulb mites. On a mixed diet of the two prey species hybrids also outperform the selected lines. Thus, rather than trade-off relations, heterozygote advantage explains the maintenance of genetic variation in prey preference in the laboratory culture, as well as at a small spatial scale in the field. To investigate the likelihood of hybridization, mate choice of the selected lines was analysed experimentally. It was found that mate choice of the selected line is assortative on a prey diet where this line is superior in reproductive success, but when hybrids are superior. disassortative mating predominates. Thus, diet-dependent switches in mate choice are implicated in the maintenance or breakdown of genetic variability within local populations.

Index terms: Genetic polymorphism, hybrid advantage, mate choice, assortative mating, disassortative mating, predators

[1713] LEK PARADOX RESOLVED: EMPIRICAL EVIDENCE FOR GENETIC VARIANCE IN CONDITION AND IN CONDITION DEPENDENCE

<u>S. Kotiaho</u>, L. W. Simmons & J. L. Tomkins, Dept. of Zoology, Univ. of Western Australia, Nedlands, WA 6009, Australia. E-mail: jkotiaho@cyllene.uwa.edu.au

Sexual selection through female choice is common even in the absence of direct fitness benefits arising from the choice. To explain costly female choice in such instances, genetic benefits in the form of "good genes" have been invoked. However, it is a long held expectation that there will be little genetic variance in fitness related traits because directional selection will tend to drive beneficial alleles to fixation. Therefore, it seems evident that there is little potential for female choice to result in genetic benefits giving rise to the so called "lek paradox". Recently a theoretical solution to the lek paradox has been offered in the form of a genetic model based on two robust assumptions: first that traits are dependent on condition and second that condition itself has high genetic variance. In this paper, we present results from experiments with the dung beetle *Onthophngus taurus* which show that there is female preference for a behavioural sexual trait (courtship rate), that the trait covaries positively with condition, that this covariance has significant genetic variance and finally that there is significant genetic variance in condition itself. Our set of experimental tests support a genetic model that explains the maintenance of costly female choice based on indirect genetic benefits, and thereby provide empirical evidence for the resolution of the lek paradox.

Index terms: Onthophagus taurus, good genes, indirect genetic benefits, sexual selection.

[1714] PARADOX(ES) OF THE LEK: CAN GENETIC VARIANCE OF SEXUALLY SELECTED TRAITS BE MAINTAINED BY GENOTYPE × ENVIRONMENT INTERACTION?

M. D. Greenfield¹ & F.-y. Jia², ¹Dept. of Entomology, Univ. of Kansas, Lawrence, KS 66045, USA, E-mail greenfie@ukans.edu; ²Dept. of Entomology, Kansas State Univ., Manhattan, KS 66506, USA, E-mail fjia@oz.oznet.ksu.edu.

When traits experience directional selection such as that imposed by sexual selection, their genetic variance is expected to diminish. Nonetheless, theory and findings from sexual selection predict and demonstrate that male traits favored by female choice retain substantial amounts of additive genetic variance. We explored this dilemma, a "paradox of the lek," through an ecological genetic approach and focused on the potential contributions of genotype x environment interaction to maintenance of additive genetic variance for male signal characters in the lesser waxmoth, *Achroia grisella* (Lepidoptera: Pyralidae). We artificially selected genetic variants for two male ultrasound signal characters, signal rate (SR) and peak amplitude (PA), that influence female attraction and then examined the phenotypic plasticity of these variants (high and low SR and PA lines) under a range of environmental conditions expected in natural populations. Our split-family breeding experiments indicated that two signal characters, SR and PA, and several developmental characters in both high and low SR and PA lines displayed considerable phenotypic

plasticity among the environments tested. Moreover, strong genotype \times environment interactions leading to crossover between high and low SR lines were found for SR and developmental period. Therefore, neither high nor low SR genetic variants would achieve maximum attractiveness and fitness in every environment, and those variants producing unattractive signals with low SRs under normal conditions may remain in populations provided that gene flow across environments or generation overlap are sufficiently high. We speculate that the phenotypic plasticity for SR and developmental period is adaptive in *A. grisella* populations experiencing a range of temperature and density conditions. Females mating with attractive (high-SR) males may be assured of obtaining good genes because 1) these males sire offspring that develop more rapidly and 2) a crossover for developmental period may parallel that for SR. Such parallel crossovers may be expected wherever good genes sexual selection mechanisms operate.

Index terms: genetic variance, genotype \times environment interaction, lek paradox, phenotypic plasticity, sexual selection, waxmoth.

[1715] EVOLUTION OF CONSPECIFIC EGG-CARRYING BEHAVIOR: ANCIENT AND INFANT EXPRESSIONS IN THE HETEROPTERA

<u>R. L. Smith¹</u> & A. Kaitala², ¹Dept. of Entomology, Univ. of Arizona, Tucson, AZ 85721, USA bobsmith @ag.arizona.edu ² Dept. of Biol., Univ. of Oulu, Finland.

Evolutionary biologists interested in reproductive behavior approach their studies with the expectation that males and females should exhibit adaptive traits refined by natural and sexual selection. This view suggests predictions that drive most research in behavioral ecology, and the predictions are usually approximately validated because most reproductive patterns are mature with traits well shaped to serve individual fitness. However, occasionally we encounter reproductive patterns that serve one sex imperfectly and perhaps the other not at all. Such outcomes may result from constraints, or the pattern of interest may be very young and not have had time for evolutionary refinement and gender coadaptation. Giant Water Bugs and the Golden Egg Bug both exhibit egg-carrying behavior, but the manifestations of this pattern differ dramatically between the two taxa coincident with their relative ages. The Giant Water Bugs (Belostomatidae) is an ancient family of predaceous aquatic Heteroptera whose fossils date to mid-Jurassic or earlier. Males of all extant belostomatid species brood eggs and we infer from fossil studies that paternal brooding evolved well over 150 million years ago. In the subfamily Belostomatinae, (> 100 spp. in 5 genera), males carry eggs attached to their backs by their mates. This system is obligatory and characterized by a constellation of perfected traits consistent with optimality predictions. Supportive adaptations include refined intersexual communication and cooperation, absolute paternity assurance, precision in oviposition, and efficient brooding. Giant Water Bugs make few reproductive mistakes and are unable to cheat. Egg carrying by belostomatids is evolutionarily stable and sexually symmetrical regarding costs and benefits. The Golden Egg Bug, Phyllamorpha laciniata is a terrestrial phytophagous coreid bug tied to its circum-Mediterranean host plant, Paronychia argentea. Females of this species inevitably deposit their eggs on living conspecifics, both male and female. Due to ant predation, carried eggs enjoy a dramatic survival advantage over those experimentally placed on the host plant or dead bugs. A sister species Phyllamorpha lacerata oviposits on Paronychia and not on other bugs indicating that egg carrying in P. laciniata is a recently evolved apomorphy that distinguishes this single species. Neither egg encumbered males nor females show special brooding behavior. Oviposition on conspecifies is comically clumsy and imprecise, egg carrying is not accompanied by supportive adaptations, and eggs carried by males are rarely if ever fertilized by the carrying male. Egg carrying clearly benefits mothers but not encumbered non-mothers or male carriers. Females may be selected to reciprocally exchange eggs but otherwise the system fails most optimality predictions, is clearly in a state of evolutionary flux, and contrasts vividly with the water bug system.

[1716] MONANDRY AND POLYANDRY AS ALTERNATIVE LIFESTYLES IN A BUTTERFLY

N. Wedell, Ecol. & Evol. Group, School of Biology, Univ. of Leeds, Leeds LS2 9JT, UK

Butterflies show considerable variability in female mating frequency ranging from strictly monandrous to highly polyandrous species. Degree of polyandry also varies within species, with some females only mating once and others mating multiply. One reason for multiple mating is to obtain nutritious male donations that increase both the longevity and fecundity of females. Despite the presence of male nutrient donations, some females of the green veined white butterfly (Pieridae: Pieris napi) never mate more than once. Here I examine this apparent paradox by assessing to what degree polyandry is under genetic control using a full-sib analysis. Degree of polyandry has a genetic component and appears to be traded-off against reduced longevity when denied the opportunity to mate more than once. There is also a trend across families between degree of polyandry and reduced lifetime fecundity when forced to be monandrous. It is possible that female P. napi display different reproductive strategies, with some females relying on male donations to realize their potential fecundity whereas others rely on their own resources for egg production. In nature, genetically polyandrous females may be prevented from mating multiply due to unfavourable weather. The trade-off between degree of polyandry and longevity when singly mated may aid the maintenance of genetic variability in female mating frequency in this species. Possible reasons for these different reproductive strategies are discussed. Index Terms: Sexual selection, mating systems, Lepidoptera, multiple mating

[1717] MEIOTIC DRIVE, SPERM COMPETITION AND THE EVOLUTION OF MULTIPLE MATING BY FEMALE STALK-EYED FLIES (DIOPSIDAE)

<u>G. S. Wilkinson</u>, C. Fry, S. Toll & J. Swallow, Dept. of Biology, Univ. of Maryland, College Park, MD 20742, USA, E-mail gw10@umail.umd.edu.

Sex chromosome meiotic drive causes distorted progeny sex ratios due to differential gamete development and transmission. We have recently discovered X chromosome meiotic drive (X^b) in two species, *Cyrtodiopsis whitei* and *C. dalmanni*, of sexually dimorphic stalk-eyed flies from south-east Asia. Epiflourescent microscopy reveals that male flies which carry X^D fail to exhibit normal sperm development. Approximately half of the sperm in a developing bundle fail to elongate normally and, therefore, are presumed to bear Y chromosomes since such males produce all female progeny. We determine the outcome of competition between sperm from males with or without X^D chromosomes by utilizing two populations of *C. whitei* from perinsular Malaysia and northern Thailand which differ in body color. Results reveal that X^D sperm are competitively inferior to normal X sperm – over 95% of progeny from pair-mated females are fathered by normal X sperm. Such intense sperm competition is expected to favor multiple mating by females in populations that are female-biased. We test this idea by estimating remating interval, population sex ratios, and frequency of X^D chromosomes in seven populations of *Cytodiopsis whitei* and *C. dalmanni* found in Thailand, Malaysia, Sumatra and Borneo. Using a population phylogeny derived from mitochondrial sequence data we infer the pattern of evolution between the frequency of the drive chromosome and the pattern of female mating behavior. These results are discussed in the context of sex chromosome covolution and the evolution of sexual dimorphism.

Index terms: Cyrtodiopsis whitei, Cyrtodiopsis dalmanni, meiotic drive, polyandry

[1719] POLYANDRY, MULTIPLE MATING AND OFFSPRING ENVIRONMENT - WHY DO FEMALE DUNGFLIES RE-MATE?

T. Tregenza, Ecology & Evolution Group, School of Biology, University of Leeds, Leeds LS2 9JT, UK. E-mail gentbt@leeds.ac.uk

Why females frequently mate with more than one male remains poorly understood, particularly in those species which experience no obvious direct benefits of matings. To make progress in understanding polyandry we need to identify benefits females experience as a result of mating with more than one male, independent of any differences due to increased numbers of matings (which may be with the same male). I conducted a study in which groups of female yellow dung-flies (*Scathophaga stercoraria*) were allocated either a single mating, two matings with one male or two matings with two different males. Additionally, all potential parents were genotyped for the allozyme phosphoglucomutase (PGM) using gel electrophoresis. Because differences in PGM genotype have previously been associated with differences in larval performance in relation to rearing temperature, the eggs laid by each female were split and reared under 3 different temperature regimes. The hatching success of eggs, and the sex, mass, development time and genotype of all the emerging adult offspring were determined. This revealed no direct effect on hatching success, or on offspring life history traits of different mating regimes, although there are significant effects of interactions between larval rearing temperature and female mating regime. This suggests that costs and benefits of multiple mating and polyandry can involve complex interactions between offspring and their environment. I will discuss these results and the interactions between PGM genotype, offspring life-history traits and female mating pattern. Index terms: Dung fly, Polyandry, Scathophaga stercoraria, Sexual selection.

[1718] FITNESS BENEFITS OF SPERM COMPETITION FOR FEMALE FIELD CRICKETS

L. W. Simmons, Dept. of Zool., Univ. of Western Australia, Nedlands, WA 6907, Australia, E-mail lsimmons@cyllene.uwa.edu.au

I have examined the adaptive significance of polyandry using the Australian field cricket Teleogryllus oceanicus. Previous studies of polyandry have examined differences in offspring production by females mated multiply to a single male or females mated mutiply to different males. Here I combine this approach with a study of parantage of offspring produced in the later group. I use naturally occuring polymorphisms at the beta-esterase locus to assign parentage, and to vary male and female genotypes in experimental matings. If polyandry increases female fitness by avoiding genetic incompatebility I predict that i) on average, females mated multiply to different males should produce more offspring of greater fitness than females mating the same number of times with a single male; ii) a male that induces greater offspring production in females that mate multiply with that males should have a higher paternity when in competition with males inducing lower offspring production; iii) male genotype relative to female genotype should influence offspring production in females multiply mated to single males; and iv) offspring production by females multiply mated with different males should vary with heterogeneity in the genotypes of mutiple partners. I found that i) females multiple mated to two males had a higher proportion of their eggs hatching than did females mating twice with a single male. Offspring fitness parameters were not effected. However, ii) when in sperm competition, a males fertilization success was not related to his success in fertilizing eggs when a female mated with him alone; iii) there was no effect of relative male and female genotype on hatching success when females mated multiply with single males; and iv) there was no effect of heterogeneity in genotypes of two males in competition on hatching success. These results support the notion that sperm competition between mutiple males increases offspring production for females. However, they provide little evidence that this effect arises due to genetic incompatability. Sperm competition success was not related to offspring fitness. Thus, the notion that competitively superior sperm produce competitively superior offspring is not supported either. The reason for increased fertilization success under sperm competition requires further study. Index terms: Teleogryllus oceanicus, polyandry, sperm competition, fitness

[1720] SEXUAL BEHAVIOR OF LONGHORN BEETLE MIGDOLUS FRYANUS WESTWOOD (COLEOPTERA: CERAMBYCIDAE)

<u>J. M. S. Bento¹</u>, T. M. C. Della Lucia², E. F. Vilela² & W. S. Leal³, ¹Dep. Entomol., Fitop. e Zool. Agrícola, ESALQ-USP, 13418-900, Piracicaba-SP, Brasil, E-mail jmsbento@carpa.ciagri.usp.br; ²Depto. Biologia Animal, UFV, 36571-000, Viçosa-MG, Brazil; ³Laboratory of Chemistry Prospecting, NISES, Tsukuba, Ibaraki 305-8634, Japan.

The longhorn beetle *M. fryanus* is restricted to South America. The larvae bore into the plant root system and destroyed different crops such as sugarcane, coffee, eucalyptus, grape and others. Adults males are alate and live, in average, two to three days; adults females are wingless and live for 30 days or more. From November to March in Southeastern of Brazil, the newly emerged individuals mate after a characteristic nupital flight. The attraction of the males towards the females is mediated by a strongly female sex pheromone, restricted to a narrow range of time during each day and influenced by daily climatic factors. Females remain on the soil level with only head and thorax exposed for a short period of time from 8:00 AM until noon. Once copulated with one or more males return immediately into the soil to various depths for egg-laying. On the other hand, the males remain on the ground from 7:00 AM to 3:00 PM, when return in to the soil. The possible reason for a different exposition time of the sexes, during the attraction period, is due to temperature and predation that could affect especially females. The sequence of mating is present.

Index terms: sex pheromone, attraction, mating.

[1721] ASSORTATIVE MATING, SEXUAL SELECTION, HAPLODIPLODY AND THE EVOLUTION OF SOCIAL BEHAVIOR IN INSECTS

<u>K. Jaffe</u>, Departamento de Biología de Organismos, Universidad Simón Bolívar, Apartado 89000, Caracas 1080A, Venezuela, kjaffe@usb.ve

Computer simulations of sexual reproduction among haploid, diploid and haplo-diploid organisms showed that strategies in which females produce males asexually are evolutionary stable, displacing pure sexual organisms in interbreeding populations. Haplodiploidy seems to drives evolution with a different dynamics than pure diploidy. Haplodiploidy allows for a faster adaptation to a rough fitness landscape than pure diploidy. Haplo-diplod organisms showed higher probabilities for fixing alleles coding for altruistic behavior than diploid ones, and so did organisms reproducing with assortative mating. The results allow to predict that during phylogenetic evolution of sexual organisms, diploidy will be replaced by haplo-diploidy when the appropriate mutations occur, but that the reverse is unlikely. For the study of the evolution of social behavior, a theoretical game was developed. It was based on the eventual evolution of social behavior through development of altruistic cooperative care of the offspring or extended parental care. Alleles coding for five different strategies were simulated: 1- No care: A parent invested nothing in the offspring. 2- Communal care: A parent invested in any offspring irrespective of it was his own. 3- Open care: A parent invested half its acre-energy in its own offspring and half in any other offspring. 4- Opportunistic care: A parent invested only in its own offspring but its offspring could receive care from open or communal parents. 5- Closed care: A parent invested only in its own offspring and its offspring could not receive care from any other adult. The results suggest that social behavior without social synergy is very unlikely. Social behavior should emerge in evolution when cooperation improves synergistically the corresponding egoistic behavior and when alleles coding for altruistic or social behavior can be rapidly fixed in the population, by strategies such as haplo-diploidy, assortative mating, and probably others. The main conclusion thus is that social behavior has to be economically more efficient than the corresponding solitary behavior. Data are presented showing that this prediction is supported by laboratory and field observations in ants, termites and wasps.

[1723] FUNCTIONAL POLYGYNY IN ECTATOMMA TUBERCULATUM (OLIVIER) (HYMENOPTERA: FORMICIDAE)

R. R. Hora¹, <u>E. F. Vileln¹</u> & J. II. C. Delabie¹, ¹ Departamento de Biologia Animal, Universidade Federal de Viçosa, Viçosa, MG, Brazil, 36571-000. e-mail: evilela@mail.ufv.br; ²Laboratório de Mirmecologia, CEPEC/CEPLAC/ Universidade Estadual de Santa Cruz, Itabuna, BA, Brazil, 45600-000. e-mail: delabie@nuxnet.com.br.

Colonies of Ectatomma tuberculatum were collected from South Bahia (Brazil) cocoa plantations with the objective of studying their population structure. Twenty one monogynous and 18 polygynous colonies were found, while queens were not found in a further three colonies. This species appears to be optionally polygynic. The number of queens in the polygynous colonies varied from 2 to 44, with an average of 5.9 fertilized queens. In these colonies, the number of larvae, cocoons and workers was larger than in colonies with a single queen. The behavioral categories of queens studied in laboratory showed that, most of the time, queens remained still in the nest on activities other than egg laying. Queens received grooming; however, such behavior was not made by them on other individuals. All queens laid eggs and were inseminated. The results prove the existence of functional polygyny in E. tuberculatum, without any apparent dominance, and supernumerary queens probably originating from re-adoption into the nest. There was no aggressive behavior in relation to egg-laying queens or to fresh eggs. Eggs from different queens were found joined together in the nests, in one single pile. Fresh eggs were directly, or indirectly, taken to the pile by workers or by the queen itself. No significant difference was observed between the number of oocytes and the number of yellow bodies among queens, proving that queens have similar fertility. On the other hand, queens differ according to the number of times they remained on the pile. Functional polygyny may have occurred as a response to environmental conditions on cocoa plantations of South Bahia, and this has allowed E. tuberculatum to form a component of the mosaic of arboreal dominant ants.

[1722] HYPERSENSITIVITY AND PLANT BEHAVIOR AGAINST PARASITES

G. Wilson Fernandes & D. Negreiros, gwilson@icb.ufmg.br

Hypersensitive reaction is a widespread mechanism by which plants resist the attack by herbivores, particularly galling insects. In a long term study we have evaluated the importance of hypersensitive reaction against a leaf galling insect. We also show that this induced mechanism is equaly important in other systems and that it is widespread in the plant kingdom. We argue that this plant mechanism of attacked cell localization and death may drive more general patterns of gall distribution among habitats in scales ranging from local to global.

Index terms: plant hypersensitivity, plant defenses, induced responses, Gall richness

[1724] PROCESSING OF ACOUSTIC SIGNALS IN THE AUDITORY SYSTEM OF GRASSHOPPERS: POSSIBLE CONSTRAINTS ON SIGNAL TYPES

B.Ronacher, Inst. of Biology, Humboldt-University, 10099 Berlin, Germany, email: Bernhard=Ronacher@rz.hu-berlin.de

To find a mate, many gomphocerine grasshopper species rely strongly on elaborate and highly diverse acoustic signals which constitute an important barrier against hybridization. It is the temporal patterns of a song rather than its carrier frequency content that carries species-specific information. As a consequence, the processing of the temporal pattern of conspecific signals by the receiver's auditory system is crucial for mate recognition. At the level of auditory receptors there are 50 to 100 elements per ear, which convey their spike trains to a set of interneurons located in the metathoracic ganglion, which perform first important stages of preprocessing. Higher-order interneurons ascending from the metathoracic ganglion then deliver this preprocessed and condensed information to neurons within the brain, where the final decision about acceptance or rejection of acoustic signals takes place. Most interestingly, in different grasshopper species the local thoracic and the ascending neurons, which are clearly homologous according to their morphological features, also exhibit very similar physiological characteristics. This conservation of physiological properties of auditory neurons was observed in species as different as *Chorthippus bigutalus* and *Locusta migratoria*. At present, we would conclude that there seems to exist a basic 'all-purpose equipment' of auditory neurons at the level of thoracic and ascending interneurons, which is common to very different grasshopper species and has not been changed by much during the evolution of highly diverse communication signals. Looking the other way round, this basic preprocessing machinery (from receptors up to ascending neurons) probably also has imposed constraints upon the possible signal types during the evolution of acoustic communication systems. In their spike trains, the auditory receptors do faithfully encode the songs of very different grasshopper species. Thus, we find no 'labeled-line' filtering at this stage. In addition, the receptors transmit also information about rather subtle intra-specific differences between songs of different grasshopper males. This has been demonstrated by application of stimulus reconstruction methods and spike-train classifications to the spiking responses of auditory receptors (Machens et al., in prep.). These theoretical approaches could lead to a deeper understanding of how the physiological properties of the auditory pathway of grasshoppers may have favoured certain signal types.

Session 09 – ETHOLOGY

[1725] NEUROPHYSIOLOGICAL ANALYSIS OF ACOUSTIC SIGNALS IN CRICKETS: TEMPORAL PATTERN AND SOUND LOCALIZATION

G.S. Pollack, V. Givois, & Z. Faulkes, Dept. of Biology, McGill Univ., 1205 Dr. Penfield Ave., Montreal, PQ, Canada H3A 1B, E-mail: GPOLLACK@BIO1.LAN.MCGILL.CA.

An important component of acoustic communication is sound localization; the recipient of a signal must localize its source so as to direct its behavior appropriately. In insects, sound direction is determined by comparing sound intensity at the two ears. The "localizability' of a signal depends on its acoustical properties; e.g., the relation between signal spectrum and interaural intensity difference is well documented. Our recent experiments demonstrate that another important feature of acoustic signals, temporal pattern, also affects localizability. Sound intensity is reported to the central nervous sytem by auditory receptor neurons (ARNs), which produce more action potentials as intensity increases. ARN responses are also affected by stimulus temporal pattern. Songs of the cricket Teleogryllus oceanicus consist of minutes-long trains of rapidly repeated sound pulses. Such stimuli cause habituation of ARNs; the number of action potentials decreases for successive sound pulses. Habituation increases with intensity, and herein lies a problem for computing interaural intensity difference. Habituation is greater in ARNs serving the ear where intensity is higher. As a result the interaural difference in ARN responses declines as habituation builds up; under extreme conditions the difference approaches zero, and in some individuals it may even reverse in sign. Another potential code for sound direction is interaural latency difference; ARN latency decreases with increasing intensity, resulting in interaural latency differences of up to several msec. Latency is also affected by habituation, increasing for successive responses. However, unlike the change in response strength, the change in latency is independent of intensity and thus is similar for ARNs of both ears. Interaural latency difference thus remains constant as may be a more reliable cue for sound direction. Some aspects of central neural circuitry also suggest that latency difference may be an important cue. Habituation of ARNs is a universal phenomenon, in vertebrates as well as insects, and may be an unavoidable consequence of the high rates of action potential production that characterize auditory systems. Because of its effects on encoding of localization cues, habituation may be a physiological constraint that has helped to shape the temporal structures of acoustic signals, as well as in the ways in which interaural cues are analyzed in the central nervous system.

[1726] MATE SAMPLING STRATEGIES AND MATE CHOICE IN THE ORTHOPTERA: IMPLICATIONS OF NEUROETHIOLOGICAL STUDIES

<u>R. Balakrishnan¹</u>, D. von Helversen², & O. von Helversen², ¹Centre for Ecological Sciences, Indian Institute of Science, Bangalore 560012, India, Email:rohini@ces.iisc.ernet.in; ²Institute for Zoology II, University of Erlangen, Staudtstrasse 5, 91058 Erlangen, Germany.

The rules of auditory information processing derived from neuroethological studies may constrain and allow prediction of strategies of mate sampling and mate choice in acoustically signaling insects. Theoretical models and studies of mate sampling often assume either simultaneous or sequential sampling of the songs of potential mates. Using the duetting grasshopper Chorthippus biguttulus as a model system, we argue that the pooling of auditory information from the two ears by the song pattern recognition mechanism would restrict such grasshopper species to sequential sampling, since only one song pattern can be evaluated at a given time. The nervous system of crickets can simultaneously represent two independent song patterns, allowing females to perform simultaneous sampling in a chorus of singing males. The mechanism of selective attention would, however, restrict the number of simultaneously sampled songs to two: the loudest song on each side. Evaluation of more than two songs would necessarily be a sequential process. With regard to fixed threshold versus relative (best of n) choice models of mate choice, we suggest, on the basis of playback experiments evaluating female response probability, that C. biguttulus may in fact use both mechanisms. The strong discrimination of females against the songs of one-legged males operates as a fixed choice criterion. Female response depends on the evaluation of a number of song parameters, including the ratio of syllable: pause duration, syllable shape, spectrum, and verse amplitude modulation, which may be weighted differently by different females, allowing trade-offs between these parameters. Verse length appears to be an important parameter in choosing between the songs of different males. The response probability of a female to a given song model in a sequentially presented series depends on the quality of the other song patterns presented, that is, it is modulated by the acoustic context. This suggests that C. biguttulus is at least capable of relative (best of n) choice by sequential sampling. A given species may thus use fixed choice thresholds for certain parameters and relative choice for others. Index terms: Chorthippus biguttulus, grasshopper, cricket, auditory, song.

[1727] THE FUNCTION OF COURTSHIP IN GRASSHOPPERS RELATED TO CHORTHIPPUS ALBOMARGINATUS (ORTHOPTERA: GOMPHOCERINAE)

<u>V.Yu. Vedenina</u>¹ & O.v. Helversen², ¹Inst. for Information Transmission Problems, Bolshoi Karetnyi per. 19, Moscow 101447, Russia, E-mail vedenin@iitp.ru; ²Zool. Inst. II, Staudtstr. 5, Erlangen 91058, Germany

Some gomphocerine grasshoppers demonstrate an elaborate courtship behaviour. Courtship song can consist of many sound elements with different temporal patterns. Some visual signals can be also integrated into the courtship: rhythmic movements of head. have similar and quite simple calling songs but completely different and complex courtship songs. Can the complex courtship be a component of reproductive isolation between these species? To clarify this question, we studied whether any zones of sympatry for these species exist. On the territory of Ukraine and Moldova, we found two species of this group: Ch. albomarginatus inhabiting the norhern areas of the countries and Ch. oschei occurring in the southern areas. The analysis of the song and leg-movement recordings revealed that two species overlap in their distribution within a distance of about 200 km. In this area, not only males demonstrating courtship typical for one or another species have been found, but also individuals with intermediate courtship characteristics (in terms of temporal parameters of the song and leg-movements) were revealed. Moreover, the song patterns varied greatly from one specimen to another and showed irregularities within each specimen. In behavioural experiments, the females from these localities were found to respond to the courtship of both species. The data obtained indicate that the courtship was not the component of reproductive isolation between Ch. albomarginatus and Ch. oschei. Since the song of Ch. albomarginatus consists of a series of four pattern elements while a more elaborate song series of Ch. oschei includes seven elements and is additionally accompanied by visual signals, an evolutionary aspect of the complexity of the courtship pattern is discussed.

Index terms: Chorthippus oschei, sibling species, courtship song, temporal pattern.

[1728] DUETTING IN PHANEROPTERID BUSH-CRICKETS

K. G. Heller, Dept. of Zoology II, Univ. of Erlangen-Nuernberg, Staudtstr. 5, D-91058 Erlangen, Germany, F-mail kheller@biologie.uni-erlangen.de.

In the acoustic communication of bush-crickets usually the male produces the acoustic signal and the female approaches him phonotactically. The hearing capabilities of both sexes are typically quite well adapted to the frequency range of these songs. However, in two families, in Phaneropteridae and Bradyporidae, the females of many species respond acoustically to the male song and the males approach them phonotactically or both sexes move phonotactically towards each other. In the Phaneropteridae, female acoustic responding seems to be the ancestral condition found in the vast majority of species. The carrier frequency of male songs within this large family (more than 2000 species worldwide) varies according to body and wing size, spanning at least 4 octaves. For the females, however, which differ quite often from the males in these dimensions, other song frequencies than in males are produced most efficiently. Since both sexes must hear each other, song frequencies are expected to diverge not too much and some process of coevolution must occur. In a comparative study of about 40 phaneropterid species (14 genera) the majority belonging to the tribe Barbitistini I have examined the relationships between body dimensions and carrier frequency in both sexes. Phaneropterid acoustic duets are also well known for their unusually narrow and short time relationships between male and female signals, often occurring within 0.1s. There are, however, also many species with much longer intervals between male and female signal. Using the same set of species and additional data from literature, I have correlated the male-female time relationships to morphological and phylogenetic parameters. In small and short-winged species the fastest duets are found, while in some long-winged species intervals in the range of seconds between male and female can be observed. The reasons for these differences and for the loss of acoustical responding in some species are discussed in relation to the mating system of bush-crickets and the predation pressure on these insects, Index terms: Barbitistini, Poecilimon, acoustic communication, signalling.

[1729] PROCESSING OF CARRIER FREQUENCY AND SIGNAL EVOLUTION IN SOME BARBITISTINI (ENSIFERA)

A. Stumpner, Neurobiology, Institute for Zoology and Anthropology, Georg-August-University, Berliner Str. 28, D-37073 Goettingen, Germany. E-mail: astumpn@gwdg.de

Among bushcrickets of the group Phaneropteridae, the Barbitistini have highly developed acoustic communication. The males produce relatively complex temporal patterns and the females respond with a short click of constant delay to the trigger element in the male song. The carrier frequency of male and female song may be similar (around 20 to 35 kHz in different species of Barbitistes) or may differ (male: 16 kHz, female 28 kHz in Ancistrura nigrovittata (S. Dobler et al. 1994. J. Comp. Physiol. A 175:303)). When comparing certain parameters of body size with carrier frequency, it is quite obvious that males of A. nigrovittata have unusually low song frequency. The frequency range of the auditory organs or of broadly tuned interneurones (e.g. omega-neurone 1, ON1) does not differ much between different species and is similar to next related species in the genus Poecilimon. Therefore, such a broad hearing range can be assumed to be primitive in the Barbitistini. However, certain interneurones (ascending neurone 1, AN1) transferring information from the thorax to the brain, show prominent frequency processing by receiving frequency dependent inhibitions. The resulting frequency range of excitatory response appears to be adapted to the carrier frequency of the male song. Correspondingly, we see strong inhibition above 20 kHz and below 12 kHz in A. nigrovittata (A. Stumpner 1997, J. Exp. Biol. 200:1089), while we see only low frequency inhibition and no high frequency inhibition (up to 50 kHz) in Barbitistes species. If a pharmacological blocker for certain types of inhibition (picrotoxin) is applied to the nervous system, the frequency tuning of AN1 changes in Ancistrura (A. Stumpner 1998, J. Neurophysiol. 79: 2408) and Barbitistes. In both, frequency dependent inhibition is eliminated and AN1 becomes a broadly tuned neurone similar to ON1. Therefore, it seems that in certain interneurones broad excitation and some frequency dependent inhibition existed already in primitive Barbitistini. During speciation a change in inhibition and not in excitation changed the properties of these neurones. Obviously, in A. nigrovittata the male song carrier frequency was lowered in the course of evolution. While it cannot be excluded that this was a consequence of a preexisting 16 kHz-filter (in the sense of 'sensory exploitation'), the species-specific tuning of AN1 in different species makes it more likely that the neuronal filtering properties followed the lowered song frequency in a coevolutionary process. This allowed A. nigrovittata males to reduce interference with songs of related species, and build up a more effective contrast to those species, the males of which produce similar temporal patterns (especially B. ocskayi).

Index terms: Ancistrura nigrovittata, Barbitistes, hearing, song frequency, neurophysiology.

[1730] A MIS-MATCH IN AN AUDITORY SEXUAL COMMUNICATION SYSTEM

M. G. Ritchie, Environmental & Evolutionary Biology, Bute Medical Building, University of St Andrews, St Andrews, Fife, KY16 9TS Scotland. E-mail: mgr@stand.ac.uk.

Most studies of the evolution of auditory sexual communication systems have suggested that stabilising selection will lead to the coevolution of male and female components. Hence one would expect to see a broad match between the distribution of males traits and sensitivities or preferences of females. Yet sexual selection emphasises that females may prefer extreme values of signals in males, particularly if these are indicator traits. It may also be the case that female preferences are substantially mis-matched from the distribution of a trait in males, especially if biases have arisen in a context other than sexual communication. Example of such mis-matches have been described in frogs and fishes. Here I describe preliminary studies of the preferences which females of the bushcricket Ephippiger ephippiger have for song which varies in spectral structure. Female preference is peaked at values well outside of the range normally found within the species. The strength of this preference has been explored by varying other song parameters (amplitude, chirp structure) to infer to what extent females will trade-off other traits in a preference hierarchy. Results suggest that the preference for high frequencies is robust. The distribution of carrier frequency within the Ephippigerinae is examined to infer if a preference for high frequencies represents a synapomorphy within the group. Females of two other species seem to lack such a mis-matched preference.

Index terms: Ephippiger ephippiger, feale preference, sexual selection, sensory bias, acoustic communication.

[1731] THE FUNCTION OF NUPTIAL FEEDING IN THE TETTIGONIID STEROPLEURUS STALI: FIELD EVIDENCE REFUTES THE PATERNAL INVESTMENT IIYPOTILESIS

K. Vahed, C. Braines & B. Davies, Centre for Earth, Environmental & Applied Sciences, Univ. Derby, Derby DE22 1GB, U.K., E-mail: K.Vahed@Derby.ac.uk.

The spermatophores of tettigoniids consist of an ampulla which contains the sperm and a gelatinous spermatophylax which the female eats following copulation. One hypothesis for the function of the spermatophylax is that it is maintained by selection for paternal investment in offspring. Male Steropleurus stali produce some of the largest spermatophylaces of all tettigoniids: a single spermatophore can represent over 40% of male body weight. Previous studies indicate that there is pronounced last-male sperm precedence in S.stali. Therefore, in order for the spermatophylax to function as paternal investment, eggs benefitting from the spermatophylax nutrients of the male must be laid before the female re-mates. Here, we present the results of a field study, based in the Sierra Guadarrama mountains, Spain (in August/September 1998 & 1999), designed to test whether or not this is possible. The mean duration of the sexual refractory period of females in the field was four days (range 3 - 7 days), during which time females laid an average of 12 eggs (range 0 - 41 eggs). However, field caught, sexually receptive females were found to contain an average of 27 mature eggs (range: 13 - 59 eggs). These mature eggs can have no further nutrients added to them and will be laid, and fertilized, before eggs that mature subsequently. Therefore, the eggs laid during a female's refractory period are unlikely to benefit from the spermatophylax nutrients received from the most recent mating. Consequently, the large spermatophylax of S.stali is unlikely to function as paternal investment.

Index terms: Katydids, nuptial gifts, paternal investment, spermatophylax

[1732] SINGING OUT OF TURN: SATELLITE BEHAVIOUR IN AUSTRALIAN PHANEROPTERINE BUSHCRICKETS

W. J. Bailey, Dept. of Zoology, University of Western Australia, Nedlands, Perth 6907; E-mail: wbailey@cyllene.uwa.edu.au

Duetting amongst acoustic insects is surprisingly common and insects that engage in this behaviour presumably do so to maintain a pair bond between courting partners. The interval between duetting partners is usually short preventing the intrusion of competing males. In this way duets are seldom subject to take-overs. But where the duet interval is long and follows a complex signal acoustic satelliting is possible with the satellite inserting a distracting signal within an alpha male's song. I report duetting and, to my knowledge, the novel behaviour of acoustic satelliting in phaneropterine katydids (bushcrickets). Male and female Elephantodeta nobilis (Phaneropterinae: Tettigoniidae: Orthoptera) duet with the female responding to the male's long and complex call. The duetting or alpha male's call consists of four parts where the initial sections carry information on species-identity and perhaps on male quality. The length of this section of the call can be over 5 seconds. The second two parts of the call act as triggers for the female response, where the female replies with a brief signal some 570 ms after the trigger-pulse. Non-calling males are attracted to the duet and often use this tactic to gain access to females. They insert a volley of clicks some 200 ms before the alpha male's trigger to which the female sets the timing of her response. I tested the effectiveness of the satellite's call on female phonotaxis within a two-speaker arena and although females preferred the alpha male they were nevertheless attracted to the satellite calls time regardless of relative intensity of the calls. All males appear able to adopt satellite behaviour regardless of their developmental state, however, recently mated males are more inclined to satellite than call as alpha males. Such males are able to re-mate within minutes of mating and in doing so provide an extremy small spermatophore. It is suggested that satellite behaviour may be an adaptive tactic controlled by the relative apportioning of energy between spermatophore development and calling. I discuss the apposible role of satellite calling within the context of female choice. Index terms: *Elephantodeta nobilis*, Phaneropterinae; Tettigoniidae, acoustic; alternative

strategies.

Session 09 – ETHOLOGY

[1733] PREDATION BY GLEANING AND AERIAL HAWKING BATS: ITS EFFECT ON THE EVOLUTION OF HEARING AND SOUND COMMUNICATION IN TWO GROUPS OF KATYDIDS IN PANAMA

H. Römer, I. Teppner & A. Lang, Institute of Zoology, Karl-Franzens-University, A-8010 Graz, Universitätsplatz 2, Austria. E-mail: roemer@kfunigraz.ac.at

This study combines field and laboratory investigations of acoustic behavior and neurophysiology in two groups of neotropical katydids (Orthoptera) with contrasting predation pressure by different guilds of bats. The overall aim was to relate the patterns of variability of several traits between species, and between Pseudophylline and Phaneropterine katydids, to the underlying selective processes which generate these. We test the hypothesis that the Pseudophylline species, due to predation pressure by gleaning and passively listening bats have evolved a reduced sensitivity to airborne sound and This may be advantageous for detecting increased substrate vibration sensitivity. conspecific signals in a noisy environment. By contrast, most Phaneropterine species are good flyers and thus subject to predation by aerial hawking insectivorous bats, and have evolved sensory and central nervous traits that enable them to escape from a bat attack in flight. This includes increased sensitivity of the ears through enlarged auditory spiracles and probably increased ultrasonic sensitivity of certain interneurones. In particular we have focussed on the consequences of these adaptations for intraspecific acoustic communication, and how environmental gradients in predation pressure and noise influences the detection of conspecific signals. Signal Detection Theory (SDT) was used to examine the ability of katydids to detect these sounds and bat sonar in the field, based on long-term recordings of identified interneurones. A portable neurophysiological recording device and natural sound stimuli (or signals varied with respect to intensity, duration and redundancy), were employed for playback experiments performed on a rainforest transect. The rate of "hits", "misses" and "false alarms" in the various microhabitats and at different times of day/night were determined, and special attention was given to the degree of noise on the transmission channel. In another approach we have established preparations of the two INs in habitats selected for their different bat communities, i.e. open space and open cluttered space compared to highly cluttered space, together with a hat-detector for longterm recordings. This analysis will tell us how much of the neuronal activity was elicited by ... bat-like" or ... katydid-like" sound.

[1734] VIBRATIONAL COMMUNICATION IN ORTHOPTERA

A.A. Benediktov & <u>R.D. Zhantiev</u>, Moscow State Univ., Moscow, 119899, Russia, Email: zhantiev@1.entomol.bio.msu.ru

Vibrational communication is widespread in many insect orders. But among Orthoptera which use for communication mostly sound signals it can be found rather seldom. Untill recently vibrational signals (VS) have been recorded only in some Tettigonioidea (Ephippiger, Meconema). Besides it is known that such signals can be produced by some species of Acridoidea (Oedipodinae) and Grylloidea (Arachnocephalus). For the first time we have studied VS in two species of Tetrix (Tetrigoidea) and Arachnocephalus vestitus (Mogoplistidae, Grylloidea). For recording VS piezo-electric receivers were used. Tetrigids males produce signals of the three types: calling, rivalry and courtship, using mostly middle legs which do not produce any visible movements. Besides, body tremulation and periodical openings of wings can be seen. All the VS consist of more or less distinct pulses united into rythmically repeated groups - echemes and sequences. At least calling and courtship have distinct species-specific characters. Males of A. vestitus produce VS by percussive drumming of palps or tip of abdomen and also use tremulation of front and middle legs. The VS recorded by us are produced by the males only in the presence of females and therefore can be considered as courtship ones. The females answered the males with abdominal percussion. Comparison of vibrational communication in different groups of Orthoptera shows that VS are produced with the use of percussion and visible or invisible tremulation. In the latter case vibrations are emitted, as we expect, by rhythmic isometric contractions of muscles. The VS frequency depends on the features of the substrate. The temporal patterns of these signals are rather complicated - mostly not less than those of sound signals of Orthoptera. In all investigated orthopterans vibrational communication is likely to be a secondary phenomenon. The transition from sound communication to vibrational one leads to decrease of range of communication but on the other hand also reduces decamouflaging effect. Domination of vibrational communication in the abovementioned orthopterans is determined by specific features of their behaviour and first of all by the features of their populations and communities. Index terms: vibrational signals, communication, Orthoptera.

[1735] SERAGLIOS AND SIGNALING IN BLADDER GRASSHOPPERS

M. J. van Staaden¹ & II. Römer², ¹Dept. of Biological Sciences and JP Scott Center for Neuroscience, Mind & Behavior, Bowling Green State Univ., Bowling Green, OH 43403, USA, E-mail mvs@caspar.bgsu.edu; ²Institute for Zoology, Univ. of Graz, A8010, Austria.

Communication mechanisms bringing mates together to achieve syngamy are key components of the specific mate recognition system. Understanding the evolution of such systems and their role in the process of speciation requires knowledge of both proximate mechanisms underlying a particular sensory modality as well as the ultimate behaviors they mediate. While the former can be directly investigated, aspects of the mating system (e.g. breeding tactics, territoriality, sexual selection, dispersal) must often be inferred indirectly. We investigated an ancient, endemic African grasshopper with unique exaggerations of anatomy and behavior for long-distance acoustic communication. Bullacris membracioides (Pneumoridae), is a nocturnal, cryptic and specialized herbivore, with extreme sexual dimorphism. Winged, adult males have a conspicuously inflated abdomen absent in micropterous adult females. An alternative male morph does not call or fly, but is capable of mating adult females. Pneumorid acoustic signaling is unusual in several respects: although atympanate they harbor 12 mechanosensory organs for sound reception [van Staaden & Römer, Nature 394, 773]; four signals are produced by three different mechanisms; and roving primary males produce highly exaggerated signals. B. membracioides locate mates by antiphonal duetting that is asymmetrical in terms of mechanism, signal intensity and degree of stereotypy. Males achieve transmission distances of ± 2 km by combining high amplification, sensitive hearing, and exploiting optimal weather conditions. The differential female response is mediated by serial ears, and depends on intensity but not temporal structure of the male call. Viscous population structure means that alternative males mate only in a seraglio of females who tend to be his relatives. Morphometric data suggests that this form is not simply neotenic but presumably the result of selection for both high and low risk strategies in an unpredictable environment created by patchy habitat with cyclical drought and fire. Genetic analyses indicate that competition amongst primary males determines which individuals monopolize key mating areas and enjoy high reproductive success. Despite the exaggerated male signal and a large intersexual difference in active signal space, there is little evidence for sexual selection by females. The evolution of bladder grasshopper signals and mating system will be interpreted within a phylogenetic context, and the potential for coupled sender and receiver precursors will be discussed. [1736] THE EVOLUTION OF SIGNALING MECHANISMS IN KATYDIDS AND THEIR RELATIVES (ORTHOPTERA: ENSIFERA: TETTIGONIOIDEA)

<u>P. Naskrecki</u>, Dept. of Ecology and Evolutionary Biology, University of Connecticut, Storrs, CT 06269, USA, E-mail piotr@neca.com.

Acoustic communication in the Tettigonioidea (katydids and relatives) employs a gamut of mechanisms of sound production, both substrate mediated and airborne. Although the primary mode of communication in Tettigonioidea is based on airborne signals produced by wing stridulation, other mechanisms have evolved independently in different clades of the superfamily. The most basal mechanism seems to be ambidextrous tegminal stridulation, present in members of the Prophalangopsidae. Within the Tettigoniidae there is a tendency to develop asymmetrical stridulatory mechanisms, with only a few known cases of acoustic ambidexterity (Nedubini). Several lineages have evolved alternative mechanisms of communication, and the complete loss of acoustic communication is known in others. At least two lineages, Meconematinae and Phyllophorinae, exhibit the "explicit" loss of tegminal stridulation, not coupled with the complete wing loss (anaptery). The latter occurred at least three times independently within Tettigoniidae (subfamilies Mecopodinae, Tettigoniinae, and Phasmodinae). Some neotropical Pseudophyllinae show a tendency for switching from airborne to substrate communication despite well developed tegminal stridulatory apparatus in males. Tremulation in such species exhibits highly species-specific, often very complex patterns. Several theories have been proposed to explain this behavior. A few lineages of katydids are known to use at least two, and often three independent modes of communication simultaneously. Some Copiphorinae produce airborne signals along with the substrate tremulation and feet drumming, and palpal drumming accompanies stridulation in some Pseudophyllinae. In addition to acoustic communication, some Tettigoniidae employ sound in their defensive behavior. Tegminal, femoro-abdominal, and labral stridulation is known to be employed as a defensive mechanism in several lineages. Usually both sexes, and in the case of the last two mechanisms also nymphs, produce defensive sounds. Female tegminal stridulation has evolved at least three times independently in katydids. The stridulatory apparatus of the females is either homologous or independently derived from that of the males. Index terms: stridulation, tremulation, Tettigoniidae, Prophalangopsidae

[1737] BEHAVIORAL AND EVOLUTIONARY SIGNIFICANCE OF THE DIVERSITY OF STRIDULUMS AND CALLING SONGS IN CRICKETS

L. Desutter-Grandcolas, ESA8043 CNRS, Lab. Entomologie, Muséum National d'Histoire naturelle, 45 rue Buffon, F - 75005 Paris, FRANCE. E-mail: desutter@mnhn.fr

The structure and functioning mechanism of the stridulum have direct consequences for the sounds taxa are able to emit. In crickets, the stridulum consists in a sound generator and a resonator, which are sharply tuned; the calls are characterized by their rythm and by their carrier frequency, which corresponds to the resonant frequency of the resonator. The biological and phylogenetic diversity of crickets shows a much larger array of stridulums than usually considered (Desutter-Grandcolas 1995, 1997a, 1998a,b). Similarly, "unusual" calls have been documented, among which broad frequency modulations, pulse duration 3 to 6 times longer than usually admitted in cricket calls and poorly resonant calling songs (Desutter-Grandcolas 1997a, 1998a,b). Combined analyses of tegmina and songs actually reveal that several functional types of stridulum exist in crickets. They also demonstrate that the "unusual" calls are emitted by perfectly functional stridulums, even though the structures of the tegmina are more or less deeply modified. Conversely, a mismatch between the tegmina results in an irregular (both in time and frequency) burst of sound (Desutter-Grandcolas 1998c). These data have direct consequences for our understanding of cricket biology and evolution. Most singing crickets have stereotyped calls and their stridulums correspond to one functional type. Exceptions concern other stridulum types and "unusual" calls, which have appeared convergently in distantly related cricket taxa. If one also consider the evolutionary lability documented in some cricket clades for acoustic behavior (Desutter-Grandcolas 1997b,c), the ensuing pattern for cricket evolution is extremely complex. It is argued that the factors responsible for the effectiveness of calling songs shoud be reconsidered and that a better understanding of these could help to clarify the evolution of acoustic communication in crickets.

Index terms : Orthoptera, Grylloidea, Acoustic communication, Stridulation.

[1739] SEXUAL SELECTION, SPECIES ISOLATION, AND CHARACTER DISPLACEMENT IN MALE SONG AND FEMALE PREFERENCE FOR SONG IN THE FIELD CRICKET GRYLLUS TEXENSIS

<u>D. A. Grav</u>¹ & W. II. Cade^{1,2}, ¹Biological Sciences, Brock University, St. Catharines, Ontario, L2S 3A1, Canada, E-mail dgray@spartan.ac.brocku.ca; ²President's Office, The University of Lethbridge, Lethbridge, Alberta, T1K 3M4, Canada.

Cricket calling song was historically viewed as a species isolating trait. Renewed interest in sexual selection subsequently promoted the view that the temporal structure of song may be influenced by sexual selection via female choice acting on naturally occurring song variants. Here we use the Texas trilling field cricket, Gryllus texensis, in an attempt to integrate the species isolating and sexual selection viewpoints. We examine male song and female preference for song across a broad geographic area encompassing allopatric populations, as well as populations sympatric with G. rubens, a cryptic sibling species best distinguished by pulse rate differences in calling song. By testing the offspring of fieldcaught females, we were able to address the following questions: (1) are female phonotactic preferences sufficiently strong to act as effective pre-zygotic isolating mechanisms? (2) is there any evidence for reproductive character displacement in either male song or female preference for song? (3) is there evidence of genetic effects on male song and/or female preference for song?, and (4) are the genes for male song and female preference genetically correlated? Together these questions help define the role that sexual selection may play in speciation, either as a factor promoting speciation directly or simply maintaining species integrity following divergence due to other causes. At the time of abstract submission, we have obtained the following partial answers: (1) virtually all females of both species show a very strong preference for conspecific song, although a significant proportion also show response > 0 to heterospecific song, (2) *G. texensis* populations do not differ with respect to allopatry/sympatry with G. rubens. We also tentatively conclude that genetic effects are likely, and that the male and female components may be genetically correlated, although genetic analyses are not yet complete. Further work will examine the behavior of laboratory-produced hybrids.

[1738] THE EVOLUTION OF MATING SYSTEMS IN SHORT-TAILED CRICKETS (GRYLLIDAE: ANUROGRYLLUS SPP.)

T. J. Walker¹, ¹Dept. Entomology and Nematology, Univ. Florida, P.O. Box 110620, Gainesville, FL 32611-0620, USA, E-mail: tjw@ufl.edu.

Unlike prototypical crickets, short-tailed crickets have vestigial ovipositors and construct complex burrows in which mothers lay their eggs and care for their young. During mating, the spermatophore is held by the male rather than attached to the female. Sexual behavior has been studied in three species: Anurogryllus arboreus, A. muticus, and A. celerinictus. Males of all three call for limited periods beginning after sunset. Their calling songs are long-sustained trills with pulse-repetition rates of 65 to 185 per second, depending on species and temperature. In A. muticus (in Panama) and A. celerinictus (in Jamaica), males either call the entire singing period from thumb-print like depressions that they construct at the entrances to their burrows to amplify and direct their calls, or they call for several minutes at many stops as they move over the surface. Depression-calling males should primarily attract flying females, because their calls are directed upward. Males that intersperse locomotion with calling may primarily attract burrow-inhabiting females to their calls. In addition, they may be searching for the burrows of nonphonotactic but receptive females as they wander. Females of these two species may rear more than one brood. A. arboreus (in Florida) is flightless and univoltine, and females rear a single-brood. Males most often call from perches about 1 meter up but also call from the ground, either at the entrance to their burrows or away from any burrow but without wandering. Females attracted to calling males mate at the site of calling. If at the male's burrow, the mating occurs within the burrow and the male yields his burrow to the female afterwards. The calling period of A. arboreus is more limited than the other two species and males without burrows spend most of the night silently searching for the burrows of receptive females. Females will mate in their burrows shortly after the final molt but will usually not leave their burrows to go to a calling male, even if nearby, for 1 to 2 weeks. Mating lasts an average of 16 minutes on perches and about 40 minutes in burrows or on the surface. Males calling on perches may mate with as many as three females during a calling period of less than 1 hour. Once mated, females no longer go to calling males but will mate additional times if found in their burrows. Loss of flight and adaptation to temperate climates in A. arboreus accounts for some of the differences in mating systems between it and the other two species.

Index terms: Anurogryllus arboreus, Anurogryllus muticus, Anurogryllus celerinictus, phonotaxis, acoustics

[1740] SINGING UNDER PRESSURE: CALLING BEHAVIOR AND MATE ATTRACTION IN CRICKETS SUBJECT TO PHONOTACTIC PARASITOIDS

M. Zatk & G.R Kolluru, Dept. of Biology, Univ. of California, Riverside CA 92521 USA; E-mail: mzuk@citrus.ucr.edu.

The field cricket *Teleogryllus oceanicus* is subject to an acoustically-orienting parasitoid fly, *Ormia ochreacea*, where both have been introduced in Hawaii. Males are therefore experiencing a relatively recent change in selection pressure on calling behavior. Other research in similar systems in North America has suggested that satellite behavior may evolve as a male strategy to avoid parasitization, but in Hawaii, although field populations contain substantial numbers of silent males, these tend to be more heavily infested, not less, perhaps because these individuals are too depleted to call. Experimentally-infested males show a decrease in calling rate, which appears to be costly because they also atract fewer females. Spermatophore production is also significantly reduced by infestation, even early in larval life when relatively little tissue damage has been produced by fly larvae. Females are also less likely to mount and mate with infested males. Index words: sexual selection, *Teleogryllus oceanicus, Ormia ochreacea*. [1741] EVOLUTION OF ULTRASONIC SIGNALING IN LEPIDOPTERA: DISCRIMINATION OF MATING CALLS FROM BAT ECHOLOCATION SIGNALS AND THE EXPLOITATION OF ANTI-PREDATOR RECEIVER BLAS BY SEXUAL ADVERTISEMENT

M. D. Greenfield¹ & T. Weber¹, ¹Dept. of Entomology, Univ. of Kansas, Lawrence, KS 66045, USA, E-mail greenfie@ukans.edu.

Hearing, and specifically ultrasonic hearing, is a widespread phenomenon among Lepidoptera that is generally believed to have evolved under the selection pressures imposed by insectivorous, echolocating bats. Sound production, however, is much less ubiquitous, and in various species it functions in sexual advertisement and courtship. The evolution of these lepidopteran signaling systems against the background of bat predation and the means by which lepidopterans discriminate mating from predator signals are major problems in animal communication. We addressed these problems in the lesser wax moth, Achroia grisella (Lepidoptera: Pyralidae), a species in which pair-formation is accomplished via male-produced pulses (100 µs) of ultrasound (100 kHz) attractive to females. A. grisella are sensitive (threshold < 50 dB SPL) to a wide range of ultrasonic frequencies, enabling them to hear the echolocation signals of both aerial-hawking and substrate-gleaning bats. Both flying and running moths exhibit defensive behaviors, dropping to the ground and cessation of locomotion, respectively, in response to simulated bat echolocations. We determined that female A. grisella discriminate the mating signals of advertising males from bat echolocations on the basis of the faster pulse rates (> 60 s⁻¹) of mating signals. Terrestrial defensive behavior is elicited by a slow rate of lengthy (≥ 1 ms) pulses, features of most searching phase bat echolocations. Unlike other insects that perceive and evade insectivorous bats, the perception of and negative responses to predators probably preceded acoustic signaling in A. grisella and other acoustic Lepidoptera. Thus, the acoustic signaling system may have originated via exploitation of an ancestral receiver bias, but development of a positive receiver response, and a possible shift in a signal character (pulse rate), must have occurred subsequently. We suggest various processes that may have allowed this radical evolutionary development and call attention to the potential role that the perception of predators and associated negative responses may have played in the evolution of signaling systems via exploitation of receiver hias.

Index terms: acoustic communication, female choice, Lepidoptera, sensory bias, sexual selection, waxmoth.

[1742] BATS, MOTHS, AND POETRY: THE EVOLUTION OF ACOUSTIC COMMUNICATION IN TIGER MOTHS (LEPIDOPTERA: ARCTHDAE)

W. F. Conner, Department of Biology, Wake Forest University, P.O. Box 7325, Winston-Salem, NC 27109, USA, E-mail conner@wfu.edu

Tympanal sound receptors clearly evolved in response to selective pressures provided by echolocating insectivorous bats. Tiger moths (Arctiidae) secondarily evolved tymbal organs with which they answer the echolocation cries of bats with broadband clicks. The presence of both sound reception and production set the stage for the repeated evolution of intraspecific ultrasonic communication systems for the purpose of detecting, finding, and obtaining mates. The use of ultrasonic signals in courtship will be documented for the species *Cycnia tenera*, *Euchaetes bolteri*, *Syntomeida epilais*, and *Empyreuma affinis*. The use of ultrasound in courtship has evolved a minimum of five times with the Arctiidae. Ultrasound use in courtship has evolved a minimum of five times with the Arctiidae: once within the subfamily Lithosiinae, once within the tribe Arctiini, once within the tribe Callimorphini, once with the tribe Phaegopterini and once within the tribe Euchromiini.

Index terms: Lepidoptera, Arctiidae, ultrasound, courtship

[1743] THE DYNAMICS OF SEXUAL SELECTION AND THE EVOLUTION OF NOVEL ACOUSTICAL SIGNALING IN HAWAIIAN DROSOPHILA

K.Y. Kaneshiro, Center for Conservation Research & Training, Univ. of Hawaii, 3050 Maile Way, Gilmore 406, Honolulu, Hawaii 96822, USA, E-mail kykanesh@hawaii.edu.

It has been suggested that sexual selection and the dynamics of sexual selection have played a critical role in the evolution of the tremendous speciation of Drosophilidae in the Hawaiian Islands. During periods of small population size, there is strong selection for females that are less choosy in mate selection which results in an increased frequency of less choosy females in subsequent generations of small population size. It is suggested that such conditions result in a shift in gene frequencies toward the genotypes of the less choosy female. Perturbation of the balanced genetic system results in a destabilized genetic condition and the break-up of co-adapted genetic elements, which in turn, promotes the generation of novel genetic recombinants previously not present in the population. These novel genetic elements then provide the raw material upon which natural selection or sexual selection can operate in the population's ability to adapt to the new habitat or to changing environmental conditions. Some selection experiments involving morphological characters will be used to illustrate the pleiotropic effect of the sexual selection system and this model will be used to explain the four different mechanisms of acoustical signaling observed among the Hawaiian Drosophila species. While wing vibrations are known to produce acoustical signals among dipteran species, several species of Hawaiian Drosophila also produce sounds by vibrating two pairs of muscles that adjoin the thorax and abdomen. Other species produce a high frequency sound which is beyond the sensitivity level of the typical receptor found in Diptera, i.e. the arista. Still other species are able to modulate the frequency of their wing vibrations resulting in a much more complicated set of signals previously unknown for dipteran species. It is suggested that the novel acoustical signaling mechanisms in the Hawaiian Drosophila are pleiotropic results of shifts in the sexual selection system during founder events or during population bottlenecks.

[1744] EVOLUTION OF APOSEMATIC SIGNALS IN MUTILLID WASPS (HYMENOPTERA)

G. Tschuch¹ & D. J. Brothers², ¹Inst. f. Zoologie, M.-Luther-Univ., Domplatz 4, 06099 Halle, Germany, E-Mail tschuch@zoologie.uni-halle.de; ²Univ. of Natal Pietermaritzburg, School of Botany and Zoology, Private Bag X01, Scottsville, 3209 South Africa.

Female mutillid wasps are extremely robust and have a very powerful sting. This enabled the evolution of aposematic signals although these insects are solitary and their strategy is k-selection. Mutillid wasps have evolved aposematic signals in a mutimodal fashion, involving optical (conspicuous bright contrasting colours), mechanical (acoustic, vibrational), and chemical signals. The present paper deals with the acoustic and chemical signals. Acoustic and vibratory signals are produced by stridulation, the stridulatory file being on the third metasomal tergum. The airborne signals have a broad spectrum with many harmonics. This may be important for aposematic acoustic signals because potential predators are phylogenetically very different or because the signals may have evolved in Mullerian mimicry to hissing by vertebrates. The chemical signals in mutillid wasps are produced by secretions of the mandibular glands, containing a cocktail of allomones. Apart from ketones, alcohols and acetophenone, probably acting as substances that are toxic or unpleasant to some predators, alkylpyrazines and other chemicals which may act as warning signals have been found. They are perceptible by manunalian and avian predators even at very low concentrations. The reason for multimodality of the signals will be discussed. Parts of this study were financially supported by the Deutsche Forschungsgemeinschaft grant number Ts 53/1-1 and Ts 53/1-2 (to GT) and the University of Natal Research Committee (to DJB).

Index terms: Mutillidae, stridulation, allomone.

Symposium and Poster Session

[1745] EVOLUTION OF SOUND AND VIBRATION PRODUCING ORGANS IN HETEROPTERA AND HOMOPTERA - AUCHENORRHYNCHA

M. Gogala, Prirodoslovni muzej Slovenije, (Slovenian Museum of Natural History) Presernova 20, SI-1001 Ljubljana, Slovenia, E-mail: matija.gogala@uni-lj.si.

During the last 30 years it became clear that communication with vibrational signals is widely spread in Heteroptera and Homoptera Auchenorrhyncha. Another discovery was that in Heteroptera various stridulatory structures are not the basic vibrational or sound producing mechanisms. Much more common, but not easily recognizable, is the presence of structures producing low frequency vibrational signals with a frequency range between 50 and 250 Hz. These signals are certainly not produced by different reasonably well known stridulatory organs which produce also in vibrational communications mainly broad band medium frequency signals (500 Hz - several kHz). Body vibrations are produced in some systematic groups by a tymbal mechanism (e.g. Cydnidae) and in others by simpler body part vibrations (e.g. Pentatomidae). Similar structures situated in the first abdominal segments are present in planthoppers, leafhoppers, and other related groups of Auchenorrhyncha with the sole exception of the singing cicadas that possess specialized tymbal membranes and use the airborne sound for communication. But even in this case the tymbals are situated in the same part of the insect body and every year more additional sound producing structures and mechanisms become known in this group of Homoptera also. In other Auchenorrhyncha, the basic type of acoustic signals are also low frequency vibrations produced by the longitudinal and/or dorsoventral muscles in the first two addominal segments. Probably in most cases the muscle action is enhanced and modulated by tymbal structures. Therefore, it is evident that a vibration-producing structure in the first two abdominal segments is an old acquisition in the evolution of all Hemiptera. Other sound or vibration producing organs such as stridulatory organs or wing clapping mechanisms developed independently in various groups of Hemiptera. Index terms: Hemiptera, acoustics, communication

[1746] THE ROLE OF ACOUSTIC COMMUNICATION IN SPECIATION OF PLANTHOPPERS (HEMIPTERA: FULGOROMORPHA)

H. Hoch, Museum für Naturkunde, Humboldt-Univ., Invalidenstr. 43, D-10115 Berlin, Germany, E-mail hannelore.hoch@rz.hu-berlin.de.

To ensure survival and reproductive success of a given species, it is essential for conspecific individuals to communicate, i.e., to interact, so as to pass on information to potential partners. Generally, mobile, sexually reproducing organisms have developed specific mate recognition systems (SMRS) which may consist of optical, chemical, tactile or acoustic signals, or a combination thereof. In case the SMRS of two given populations diverges - regardless whether by natural or by sexual selection, or by genetic drift - to a point where conspecific partners fail to recognize each other as such, reproductive isolation is the result. Thus, the two populations have attained species status. An excellent model to study the evolution of SMRS is obligately cavernicolous planthoppers in Cixiidae from Hawaii. In troglobitic planthoppers, the main element of the SMRS is lowfrequency vibrational signals produced in a specialized abdominal structure and transmitted via the legs to the host plant, roots of native trees. Thus, we can expect a high selection pressure on the maintenance of a signal structure that will serve its purpose most effectively. Our research on Oliarus polyphemus from lava tubes on Hawaii Island revealed: 1) as compared to epigean planthoppers, all cave populations studied display a simplified call structure, with single signals consisting of more or less homogenous pulse trains, 2) within a given population variation is usually low, and 3) in Hawaii, O. polyphemus populations from different lava tubes showed high variation among populations. The results of playback experiments suggest that at least some of the populations studied are reproductively isolated, i.e. they can be regarded as separate species. The evolution of this species complex is most likely independent of adaptive processes as all O. polyphemus populations studied colonize very similar types of habitat. A study is under way to investigate the genetic information underlying the differentiation of the SMRS within the O. polyphemus species complex. At present, our research focuses on the period gene which is expected to provide insight in the genetic basis of signal structure. This information will not only contribute to our understanding of the time frame within which the observed divergence may have occured, but will be integrated with other empirical data sampled over the past decade, such as structure and size of O. polyphemus populations, life history, reproduction and migration rate, to develop a mathematical model to describe speciation processes.

Index terms: Cixiidae, Oliarus polyphemus, cavernicolous species, SMRS

[1747] FREQUENCY DISCRIMINATION IN CICADAS: A FRAMEWORK FOR EVOLUTION OF COMPLEX SIGNALS?

P. Fonseca

ABSTRACT NOT RECEIVED

[1748] DEVELOPMENT AND UTILIZATION OF ANAPHE INFRACTA

II. Akai & T. Nagashima, Department of Agriculture, Tokyo University of Agriculture, Funako, Atsugi, Kanagawa 243-0034, Japan

Anaphe silkmoths behave as a group in their feeding, molting and movement during their larval stage, and the offspring from a single mother moth collaborate to make a huge silk nest. They belong to Thaumetopoeidae in Notodontoidea. Anaphe silkmoth makes a very large silk nest, about 25 X 15 cm in diameter, which contains numerous individuals in a single cocoon. Our interest in this insect is in the following : 1) Are they social insect? 2) How they collaborate to make their silk nest? 3) What are the structural characteristics of the cocoon and cocoon filaments? We will describe preliminary findings on this moth and its silk. An egg mass laid on a leaf is covered with a thick blanket containing scales and silk fibers originating from the moths. Matured larvae collaborate to make a huge silk nest which is composed of a common silk shell and numerous individual cocoons. A special stimulating vapor released from the silk nest causes the skin to itch when touched by the hand. Following degumming of cut nest, we no longer feel this sensation which means that the stimulating chemical is contained in sericin of the cocoon filaments. Each silk filament is extremely flat in cross section and compact, without any fine porous structure. Degumming of a bisected Anaphe silk nest was impossible by usual method, and a new method was developed.

Index terms: Anaphe, stimulating vapor, silk nest, cocoon filament, degunuming method

[1749] ANALYSIS OF SOME IMPORTANT FACTORS AFFECTING OVIPOSITION AND LONGEVITY OF THE ECTOPARASITIC WASP LAELIUS PEDATUS (HYMENOPTERA: BETHYLIDAE), A PARASITOID OF DERMESTIDE PESTS

A.-G. Al-Kirshi¹, II. Bochow², W. E. Burkholder³, Ch. Reichmuth⁴, ¹General Department of Plant Protection, P. O. Box 12724, Sana'a, Yemen; E-mail alkirshiabdul@y.net.ye; ²Humboldt-University of Berlin, Faculty of Agriculture and Horticulture, Department of Phytomedicine and Phytopathology, Lentzallee 55-57, Berlin 14195, Germany; ³USDA-ARS, Department of Entomology, 1630 Linden Drive, University of Wisconsin, Madison, W 53706 U.S.A; ⁴Federal Biological Research Center for Agriculture and Forestry, Institute for Stored Product Protection, Königin-Luise str 19, Berlin 14195 Germany.

The present study was designed to analyse the factors of temperature, relative humidity and diet and their effect on oviposition and longevity of the wasp L. pedatus as a possible antagonist to use it in biological control of dermestide pest in the store. Most egg-laying activity of the wasp occurred at temperature levels of 25°C - 28°C. Oviposition was not possible at 15°C and below. At 28°C and 50 - 60 % relative humidity a single female was able to deposit 52.3 \pm 6.3 eggs on the larvae of Trogoderma angustum. The average number of eggs per female and day was 1.42 ± 0.2 . The egg-laying activity occurred at both low and high relative humidity. The average numbers of eggs laid at extremely low humidity levels below 10 % and at high humidity levels above 90 % at a temperature of 28° C were 62 ± 12.6 and 25 ± 8 per female, respectively. Longevity of the female wasp increased with decreasing temperature down to 15°C and could also be prolonged by supplying the wasp with a diet of honey. The average life time of females fed with only host larvae lasted from 3 weeks at 35°C up to till 16 weeks at 20°C. At 28°C and 50 - 60 % relative humidity, about 80 % of the deposited eggs (n = 107) developed to adults. This number indicates, by consideration of the natural mortality of the larval and pupal stages, that the eggs' hatching rate was higher than 80 %. The total developmental time from eggs to adults under these conditions lasted 34.7 ± 1.8 days (n = 150). The observed biological characteristics of L. pedatus render the wasp a suitable agent to control dermestide pests like Trogoderma granarium, T. angustum and Anthrenus verbasci. However, field investigations in the store are needed to verify these results.

[1750] FRAGRANCE COLLECTION BY MALE EUGLOSSINE BEES, EUGLOSSA TOWNSENDI (IIYMENOPTERA, APIDAE) IN FLOWERS OF CRINUM PROCERUM

A. K. Braga¹ & C. A. Garófalo, Depto. Biologia, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto-USP, 14040-901, Ribeirão Preto, SP, Brasil, E-mail: ¹ akbraga@usp.br.

Male euglossine bees collect fragrances from the flowers of orchids and other plants, and broken and decaying vegetation, and store them in their tibial organs. The exact function of these fragrances is not entirely understood, but they possibly play a role as pheromones. Fragrance collecting by males of Euglossa townsendi from Crinum procerum was observed on the campus of the University of São Paulo, Ribeirão Preto, State of São Paulo, Brazil, in December 1998, February, March, November and December 1999, and January 2000. The plants were grown in a study plot, 12.25 m^2 (2.85 x 4.30m), established near the laboratory. The number of flowers on each of the inflorescences of *C. procerum* ranged from 6 to 8, and each flower had 6 tepals. The pattern of daily visitation by males was determined by continuous observations from 0700 to 1800h during 22 days. The males (n= 141) visited C. procerum inflorescences from about 0730 to 1600h, but most of them (n= 77) were active between 0900-1200h. When the males arrive at the inflorescences, they hover in front of one or more flowers for some seconds and then land near the edge of the tepals on the ventral (n = 70 cases) or dorsal (n = 45 cases) surface. After that they begin to brush on the surface of the tepals with their front tarsi. This activity is often interrupted when the males fly off the tenals to hover near the flower and to transfer the fragrance from the front tarsi to the hind tibiae. After finishing the transference of the fragrance, the males land and brush again, repeating the cycle of brushing and hovering several times until they fly away. The time of permanence of the males at the flowers ranged from 4 to 58 min (x = 22.6 \pm 12.3 min; n = 100) and they spent 123-2886 sec (x = 1105 \pm 657.3 sec; n = 100) brushing on the surface of tepals and from 3 to 991sec (x = 252.3 ± 187.4 sec; n = 100), transferring perfume from the front tarsi to the hind tibiae. The fragrancecollecting behavior showed by the male Eg. townsendi was similar to that described for other Euglossini species. The pattern of daily visitation of Eg. townsendi to the inflorescences of *C. procerum* resembled the pattern of visitation to artificial bails observed for males of several other species. The identification of the components of floral fragrances produced by C. procerum could explain why males Eg. townsendi have rarely been attracted to artificial baits.

Index terms: Euglossini, behavior, floral fragrance.

[1751] OVIPOSITION BEHAVIOR AND BIOLOGICAL CHARACTERISTICS OF TWO PHORID FLY PARASITOIDS OF THE LEAF-CUTTING ANT ATTA LAEVIGATA

M. A. L. Bragança & A. Tonhasca Jr., Universidade Estadual do Norte Fluminense, CCTA/LPP, 28015-620, Campos dos Goytacazes, RJ, Brazil. E-mail: braganca@uenf.br

Phorid flies Neodohrniphora spp. are common parasitoids of several species of leafcutting ants, and Atta laevigata hosts at least two species not yet described of that genus. Ovipositing females of two species of Neodohrniphora were collected in the field and released singly inside an observation chamber placed between a laboratory nest of A. laevigata and its foraging arena. One of the phorids (SP1) approaches the front or side of the ant head and apparently introduces the ovipositor in the host foramen magnum. The other species (SP2) approaches the ant gaster from behind and seems to insert the ovipositor through the anal opening of A. laevigata. The A. laevigata workers usually defend themselves from attacks of SPI by leaning on the medial and posterior legs, and attacking the fly with the anterior legs and jaws. The workers attacked by SP2 curl the gaster inwards to avoid the oviposition and try to "kick" the fly with the posterior legs. These movements suggest an attempt to scare away the fly. Unlike SP2, SP1 is not generally able to oviposit in the loaded ants because leaf fragments hinder its approach. The number of successful attacks/h (mean ± 1 s.d.) for SP1 (4.9 \pm 3.4, n = 26) was significantly larger (t = 4.91, P < 0.0001) than for SP2 (1.1 ± 1.9, n = 28). Dead parasitized workers were deposited by nestmates in nest refuse piles and identified by the presence of a phorid puparium betweem their jaws. This presence indicates the migration of SP2 larva from the gaster to host head. Attacks of SP1 and SP2 resulted in 46% and 19% of ants being parasitized, respectively. Adult flies emerged about 35 days after oviposition. The head width of ants (mean ± 1 s.d.) attacked by SP2 (3.5 \pm 0.6 mm, n = 162) was significantly larger (t = 5.77, P < 0.0001) than the head width of ants attacked by SP1 (3.1 \pm 0.5, n = 111). Since SP1 and SP2 select hosts of different sizes, and phorids in general affect the foraging behavior of Atta spp., both parasitoids shoud have an additive effect on reducing foraging activity of A. laevigata.

Index terms: Phoridae, Neodohrniphora, parasitism

[1752] NEST ARCHITECTURE AND NESTING BEHAVIOR OF ALEPIDOSCELES FILITARSIS (APIDAE, ANTHOPHORINAE)

<u>G. Cilla¹</u> & J. F. Genise², ¹Laboratorio de Icnología, Museo Argentino de Ciencias Naturales, Angel Gallardo 470, (1405) Buenos Aires, Argentina. E-mail: <u>gcilla@muanbe.gov.ar</u>, ² Departamento de Icnología, Museo Paleontológico Egidio Feruglio, Fontana 140, (9100) Trelew, Chubut Argentina. E-mail: mel002@infovia.com.ar.

The nest architecture and behavior of a species of the genus Alepidosceles (Emphorini) is reported herein for the first time. Data on nesting behavior of Alepidosceles filitarsis were obtained in La Rioja, Argentina, during December 1999. Several females were nesting in gravelly to sandy, well insolated, soil, having scattered plants of flowering Portulaca sp. from which the bees collected pollen. There was a single female per nest. In contrast to many Emphorini, bees did not bring water to soften the substrate during excavation. The soil was excavated with the mandibles and pushed outside the tunnel with lateral movements of the abdomen and the hind pair of legs. During the excavation of the nest, the sand was deposited around the entrance, forming a tumulus of loose soil (diameter ranging from 4.2 cm to 6.7 cm). The tumulus showed around the burrow entrance a distinct, more consolidated tube, like a "chimney" (length ranging from 0.7 cm to 1.6 cm). Although this chimney was not constructed actively by the bee, it was probably cemented by some secretion considering that it remained standing even when the wind blown up the rest of the tumulus. The main tunnel was excavated at a right angle from the soil surface (0.5 cm of diameter and length ranging from 3.3 cm to 4.6 cm). It showed from two to three lateral tunnels, at inclined angles, which leaded to series of cells. Abundant stones in the soil commonly produced sharp deviations of tunnels. The deepest cell of a series might contain either the oldest or the youngest larvae, suggesting that the direction of cell excavation was indistinct. Cells were provisioned with a ball-shaped mass of pollen. Eggs were laid in the lower side of pollen mass. Foraging took place during the morning and midday, when flowers were open, whereas in the afternoon, when the availability of flowers decreased, the construction activities were most important. Key words: bee, nests, excavation, foraging

[1753] THE LANGUAGE AND DIALECTS OF THE SOUTHERN GREEN STINK BUG NEZARA VIRIDULA, AN INSECT WHICH COMMUNICATES THROUGH PLANTS

<u>A.Čokl.</u> M. Virant-Doberlet & N. Stritih, Dept. Invertebrate Physiol., Natl. Inst. Biol., Večna pot 111, P.O.Box 141, SI-1001 Ljubljana, Slovenia, E-mail andrej.cokl@uni-lj.si

The southern green stink bugs Nezara viridula (Pentatomidae, Heteroptera) communicate in the premating time with chemical and vibratory signals. Vibratory signals constitute songs which are transmitted between communicating partners through plants as bending waves. The presence of a male triggers a female to emit the calling song to which a male responds with the calling and courtship song. The latter induces female courtship song emission which preceeds copulation. Males sing the rival song when courting the same female and females emit the repelling song when not ready to mate with courting males. Such a song repertoire has been confirmed in populations from Australia, Brasil, Florida, France, Guadalupe, Greece, Italy, Japan and Slovenia. The dominant frequency peak of their songs lies between 80 and 150 Hz and spectrally different and frequency modulated subunits are present within the same pulse and/or pulse train. Spectrally different and frequency modulated subunits decrease extensive intensity variations with distance as characteristic at nodes and antinodes for pure tones in standing wave conditions. The average duration of pulses and pulse trains differs between different populations more in the calling than courtship songs and the repetion time of song units varies extensively between them. Despite of different temporal structure normal communication could be shown between the Slovenian and Brazil, Florida and Italian and Guadalupe and Greece populations. Hybrids between the bugs from Brazil and Slovenia emitted songs which varied distinctly from parental and described differences could be attributed to genetic factor. Some parameters were intermediate between the parental ones and some were apparently sex-linked. Males showed vibrational directionality on a plant mediated by the female calling song. Intensity differences measured with Laser Doppler vibrometer between adjacent points on stem and petioli at relevant distances of about 1 cm were high enough to release differential nerve activities of vibration receptor cells of different legs. Males recognize the female calling song mainly by the duration of pulse trains when the frequency of the latter lies between 80 and 200 Hz. Males are more tolerant to prolonged artificial signals but stop responding when signals are shorter than the range of duration variation of natural ones. This phenomenon may be explained by signal prolongation due to echoing when transmitted through plants.

Index terms: Heteroptera, Pentatomidae, vibrational communication, mating behaviour.

[1754] APOCRINE SECRETION OF AMYLASE AND EXOCYTOSIS OF TRYPSIN ALONG THE MIDGUT OF *TENEBRIO MOLITOR* LARVAE

P. T. Cristofoletti¹, A. F. Ribeiro² & W. R. Terra¹, ¹Depto. de Bioquímica, Instituto de Química, Universidade de São Paulo, C.P. 26077, 05513-970 Brazil, E-mail ptcristo@quim.iq.usp.br; ²Depto. de Biologia, Instituto de Biociências, Universidade de São Paulo, C.P. 11461, 05422-970, Brazil.

Amylase and trypsin were purified from Tenebrio molitor midgut larvae and used to raise antibodies in a rabbit. A western blot of T. molitor midgut homogenates, after sodium dodecyl sulfate-polyacrylamide gel electrophoresis using amylase and trypsin antiserum, showed only bands co-migrating with the purified enzymes. The antiserums were used to localize the enzymes by immunofluorescence and immunogold labeling. Amylase occurs in a few regularly disposed anterior midgut cells. Non-amylase-secreting anterior midgut cells are supposed to be water-absorbing cells based on morphology and dye movements. Amylase is found inside vesicles originating from Golgi areas that seem to fuse one with another before their release together with the now disorganized apical cytoplasm (apocrine secretion). Trypsin precursors concentrate inside small vesicles near the apical cytoplasm of posterior midgut cells, suggesting an exocytic mechanism of secretion, followed by putative trypsin activation. Apocrine secretion is thought to be an adaptation to enhance the dispersion of secretory vesicle contents released from an water-absorbing tissue, whereas exocytosis is an efficient secretory mechanism in an water-secreting tissue. Index terms: digestion, enzyme, microapocrine, immunocytochemical study, peritrophic membrane

[1755] BEHAVIOR OF HEDYPATHES BETULINUS (COL., CERAMBYCIDAE) ON ILEX PARAGUARIENSIS

M. d'Ávila¹, J. V. C. Guedes¹, S. H. B. Dornelles¹ & E. C. Costa¹, ¹Departament of Crop Protection, Santa Maria Federal University, 97105 900, Camobi, Santa Maria, RS, Brazil, E-mail jvcguede@carpa.ciagri.usp.br.

The larvae of *Hedypathes betulinus* (Klug, 1825) (Coleoptera: Cerambycidae) feed on Paraguay tea (*llex paraguariensis*) and causes a relevant economic loss to plants and determines the use of the chemical control which is ineffective in most of the cases. The trial was carried out in the experimental area of the Crop Protection Department of the Federal University of Santa Maria in Rio Grande do Sul State - Brazil, to study the behaviour of mating, egg-laying, feeding and movement of beetles on the Paraguay tea plants (*l. paraguariensis*). These behaviour were monitored during four days (24 h day every one hour) in two screen cages, envolving a branch of a plant and containing two adult couples of *H. betulinus*. When approaching a female, the male tried to copulate immediately and usually mated several times during the day mainly between 2 and 6 p.m. and on along the branch. Egg-laying was more frequent on branches between 15 and 20 mm in diameter. The adults showed limited movement and sedentary behaviour.

Index terms: pest, Hedypathes betulinus, forest plant

[1756] HOW WELL DOES FOGGING SAMPLE A HIGH CANOPY EPIPHYTE?

M.D.F. Ellwood' & W.A. Foster', 'Dept. of Zoology, Univ. of Cambridge, Downing Street, Cambridge, CB2 3EJ, United Kingdom, E-mail: mdfe2@cam.ac.uk

It is widely postulated that rainforest canopies accommodate unusually high numbers of arthropod species. However, the canopy of most rainforests is incredibly difficult to access. Not surprisingly, this makes ground-based collection techniques seem more attractive. Since Erwin's landmark fog in 1981, many workers have opted to collect data by fogging canopies with insecticide. As a result, estimates of arthropod diversity in tropical rainforests, and even global biodiversity, have largely been based on data derived from fogged samples. Understanding the limitations of fogging is therefore important and widely relevant. New ascension techniques have allowed us to work within tree-crowns of the emergent dipterocarp species, Parashorea tomentella. One of the most common epiphytic plants in emergent trees is the Bird's Nest Fern, Asplenium nidus. This epiphytic fern, which commonly reaches dimensions of 2m x 3m, and weights of approximately 200 kg, may support a greater diversity of arthropods than the tree-crown of its host. However, fogging only sampled a fraction of the animals associated with this fern; essentially those on its extremities. Moreover, as the stunned arthropods fell to earth, those from the fern became inextricably mixed with the tree-crown fauna. A new fogging protocol has enabled us to make a precise distinction between fern samples and tree-crown samples. Thus, we can assess how well fogging samples the arthropod inhabitants of this epiphytic fern, and to what extent true canopy diversity could potentially have been underestimated in this study.

Index terms: Asplenium nidus, Parashorea tomentella, arthropods, diversity, tropical rainforest

[1757] DIAPAUSE TO FACILITATE THE REARING OF *HELICOVERPA* ARMIGERA (HBN.) (LEPIDOPTERA, NOCTUIDAE)

<u>E. Figueiredo¹</u> & A. Mexia², ¹DPPF/SAPI, Inst. Sup. Agronomia, Tapada da Ajuda, 1349-017 Lisboa, Portugal, ²INIA/EAN, Quinta do Marquês, 2784-505 Oeiras, Portugal; E-mail elisalacerda@isa.utl.pt.

Introduction: Consanguinity is a major problem in the laboratory rearing of *II. annigera* and some other noctuids. Normally, consanguinity is avoided through careful crosses of insects from different origin and periodical rearing refreshing.

However, another possible achieve, specially in small labs or in labs where H. armigera is only marginally studied, consists in rearing this insect only when it is necessary to run experiments by inducing and breaking diapause. Methodology: Based on information from Murray & Wilson (1991), the diapause was obtained submitting L2 larvae to a temperature from 17 to 19°C and an 11L: 13D photoperiod feeding on artificial diet based on maize. These conditions applied on L1 result in a high mortality level and after L2 the rate of no diapausing pupae increases a lot. Diapause condition was confirmed by the observation of the eyespots on pupal stage A (Shumakov & Yakhimovich, 1955). The weight was registered and the quantification of pupae malformations was done. Weight of pupae from larvae reared under conditions of 25°C temperature and 16L: 8D was also registered as well as weight of larvae from the diapausing insects progeny; data was used to carry out an ANOVA analysis using Statistica®. Time and conditions necessary to break diapause was also reported. Results and discussion: Diapausing pupae were stored at 15°C in obscurity for 2-3 years without having apparent reduced progeny. Weight from diapausing pupae $(0.337 \pm 0.036 \text{ g})$ was not significantly different both from their descendent pupae (0.317 \pm 0.030 g) and from normal rearing ones (0.328 \pm 0.033 g) (p=0.204; d.f.=1, 89), either considering both sexes or each one separately, which could be an indication of no redution in the progeny of diapausing insects. Nevertheless, irregular pupation was very frequent. The proportion of malformed pupae reached 30% (27.5-31.4%). In most of them larval exuvia remained in the head frontal region (hormonal irregularities?). Some larvae also died from disease and/or other causes, to which they are more sensitive in those inadequate rearing conditions. Diapause break could be achieved by submitting pupae to 20-25°C and 16L: 8D during about a month. Compared to males, females should be submitted to lower temperatures during some days to avoid their tendency to emerge first. Index terms: storing insects, diapause induction, diapause breaking

[1758] INTERSPECIFIC AND INTRASPECIFIC VARIATIONS IN APHID HONEYDEW: IMPACT ON THE MUTUALISM WITH ANTS

M. K. Fischer, W. Völkl & K. II. Hoffmann, Dept. Anim. Ecol., Univ. Bayreuth, 95440 Bayreuth, Germany; E-mail: melanie.fischer@uni-bayreuth.de

The honeydew composition of eight aphid species was studied. These species occupy different feeding niches (root, root collar, stem, leaves) on tansy (Tanacetum vulgare) and show a different host range (monophagous on tansy, oligophagous on perennial composites, polyphagous on various plant families). The honeydew sugar composition and the relative amounts of the detected sugars varied significantly between aphid species but not within different age classes of a particular aphid species. The monosaccharids glucose, fructose and the disaccharid sucrose were always present in the honeydew of all aphid species, while large concentrations of the trisaccharids melezitose and erlose were detected only in four species: the monophagous Metopeurum fuscoviride, the oligophagous Coloradoa tanacetina and Aphis vandergooti and the polyphagous Brachycaudus cardui. Neither the feeding niche nor the host range of aphid species seemed to be correlated with honeydew composition. By contrast, the quantitative honeydew production depended on the feeding niche of the aphid. Species sucking on leaves or on the shoot tip produced less amounts of honeydew than species feeding on the main stem or on the roots. Qualitative and quantitative honeydew production also help to explain the relationship with honeydew-collecting ants. Lasius niger, the most frequent ant species in the study area, attended aphid species dwelling on roots or stem, which produce large amounts of honeydew. The honeydew of unattended aphid species, which accumulated on neighbouring leaves, was collected only when it contained large proportions of trisaccharids. The other aphid species were disregarded by L. niger and often served as prey.

Index terms: Metopeurum fuscoviride, Aphis vandergooti, Coloradoa tanacetina, Brachycaudus cardui, Lasius niger.

[1759] WHAT IS SEXY ABOUT FIELD CRICKET COURTSHIP SONG?

M. J. Fitzpatrick, D. A. Gray & W. H. Cade. Dept. of Biological Sciences, Brock Univ., 500 Glenridge Ave., St. Catharines ON, Canada, L2S 3A1 E-mail: mf94az@badger.ac.brocku.ca.

The field cricket mating system is composed of three song types used by males. Calling song is used to attract females from distances, aggressive song is used for territorial aggressions between conspecifics, and courtship song is necessary for mating. Much is known about calling song phonotaxis in field crickets. In the Texas trilling cricket, Gryllus texensis (formerly G. integer), females have a net stabilizing selection for the average male calling song. The courtship song is far less studied across all field crickets. We used G, texensis as a model to investigate if females show preferences for characters in the male courtship song. Both correlational and experimental trials have shown that females were selecting males using courtship song. Composed of two types of sound pulses, high frequency and low frequency ticks, females were selecting for shorter time intervals (silences) between the ticks - termed Gap 1. This gap was also correlated with male condition such that males with long silences were significantly in poor condition (light for their body size) when compared to males having short silences. Both Gap 1 and condition were repeatable, an indication of the amount of variation that can be attributed to consistency among males, suggesting a possible genetic basis. If heritable, females can increase the probability of mating with a genetically superior male by selecting against long Gap 1 durations - a potential example of the good genes model of selection. Index terms: Gryllus texensis, female choice, sexual selection

[1760] BEHAVIOR OF ACTINOTE PELLENEA PELLENEA (LEPIDOPTERA: NYMPIIALIDAE) IN SE BRAZIL OVIPOSITING IN ITS FOOD-PLANT EUPATORIUM INULAEFOLIUM

R.B.Francini¹, **A.V.L.Freitas**², ¹ Museu de História Natural, FAFIS, Univ. Católica de Santos, Rua Euclides da Cunha, 247, 11065-902, Santos, SP, Brasil, E-Mail francini@unisantos.com.br, ². Mus. Hist. Nat., IB-UNICAMP, .CP-6109, Campinas, SP, 13083-970, Brazil, E-mail: baku@atribuna.com.br. Financial support: FAPESP, CNPq, CAPES.

The oviposition by many females in a unique food plant seems to be a common fact in Actinote butterflies and it was already observed in six species. In this work, emphasis was given to A. pellenea pellenea and observations were made in two areas in SE Brazil: the "Vale do Rio Cubatão" (VRCUB), and "Morro do Japui" (JAPUI), SP. Females always lay eggs in clusters on the underside of mature leafs (n>500 observations in more than 50 sites in SE Brazil). Oviposition size ranged from 86 to 1266 eggs (mean = 479.2, SD = 228.93, n = 56) in JAPUI, and from 100 to 833 (mean = 422.3, SD = 199.01, n = 26) in VRCUB. After laid, eggs are light yellow, changing to orange and finally red (2 days before eclosion) and in this work, less than 10% of the eggs by oviposition are infertile although the percentage of ovipositions with infertile eggs were high (JAPUI = 94% and VRCUB = 71%). Multiple ovipositions in one plant are common, and up to three different ovipositions can be found in a single leaf. Of these observations, the following questions emerged: (1) is the choice of the food-plant by the female random ? (2) the presence of an previous ovipositions will affect the size of the following ? (3) is the foodplant choice owed mainly to habitat factors or the characteristics of the plant ? Were studied 23 plants of E. inulaefolium in JAPUI, and 11 in VRCUB. The distribution of those plants in VRCUB was random but in JAPUI was not as indicated by the dispersion index. The number of ovipositions by plant were not random in both places, being grouped, and similar to a negative binomial. In all cases of double oviposition in the same leaf, the "new" ones (lighter eggs) were significantly lower than the "old" (darker eggs, tending to red). There were no significant correlation between the number of oviposition icating to req. Increase were no significant correlation between the number of oviposition in each plant and habitat and plant characteristics as: plant height and an "appearance index" (calculated in relation to the sizes and distances of the three nearest neighbors). Also the number and density of eggs by eviposition was not correlated with some leaf characters as area, orientation and inclination. Due to the highly unstable nature of the environments originally accupied by the host plants of *A. pellenea*, the pressures should be in the direction of (Wing many every fast, without choreirs the above. It is the above. in the direction of raying many eggs very fast, without choosing the plants. However, chemical actors were not evaluated, and could be important in defining the first ovicusitions, serving as cues to the following females. Index terms; super-oviposition, habitat diversity.

[1761] THE CHANGES OF SIGNALS IN MALE-FEMALE DUETS OF THE DEPHALICIDAE LEAFHOPPER, NEPHOTETTIX NIGROPICUTUS

M. Fukui & S. Nakao, Lab. of Insect Physiology, Graduate School of Agriculture, Kyoto Univ., Kitashirakawa, Kyoto 606-8502, Japan. E-mail mfukui@kais.kyoto-u.ac.jp.

In Japan, at least four Dephalicidae leafhoppers (Nephotettix nigropicutus, N. virescens, N. cincticeps, N. malayanus) are sympatrically distributed in the subtropics and tropics: N. nigropicutus and N. virescens inhabit on rice plant as common host plant in the tropics, N. nigropicutus, N. virescens and N. cincticeps on the rice plant in the subtropics, N. nigropicutus and N. malayanus on the gramineous Leersia hexandra in the subtropics and tropics. The distinct differences in male-female vibrational duets of the four sibling species indicated presence of pre-mating barrier, i.e. sexual isolation, among them. That also suggested that N. nigropicutus appear to be more discriminating than other three sibling species in choosing between mates of their own and that of other species. On the other hand, the production of vibrational courtship signals in females as well as males of planthoppers gave a contrary explanation towards choosy females: males appear to be more discriminating than females in choosing between mates of their own and other species, although other aspects of sex roles do not seem to be reversed in planthoppers (Andersson, 1994). As a first step to verify above two hypotheses, we have reconfirmed male-female courtship signals (duets) in Nephotettix nigropicutus. After a sexually receptive male spontaneously produced a advertising call, consisting of single trill and ca.12 chirps, female soon responded to him a answer call with two to four simple trills. This male-female duet was repeated twice or three times. Furthermore the male answered her with a call having two to four increased number of trills and the female called the male back again; the result was continuous duets between receptive partners until male copulatory attempt. Female trill in a duet was slightly different from that in spontaneous calling signal that was sometimes advertised by a sexually receptive female. The differences of signals between duet and spontaneous calling in both sexes may be resulted from the conspecific recognition and the proper mate recognition. We present more evidence for the changes in a reciprocal signaling involving both sexes. That biological significance will be also discussed.

Index terms: Nephotettix nigropicutus, vibrational courtship signal, male-female duet

[1763] FORAGING BEHAVIOR OF EPICHARIS BEES (HYMENOPTERA, APOIDEA, CENTRIDINI)

M. C. Gaglianone, Depto. Biologia, Pós-Graduação em Entomologia, FFCLRP, Univ. de São Paulo, Av. Bandeirantes, 3900, 14040-901 Ribeirão Preto (SP) Brasil, E-mail: mcrisgag@usp.br.

Epicharis is a Neotropical group of solitary and ground-nesting bees, more abundant and diversified in the "Cerrado" of central Brazil. Besides pollen and nectar, Epicharis females collect floral oils that are used in nest construction and, mixed with pollen, as larval food. The aim of this work is to describe and analyse the foraging behavior of Epicharis bees on flowers, mainly on Malpighiaceae, the only floral oils source known for these bees. The observations were made in a "Cerrado" ecosystem, in Luiz Antônio, SP, Brazil. Twelve species of Epicharis, belonging to subgenera Epicharis, Hoplepicharis, Epicharoides, Epicharitides, Triepicharis and Anepicharis, were found on flowers from August to May. Flowers of Bignoniaceae, Oxalidaceae, Vockysiaceae and Rubiaceae were used as nectar sources for both males and females. In flowers with tubular corolla, the bees always come into the flowers through its opening and can pollinate. The females collected pollen on flowers of Solanaceae, Styracaceae and Leguminosae by vibration -"buzz behavior" Twelve of the eighteen observed species of Malpighiaceae were visited by females of Epicharis to collect pollen and floral oils. The pollen collecting by E. cockerelli and E. nigrita was observed only on flowers of Byrsonima intermedia (Malpighiaceae). The analysis of the scopae and containing of brood cells of E. nigrita indicate that B. intermedia was the only source of pollen for this bee species in the study area. The behavior of the bees on Malpighiaceae is very similar among the species from different subgenera of Epicharis. The female lands on the center of the flower, grasps the base of the flag petal with her mandibles and scrapes the elaiophores on the undersurface of the sepals, using specialized setae disposed in fore and middle basitarsi, to collect floral oils. The female can gather pollen immediately after oil gathering, in the same flower, raising her hind legs and vibrating the body. The pollen grains of Byrsonima intermedia are dry and fine and, during vibration, they are expelled from the anthers and adhere to the ventral side of the bee body. The female can also perform visits for collecting only pollen or oil. Females collected only oil from flowers of Banisteriopsis spp., Peixotoa reticulata, Mascagnia cordifolia and Heteropterys byrsonimifolia. The small anthers and humid, larger pollen grains, when compared to those of B. intermedia, do not favor buzzing behavior. There is no specificity in the interactions between Epicharis bees and species of Malpighiaceae, in relation to oil foraging.

Index terms: Apidae, buzzing, floral resources, oil-gathering behavior, pollination

[1762] BOLL WEEVIL: BIOLOGY IN ALTERNATE HOST BY ARTIFICIAL OVIPOSITION

<u>D. Gabriet</u>¹, ¹Inst. Biológico. CP 70. CEP 13001-970. Campinas, SP. Brazil. E-mail ceib@dglnet.com.br Project "Integrated pest management of the cotton boll weevil in Argentina, Brazil and Paraguay-ICAC/04".

Alternate host play a significant role in boll weevil survival, especially during host-free periods. It was determined boll weevil life cycle when reared at noncotton plants and the longevity but feeding with cotton squares. The eggs or 1st instar larvae were transferred from cotton squares to flower bud of Hibiscus tiliaceus, Hibiscus rosa-sinensis, Hibiscus schizopetalus, Hibiscus sabdariffa, Abelmoschus esculentus and Gossypium hirsutum (control). The flower bud's stalks of the potential hosts were surrounded by cotton moistened with distilled water to promote enough humidity for larval development. The buds were each placed in plastics recipients kept in climatic chamber at 21°C photoperiod 14:10 (L : D) for 17 days. After that the flower buds were removed and sheltered by a glass recipient covered with a nylon screen to arrest the adults later on transferred to similar recipient bigger than the first one. Both recipients (emergence and feeding adults) were kept in the laboratory at 24°C, R U 70 % photoperiod 14:10 (L : D). The adults received every other day one cotton square and were maintained isolated from emergence to death. As soon as boll weevil died the sex was recognized and established the longevity. The percentage of adults was the following: Hibiscus rosa-sinensis 34.0, Gossypium hirsutum 30.0, Hibiscus schizopetalus 16.7, Hibiscus tiliaceus 10.0, Hibiscus sabdariffa 6.7 and Abelmoschus esculentus 6.7%. The life cycle of female and male was, respectively to H.rosu-sinensis 24.1 and 23.7, G. hirsutum 25.3 and 25.5, H. schizopetalus 26.0 and 24.7, H. tiliaceus 25.3 and 25.7, H. sabdariffa 26.0 and 32.0 and Abelmoschus esculentus 26.8 and 26.8 days. The mean weight of female and male was, respectively to H. rosasinensis 1.9 and 1.9, Gossypium hirsutum 2.1 and 1.9, H. schizopetalus 1.4 and 1.6, H. tiliaceus 1.8 and 1.9, H. sabdariffa 0.5 and 0.7 and A. esculentus 1.8 and 1.4 mg. The longevity of female and male was, respectively to H. rosa-sinensis 106.2 and 73.2, G. hirsutum 66.3 and 47.1 H. schizopetalus 78.0 and 54.0, H. tiliaceus 53.5 and 70.5, H. sabdariffu 2.5 and 18.0 and A. esculentus 88.0 and 56.4 days. The results showed that boll weevil can be developed in all species investigated however the adults mean weight was very low if confronted with boll weevil from cotton field (5.8 mg) in spite of that if at all the female could be able to lay eggs in them the best was II rosa-sinensis that presented bigger percentage of adults, minor life cycle, bigger longevity and adults mean weight near to control Gosypium hirsutum.

Index terms: Anthonomus grandis, alternate host, life cycle, longevity

[1764] DOES THE FRUIT SIZE INFLUENCE THE PARASITISM OF FRUGIVOROUS LARVAE BY EUCOILINAE SPECIES?

J. A. Guimaraes¹, M.F. Souza Filho², R. A. Zucchi¹, N. B. Diaz³, ¹ Dept. de Entomologia, Fitopatologia e Zoologia Agrícola (ESALQ/USP), Av. Pádua Dias 11, CP 9, CEP: 13418-900, Piracicaba – SP, Brasil, e-mail: jaguimar@earpa.ciagri.usp.br; ² Instituto Biológico, CP 70, CEP: 13001-970, Campinas – SP, Brasil; ³ Museo de La Plata, Dep. Científico de Entomología, Pasco del Bosque s/n, 1900, La Plata, Argentina. (research supported by FAPESP).

The species of Eucoilinae (Hym.: Cynipoidea: Figitidae) are larval-pupal parasitoids of cyclorrhaphous dipterous. Several species have been associated with tephritids (fruit flies) and lonchaeids larvae. Some species of these dipterous cause serious damage to fruit crops. In order to minimize their damage, the biological control with hymenopterous parasitoids has been used. In fact, the biological control with parasitic wasps has increased, but in some cases these parasitoids have not given satisfactory results. This is due to the little knowledge about basic studies, mostly on taxonomy, biology, behavioral aspects and trophic relations. As the fruit fly larvae develop inside fruits, it is very important to know the influence of the fruit size on the parasitism by hymenopterous parasitoids. Thus, fruits of different sizes from twenty species were evaluated in this study. The fruit size ranged from about 1g (Citharexilum myrianthum, Verbenaceae) to 240g (Mangifera indica, Anacardiaceae). The fruit samples were collected in several localities of the State of São Paulo, Brazil. Six species of Eucoilinae (Aganaspis pelleranoi, A. nordlanderi, Dicerataspis flavipes, Lophencoila anastrephae, Odontosema anastrephae and Trybliographa sp.) have been reared in association with fruit-infesting tephritids. However, the fruit size influence on the parasitism by eucoiline was determinated only for the three most common species - A. pelleranoi, I., anastrephae and O. anastrephae. There were no significant correlation between the size of fruits (estimated by weight) and the percentage of parasitism for these species. Probably this fact is due to the behavior observed for A. pelleranoi, in which female is able to get into big fruits searching for frugivorous larvae. This behavior has not been observed to others eucoiline species yet. Index terms: Hymenoptera, Eucoilinae, Diptera, Tephritidae, parasitoids

[1765] GOING WALKABOUT: MOVEMENTS OF INDIVIDUAL ADULTS IN A BREEDING POPULATION OF THE SPECKLED BUSHCRICKET, LEPTOPHYES PUNCTATISSIMA

M. J. Hall¹, D. J. Robinson¹ & J. Rheinlaender²

¹Dept. of Biological Sciences, Open Univ., Milton Keynes, MK7 6AA, UK, E-mail: mj.hall@open.ac.uk; ²Johan Wolfgang Goethe-Universitat, Zoologisches Institut, Siesmayerstrasse 70, Postfach 11 1932, D-6000 Frankfurt, Germany.

The speckled bushcricket, Leptophyes punctatissima, has been little studied in the wild. Duncan (1960) carried out some limited field observations in an oak-birch wood in the UK during the 1950s. On the basis of that study, plus some observations on a laboratory population, he concluded that (1) newly-emerged nymphs are found on shrubs and lowgrowing herbs; (2) late-instar nymphs and adults move up into the trees where they remain relatively inactive except for some increase in activity immediately before oviposition, which takes place in late August and September; and (3) towards the end of their life, in October, the adults become scattered. We have been studying a wild population of L. punctatissima in northern Germany. Individuals were marked soon after emerging as adults and their movements were then followed around the clock until the peak of the breeding season was over. Like Duncan, we found that newly-emerged nymphs are mostly found in low-growing vegetation, that there is some tendency for late-instar nymphs and adults to move up into the tree canopy, and that adults initially are relatively inactive. There were however some major differences between our observations and his. The movement from low to high vegetation was much less clear-cut than the behaviour he described: we found early-instar nymphs high in the tree canopy, for example, while many adults remained in low-growing vegetation. More important, once they became sexually mature (about a week after eclosion) the adults were far from inactive. Both males and females 'went walkabout', moving long distances and travelling between different trees and different vegetation types. Initially L. punctatissima was localised in a few pockets with a high concentration of late-instars and adults but, once the walkabout started, the population rapidly became much more thinly and widely spread. The implications of this

behaviour for mate choice and mating success in these insects will be discussed. Reference: Duncan, C. J. (1960) The biology of *Leptophyes punctatissima* (Bosc.) (Orthoptera: Tettigonidae). *Entomologist*, 93, 76–78.

Index terms: Leptophyes punctatissima, bushcricket, movement, life cycle.

[1767] CLADISTIC ANALYSIS OF NEOTROPICAL GENERA OF PHILEURINI (COLEOPTERA, SCARABAEIDAE, DYNASTINAE)

S. Ide, Centro de Sanidade Vegetal, Instituto Biológico, Av. Cons. Rodrigues Alves 1252, São Paulo SP 04014-900, Brazil, E-mail ide@biologico.br.

The tribe Phileurini was established in 1847 by Burmeister. It includes more than 35 genera and 220 species predominately distributed by the Southern Hemisphere, with species also occurring in the United States, China. Korea and Japan. In the Neotropics 142 species in 20 genera were recorded. The monophyly of the tribe is assured by an expanded mentum that covers almost entirely the first pair of palpomeres. A phylogenetic hypothesis was proposed for the Neotropical Phileurini genera employing the methodology of phylogenetic systematics. The transformation series (binary or multistate) were polarized through the out-group comparison. The available species of Phileurini genera *Cryptodus*, Eophileurus, Hovophileurus, Pseudosyrichthus, Rhizoplatys, Syrictes, and some Dynastini (Allomyrina, Chalcosoma, Dynastes, Golofa, Megasoma, Xylotrupes) and Cyclocephalini (Cyclocephala) species were selected as outgroups. In a previous analysis, only taxa at generic level were considered. However, some of them were polymorphic and were broken up into monomorphic units, so each terminal is based on a unique set of character states. Parsimony analysis was performed with software Hennig& employing mh* and bb* algorithms and operated in Windows[®] environment by TreeGardner. Character evolution was traced by Clados computer program. The analysis based on matrix with 29 terminal (including an hypothetical ancestor) taxa and 34 characters with 58 derivate states resulted in two equally parsimonious cladograms (118 steps, CI = 49, RI = 70). The strict consensus cladogram (119 steps, CI = 48, RI = 69) presented the following relationships: ((Cnemidophileurus, Actinobolus) ((Haplophileurus, Chiliphileurus) (Archophileurus/ (Microphileurus ((Metaphileurus/1, Metaphileurus/2) ((Oryctophileurus, Amblyodus) (Trioplus, Goniophileurus)))) (Archophileurus/2 (Mictophileurus (Amblyoproctus/1, Amblyoproctus/2) ((Hemiphileurus/3 (Hemiphileurus/2 (Hemiphileurus/1 (Planophileurus, Palaeophileurus)))) (Paraphileurus (Phileurus/3 (Phileurus/1, Phileurus/2 (Ceratophileurus (Homophileurus/1, Homophileurus.2))))))))). Mentum with a Philcurus/2 depression supports the monophyly of Neotropical Phileurini. Platyphileurus was removed from the tribe as result of the analysis.

Index terms: Platyphileurus, Cyclocephalini, Dynastini, phylogenetic systematics.

[1766] EFFECTS OF MATING FREQUENCY ON FEMALE REPRODUCTIVE OUTPUT IN THE CAT FLEA, CTENOCEPHALIDES FELIS (SIPHONAPTERA: PULICIDAE)

M. H. Hsu¹ & W. J. Wu¹, ¹Dept. of Entomology, National Taiwan Univ., 106 Taipei, Taiwan, E-mail catflea@mail.ht.net.tw

Multiple mating behavior of the female cat flea *Ctenocephalides felis* was confirmed in this study, and its effects on fecundity and fertility were investigated as well. Fertility of mated females was close to nil within 7 d following removal of males, but it was resumed when females were exposed to males again on day 7. Multiply mated females displayed significantly higher fecundity (400.3 eggs per female) and fertility (182.8 viable eggs per female) than singly mated females (61.7 and 19.0, respectively), suggesting that multiple mating by females is an advantageous strategy for cat fleas. Duration of 1st mating was 63.1 min on average. High ratio (55.56%) and short duration (34.0 min) of impotent mating hint that cryptic female choice may be involved during copulation. Low hatchability (29.8 – 45.7%) of eggs in multiply mated females indicates that the nonviable eggs may have some functional significance. Index terms: fecundity, fertility, mating duration.

[1768] COOPERATION AND DIVISION OF LABOR BETWEEN UNRELATED INDIVIDUALS IN THE ANT *PACHYCONDYLA 'INVERSA*'

J. Heinze¹, K. Kolmer¹, B. Trunzer² & B. Hölldobler², ¹ LS Biologie I, Univ. Regensburg, Universitätsstrasse 31, D-93040 Regensburg, Germany, ² Biozentrum, Univ. Würzburg, Am Hubland, D-97074 Würzburg, Germany.

Instead of starting a new colony solitarily, young queens of the neotropical ponerine *Pachycondyla inversa*' may cooperate during colony founding (pleometrosis). In contrast to many other ants, where founding queens have enough body reserves to produce their first young, queens of *Pachycondyla inversa*' have to forage for food. In pleometrotic associations, one queen specialises for this risky task, whereas the others do not leave the nest. Division of labour is strongly affected by antagonistic interactions: the dominant queens aggressively force the most subordinate queen to leave and forage. The frequency of attacks increased with the duration since food was last added to the foraging arena. Multilocus DNA fingerprinting suggests that co-foundresses are unrelated. Our study therefore is the first demonstration of status-related division of labour among unrelated individuals in eusocial insects. It stands in contrast to previous assumptions that cooperation among co-founding queens may be group-selected. Index terms: Ponerinae, dominance hierarchy, colony founding, pleometrosis

ABSTRACT BOOK I – XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[1769] SPECIES RICHNESS AND SEASONAL ABUNDANCE OF MALE EUGLOSSINE BEES (HYMENOPTERA: APIDAE) IN A SEMIDECIDUAL STATIONAL FOREST OF THE SÃO PAULO STATE

B.M.V. Jesus¹ & C.A. Garófalo, Depto. Biologia, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto-USP, 14040-901 – Ribeirão Preto, SP, Brasil, E:mail: ¹bmvjesus@usp.br.

Seasonal changes in species richness and abundance of male euglossine bees were determined by attracting individuals with three chemical baits: cineole, eugenol and vanillin. The study was conducted at Mata da Virginia, one of the biggest remnants of semidecidual stational forest of the São Paulo State. The forest has 2 072 ha and is located in the Municipios of Matão and Tabatinga (21° 38' S and 48° 32' W). Male euglossine bees were sampled by collecting them as they were attracted to chemical baits. The baits were presented for 3 consecutive hours between 0900 and 1300h, on absorbent paper pads suspended 4 m apart from the twinges by a string 1.5 m above the ground. The census was made monthly from January to December, 1996. A total of 814 individuals belonging to 4 genera and 10 species were captured. Euglossa pleosticia was the most abundant species (44.6% of the males collected) followed by Eufriesea violacea (38.1%). Eulaema nigrita (8.1%), Euglossa fimbriata (3.7%) and Euglossa annectans (3.3%). The other species, Euglossa truncata, Euglossa securigera, Euglossa cordata, Euglossa violaceifrons and Exacrete smaragdina were less frequently sampled, representing only 2.2% of the total sample. The number of species sampled in each season was similar (n = 8) but the abundance of bees was strongly seasonal, and the greatest number (n = 639) was attracted during the wet/hot season (September-March). Euglossa pleosticta and El. nigrita were recorded every month while Ef. violacea was attracted to baits only in November and December, Of the 10 species sampled, five were attracted to only one chemical (cineole). four were attracted to two (cineole and eugenol, Eg. truncata and Eg. annectans, or cineole and vanillin, Ef. violacea and El. nigrita) and one (Eg. pleosticta) was attracted to all three chemicals. When compared with other studies carried out in the São Paulo State, our results indicate: 1 - species richness higher than those found at Santa Carlota Farm, Santana Section, Cajuru, and at Estação Experimental de Zootecnia, Sertãozinho, and lower than those found at Santa Carlota Farm, Itaoca Section, and Serra do Japi, Jundiai; 2 - species composition more similar to that found at Serra do Japi: 3 - bee abundance highest at Mata da Virginia and 4 - seasonal abundance pattern similar to those related in other studies.

Index terms: Euglossini, diversity, bees, phenology.

[1771] INTERACTION BETWEEN PREDATORY BEE EATER AND DEFENCE-ATTACKING GIANT HONEYBEE $APIS\ DORSATA$

<u>G. Kastberger¹</u>, ¹ Department of Zoology, University of Graz, Austria. Supported by the Austrian scientific foundation, grant P13210-BIO, and epo-film Graz.

The South-East Asian Giant Honeybee (Apis dorsata) is named as "giant" because it is bigger than other honeybee species. It builds large nests of up to 2m wide. As many as 200 colonies may aggregate on a single tree. It is also known as the most ferocious stinging insects on earth. Visual or mechanical disturbance by unusual movements or vibrations nearby the nest may excite the colony, thus initiating alarm, defence and attack. Then several thousands of individuals may be recruited within seconds to persue the predator even for a kilometre or more. We investigated defense behaviours in Apis dorsata in Assam (Northeast India) when interacting with raiding bee eaters in an aggregation of fifty Giant honeybee (Apis dorsata) colonies on a bee tree in Assam, India. We filmed two scenarios with an Arriflex camera at 150 frames per second, first, when the bee eater passed parallel to a nest, threatening only the sunny side of the colony, and second, when the bird passed a nest laterally in perpendicular direction, eliciting attacking swarms from both sides of the colony. In the first scenario, we assessed around 500 bees in the attacking swarm, comprising 2-3 per cent of colony members. These bees followed the bird and continued patrolling the canopy during the subsequent minutes. We also found the first evidence for intercolonial group defense in Apis dorsata, which means that colonies or parts of them, which were not directly threatened, joined the defense action of the threatened colony. In the second scenario, the colony released around 100 bees from that side of the nest which was directly threatened from the approaching bird, and 200 bees from its opposite side which had only viewed the disappearing bird. We discuss how unthreatened nests or parts of them can be challenged for mass attack. Bees at the more shadowed nest sides may mobilise for mass attack to a less extent than the sunny sides. Consequently, the more active parts of the nests may respond to threatening cues faster and with a greater guard force. As honeybee colony defense is incited by alarm pheromones, two further non-visual ways are proposed that less threatened nests or parts of them may get aroused to join the mass attack. Firstly, the guards of threatened colonies may release their alarm pheromones directly at unthreatened colonies to make them join in an intercolonial group response. Secondly, the pheromone cloud may be dragged by air streams, such as those induced by raiding birds, to unthreatened nests.

Index terms: Giant Honeybee

[1770] RELATIONSHIP BETWEEN MICROHABITAT AND BODY SHAPE IN ADULT PASSALID BEETLES (COLEOPTERA, PASSALIDAE)

Y. Johki¹, M. Kon² & K. Araya³, ¹Showa Women's Univ., Setagaya, Tokyo, 154-8533 Japan; ²School of Environmental Science, Univ. Shiga Prefecture, Hikone, Shiga, 522-8533 Japan; ³Graduate School of Human and Environmental Studies, Kyoto Univ., Sakyo, Kyoo, 606-8501 Japan, E-mail: <u>johki@swu.ac.jp</u>

Passalidae are the family of Coleoptera, belonging to the superfamily Scarabaeoidea, and most species occur in the humid tropics. The subsocial behavior of them has often been cited in the entomological literature. It has also been known that passalid beetles show some morphological adaptations in the adult body shape to their microhabitats. In order to know the relationship between adult body shape and microhabitats, we made measurements of the adult body shape and field observations on the microhabitats for about fifty species belonging to eight genera of the Passalidae. The proportions of (elytra length)/(body length) and (elytralwidth)/(body length) are remarkably uniform among all the species examined, whereas body thickness greatly varies both among genera and species. We found that flatter species are living under the bark of logs and the species with flattened and widened front tibiae living in the detritus-like microhabitats. Index terms: morphology, adaptation, ecology

[1772] PREDICTABILITY OF AGGRESSIVENESS IN THE GIANT HONEYBEE APIS DORSATA

G. Kastherger¹ & H. Köfer¹, ¹ Department of Zoology, University of Graz, Austria. Supported by the Austrian scientific foundation, grant P13210-BIO.

The South-East Asian Giant Honeybee (Apis dorsata) is named "giant" because it is bigger than other honeybee species; it builds large single-comb nests up to 2 metres wide; and as many as 200 colonies have been observed to aggregate on a single tree. A. dorsata is also known as the most ferocious stinging insect on earth. Visual or mechanical disturbance of the nest, like objects moving before the colony or touch the nest surface may initiate alarm, defence and attack. Within seconds, several thousands of individuals could be recruited to persue the predator even for a kilometre or more. Despite decades of studies there is a high degree of unpredictibility of the state of a colony in respect to its readiness for attack. A model for systematic and quantitative analysis of the whole range of defenseand attacking behaviour is still lacking. We investigated the condition under which mass attack, as the last link in the chain of defensive behaviour, can be released in colonies which had been proved as undisturbed. Therefore, several colonies were treated successively under standardized conditions placing mechanical shocks. Documentation of the behaviour was done by conventional video and infrared recordings. Individual and colony parameters were evaluated by OPTIMAS image-analysis software. Temperature and light intensity were continuously recorded by a data logger device. It takes between 15 seconds to several minutes to bring a colony in such an arousal state that bees start to attack. It obviously depends on various factors like temperature, time of day, past history of disturbance (such as sensitization or habituation to stimuli), colony state (whether cluster or comb nest, comprising brood cells or not, whether ready to migrate or scheduled to stay longer, etc.), when and how the colony starts to attack a predator. After having placed mechanical disturbance, guard bees are recruited for mass attack only in certain areas of the nest. In a first reponse to the mechanical shock, hot bees from the inner layers of the nest come out to the surface, ready to attack at the next occasion. During mobilization of attacking guards, structural changes of the nest were detected and quantified by two parameters: first, the body temperature of surface bees increased, in particular of those roofing bees which were concerned to the stimulus; and second, the whole nest increased in size. However, we observed in longer-lasting experiments that both criteria which provided some information about the state of mobilization were finally not correlated to the state of readiness of the colony to attack. It is assumed that the main process to prepare the colony to start an attack within parts of a second takes place on a pheromonal level.

Session 09 – ETHOLOGY

Symposium and Poster Session

[1773] SEASONAL CHANGE IN DAYLENGTH REGULATES INCIDENCE AND INTENSITY OF DIAPAUSE IN A MOTH

<u>Y. Kimura¹ & S. Masaki²</u>, ¹Aomori Agric. Exp. Sta., I-1 Sakaimatsu, Kuroishi 036-0389, Japan, E-mail DZF03663@nifty.ne.jp; ²12-13 Matsubara Higashi-1, Hirosaki 036-8141, Japan, E-mail Sinzo.Masaki@mb4.seikyou.ne.jp.

The bivoltine life cycle of the cabbage moth Mamestra brassicae in Japan is mainly regulated by the larval photoperiod that determines the type of pupal development: winter diapause in short days, and nondiapause or summer diapause in long days. In Hirosaki (40°30'N), the critical daylength for winter diapause induction is about 14 h under stationary conditions. However, the egg and larva are highly sensitive to change in daylength, and this response plays an important role in the seasonal adaptation. Adults from overwintering pupae eclose between mid May and early July, so that early-growing larvae of their progeny develop under increasing daylengths before the summer solstice, but late-growing ones under decreasing daylengths thereafter. When larvae were reared under simulated natural daylengths increasing from 15.3 to 16 h, or decreasing from 16 to 15.3 h at 20 °C, both incidence and intensity of summer diapause were higher in the former conditions than in the latter. A similar difference was observed between larvae grown under the natural conditions from late May to late June and those from early to late July. This response would subserve to fine tuning of the adult eclosion time. As adults of the first generation of the year begin to eclose in late July, their progeny would grow under daylengths within the range preventing winter diapause if stationary. In the second generation, however, the probability for overwintering became higher in simulated natural daylengths than in the comparable stationary ones. For example, daylengths decreasing from 15 to 14 h and from 14.5 to 13.5 h during the larval stage induced 43 and 99% of the pupae to enter winter diapause, respectively, although stationary 14.5 and 14 h daylength gave 2 and 57% winter diapause, respectively. Moreover, the intensity of winter diapause was greater in the decreasing daylengths than in the comparable stationary ones. A similar tendency was observed among larvae reared during different periods under natural conditions from late July to early September.

Index terms: Mamestra brassicae, changing photoperiod, seasonal adaptation.

[1774] DEGRADATION OF TEMPORAL PARAMETERS OF A GRASSHOPPER SONG IN THE FIELD

F. Lang & <u>N. Elsner</u>, Dept. of Zoology, Univ. of Göttingen, Berliner Str. 28, D-37073 Götingen, Germany, E-mail nelsner@gwdg.de, Supported by Deutsche Forschungsgemeinschaft (DFG EL 35/18-1).

In gomphocerine grasshoppers the recognition of conspecific songs depends on their frequency content and temporal pattern. In Chorthippus biguttulus males show amplitude modulation frequencies of 20-40 Hz, and females of more than hundred Hz. Our study demonstrates the degradation of the temporal patterns of these non-resonant songs in the natural low grassland habitat of this species. Behavioral studies show that female songs cannot be recognized by males over distances longer than 120 cm, whereas the songs of males are recognized by females over distances of at least 210 cm. Further, it could be shown that female songs, the modulation of which had been low pass-filtered at 100 Hz, were as attractive for males as natural songs. Songs which only contained modulation frequencies below 75 Hz, however, were no longer attractive for males, indicating that the frequency components between 75 and 100 Hz are essential for the recognition of female songs. As the male songs do not contain these high modulation frequencies, the recognition distance of male songs is not as strongly effected by the physical properties of the habitat as that of female songs. By sound measurements in low vegetation, it was found that modulation frequencies above 75 Hz are strongly degraded, which in dense vegetation could only be observed to a minor extent. In search of an explanation for this effect, we measured the echoes of short sound pulses. While in low vegetation a great number of echoes was found, this was not the case in dense vegetation. By an evaluation of the echoes it was deduced that in low vegetation in a distance 120-150 cm the delay of the echoes is long enough to account for a masking of amplitude modulations in the sensitive frequency range of 75-100 Hz. These findings possibly represent a mutual adaptation of the temporal pattern and the sound intensity in this subfamiliy of acridids, which have specialized on acoustic communication with fast amplitude modulations, for which non-resonant stridulation at low sound intensity is a prerequisite.

ABSTRACT BOOK I – XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[1775] ADDITIONAL OBSERVATIONS ON NESTING BIOLOGY OF PTILOTHRIX PLUMATA (APOIDEA, ANTHOPHORIDAE)

S. Laroca¹ & <u>M. C. de Almeida¹</u>, ¹Depto. de Zoologia, Univ. Federal do Paraná, Caixa Postal 19020, 81531-990 Curitiba, PR, Brazil, E-mail slaroca@netpar.com.br

During the field phase of an ecological and biogeographical study of the wild bee communities in a cerrado (savanna) of the northeastern of Paraná [Sengés-Jaguariaíva region], we had the opportunity to find nests of some species of these organisms. Recently, one of us (MCA) discovered two aggregations of Ptilothrix plumata, an oligolectic species, in the walls of two termite nests. As nesting biology of bees is adequate subject in the search of adaptations which could be correlated with the survival of this bee in the peculiar biotopes of this ecotonal vegetation of southern Brazil, we judge to be worthwhile to report our additional observations on this species. P. plumata is a member of Melitomini, one of the anthophorid groups whose species have a tendency toward having narrow spectrum of flower visitation. As an example of this specialization is the relatively well known dependence of Melitoma segmentaria on the pollen of certain species of Ipomoea (CAMILO, GARÓFALO & SERRANO, 1993: Revia bras. Ent. 37: 145-156). P. plumata is the most abundant of the three species (Ptilothrix relata and Ptilothrix fructifiera) in the area, in spite of being one of the rarest when its abundance is compared with those of predominant bees collected in a census done in two years of collecting efforts. P. plumata is a medium sized bee (10.12 mm of total length), whose females are predominantly brown ferruginous, with well marked yellow hairy band on the four basal tergites. In the present work we report our observations on aspects as nesting site and substrate, nesting construction, ontogeny, interactions among neighbor nest owners (females), as well as natural enemies in this ecotonal region of cerrado. Most of the informations are complementary to those of IHERING, 1904: Revta Mus. Paulista 6: 461-HIGHMARD, 100; Deutsche Ent. Zeitschr, pp. 227-237; PICKEL, 1928; Bol. Biol., S. Paulo, 14: 135-143; MICHENER & LANGE, 1958; Univ. Kans. Sci. Bull.39: 69-96, and MARTINS, GUIMARÃES & DIAS, 1996: J. Kans. Entomol. Soc. 69: 9-16. Index terms: neotropical, cleptolectic-bee, oligolectic-bee, nest, Brazilian-savanna.

[1776] BIOETHOLOGY OF PHYLLOCNISTIS CITRELLA IN APULIA (SOUTH ITALY)

M. Pizza, T. Moleas, Dip. Di Biologia e Chimica Agro-Forestale ed Ambientale, Università di Bari, V. Amendola 165/a, 70126 Bari, ITALY, E-mail: maria.pizza@agr.uniba.it.

The Lepidoptera Gracillariidae Phyllocnistis citrella was reported for the first time in Apulia on citrus, at the end of August 1995. Since then, several studies have been carried out to investigate its bioethology in Mediterranean environments. In order to assess the infestation pattern of the leaf miner, many samplings and monitoring operations have been conducted in the orange grove of the experimental farm "Martucci", which belongs to the University of Bari, located in Valenzano and in some citrus-growing farms in the province of Taranto. On the grounds of the observations made, it has been demonstrated that: this insect occurs suddenly and spreads widely between the end of June and early July, generally when maximum temperatures have achieved 30°C for a few days; conversely, on the spring flush the typical symptoms have never been recorded; the insect activity stops around mid-August, when dry and hot conditions limit plant vegetative growth. In this period relative moisture can even reach 40%, with a monthly mean of 60 to 65% and irrigation does not allow new vegetative flush. On the other hand, from September throughout October, the infestation resumes massively and P. citrella generations overlap; the infestation can continue in Winter; until February, all the insect stages may be found at the same time, even a few sporadic eggs. These phenomena can be observed on lemon, the sole plant which continues to grow also in the Winter time, when temperatures are mild; until February, larvae and pupae may be found also on leaves fallen on the ground; pheromone traps have never proved effective against P. citrella, although the sexual pheromone has been tested at different amounts (0.1 mg, 1 mg and 10 mg of Z7, Z11hexadecadienal). Indeed, the first sporadic captures have occurred in October, during the full autumn infestation; chromotropic traps, both white and yellow, have registered the insect presence since July, after the infestation outbreak. White traps, despite the low capture levels, have proved to be more effective than the yellow ones; the parasitoids which have emerged from laboratory-reared leaf miner larvae belong to the *Pnigalio* genus (Hymenoptera, Eulophidae). They have been collected in very low number, with a parasitisation rate below 1%. A release trial with Ageniapsis citricola (Hymenoptera, Encyrtidae) in the Summer has failed, infact this parasitoid has never reached its adult stage, although, in some cases, it has pupated.

Index terms: Mediterranean environments, Z7, Z11- hexadecadienal, Pnigalio, Ageniapsis citricola

[1777] HYBRID MALE STERILITY AND COURTSHIP ANALYSIS IN DROSOPHILA BUZZATH CLUSTER SPECIES (DIPTERA, DROSOPHILIDAE)

L.P. de B. Machado, J. P. de Castro e L. Madi-Ravazzi, UNESP, Rua Cristovão Colombo, 2265, CEP 15054-000, S.J. Rio Preto, S.P., Brazil.

A good correlation between reproductive isolation and phylogenetic relationships has been found in several groups of Drosophila species. In the Drosophila repleta group the establishment of subgroups and complexes made on the basis of morphological and cytological evidences is supported by tests of reproductive isolation. Among species in the repleta group, the buzzatii cluster, due to its polymorphism and polytipism, is an excellent material for ecological and speciation studies. In previous work the reproductive isolation in crosses among strains of that cluster were analyzed and some interspecific crosses involving Drosophila seriema, D. serido B, D. koepferae and D. buzzatii strains were completely sterile. In interspecific crosses involving other strains these species, F1 hybrids were produced but they did not yield F2 progeny. In the present work, data on copula occurence and courtship duration obtained in the analysis of flies from parental sterile crosses and on spermatozoon mobility observed in F1 hybrids that did not yield F2 are presented. Copula did not occur during one hour of observation and the spermatozoon also did not show mobility at any of the analyzed stages (3, 7, 9 and 10 days old). There was also a high variation in courtship average duration and in the percentage of males that courted the females. The reproductive isolation mechanisms indicated by these observations were pre and pos-zygotic, as supported by the absence of copula and male sterility. Data obtained also showed different degrees of reproductive compatibility among the strains classified as same species but from distinct geografic localities. CAPES. Index terms: reproductive isolation, hybrid inviability,

[1779] EDGE EFFECT ON GROUND BEETLES

T. Magura¹, B. Tóthmérész² & T. Molnár¹, ¹Dept. of Zoology, Kossuth L. Univ, P. O. Box 3, Debrecen, H-4010, Hungary, E-mail magura@tigris.klte.hu; ²Ecological Inst., Kossuth L. Univ., P. O. Box 71, Debrecen, H-4010, Hungary.

Classical edge effect hypothesis states that diversity is higher in ecotones than in adjacent assemblages. Forest edges are a type of ecotone, which is interpreted on the meso-spatial scale and on the community level. This study was initiated to evaluate ground beetle (Coleoptera: Carabidae) diversity in relation to forest edge between an oak-hornbeam forest and herbaceous grass, because of the significance of the edge effect to the wildlife management and the increasing need and demand for the management of animal species. Our hypothesis was that the diversity of ground beetles would be higher in the forest edge than in the forest interior. We also examined the environmental variables that may be important for distribution of ground beetles, and thus can influence edge effect. Samples were taken along three repeated forest-grass transects using pitfall traps at the Aggtelek National Park in Hungary during two years. The study revealed significant edge effect on the ground beetles. Shannon diversity increased significantly along the transects from the forest towards the grass in both years. The diversity of the ground beetles were significantly higher in the forest edge and the grass than in the forest interior. Ground beetles of the forest, forest edge and grass can be separated from each other by ordinations, both on the species composition and abundance, suggesting that all three habitats have a distinct species assemblage. Moreover, indicator species analysis (IndVal method) detected significant edge associated species. Based on this approach, using both the specificity and fidelity of the ground beetles we have distinguished five groups of species: habitat generalists, grass-associated species, forest generalists, forest specialists, and edge-associated species. Multiple linear regression analyses proved that relative air moisture, temperature of the ground and cover of the herbs are the most important factors determining the diversity of ground beetles along the transects. The other studied factors (air temperature, cover of leaf litter, shrubs, and canopy, and prey abundance) had not significant influence on the diversity in the studied situation. Our results show that the high diversity of forest edges due to the edge-associated species and the presence of species characteristic to the adjacent habitats. It emphasises the significance of forest edges in nature conservation, serving as source habitat for dispersal processes, contributing the recolonisation of ground beetles after habitat destruction or other disturbance

Index terms: ground beetles, forest edge, diversity, indicator species, nature conservation.

[1778] IS *ELASMOPALPUS LIGNOSELLUS* BEHAVIOR INFLUENCED BY SMOKE OF BURNED SUGAR CANE?

D.C. Magri¹, E.R. Lima¹, E.F. Vilela¹, O. DeSouza¹ and P.A. Viana², ¹DBA/UFV 36571-000, Viçosa, MG and ² EMBRAPA/CNPMS, C. postal 151, 35701-970, Sete Lagoas, MG. E-mail: demagri@carpa.ciagri.usp.br.

The effect of smoke and ashes from burned sugar cane in the calling behavior and oviposition of Elasmopalpus lignosellus (Zeller) (Lepidoptera: Pyralidae) was studied. Calling behavior was observed under 25 ±2°C, 60-80% RH and photophase of 14 h, in the laboratory at the Federal University of Viçosa. Forty virgin females, each one in a cage (replications) were submitted to one of the following treatments: 1- Treatment 1 (room 1control): white paper towel inside each cage; 2 - Treatment 2 (room 2- smoke followed by ashes): smoke was offered in the first day and ashes from the second day; 3- Treatment 3 (room 3- ashes): ashes were offered everyday. Daily observations of the insects at 10 min intervals were made during the scotophase, for five days. As a result, females submitted to treatments 2 and 3 called more time compared with the control. We also evaluated the influence of odors from the burned sugar cane in the oviposition behavior of E. lignosellus, using three treatments and 25 replications per treatment, as following: Treatment 1 (control) the substratum for oviposition was white paper towel; Treatment 2 (smoke followed by ashes): paper towel was previously impregnated with smoke and on the second day it received ashes from the sugar cane combustion; Treatment 3: ashes were placed in each substratum. As a result, we obtained in treatment 2, twice the number of eggs compared to treatments 1 and 3, what indicates that the smoke of sugar cane combustion is an oviposition stimulant for E. lignosellus females.

[1780] AGREGGATION, CLUTCH SIZE AND OVIPOSITION BEHAVIOR IN DROSOPHILA PHALERATA

<u>M. Martins</u>¹ & B. Shorrocks², ¹Dept. of Zoology, Museu paraense Emilio Goeldi/CNPq/MCT, P. O. Box 399, Belem Pará, Brazil, E-mail marlucia@mueugoeldi.br; ²Dept. of Biology, University of Leeds, Leeds LS2 9JT,UK b.shorrocks@leeds.ac.uk

Drosophila is one of most diverse group of insects, with more than 3000 species in the world and a high number of local species and many species utilizing the same type of resource. Drosophila has been used as model to explain the coexistence of insects that exploit a resource in ephemeral patches. The aggregation model proposed by Shorrocks & Rosewell (1979) satates that aggregation of superior competitor produces refuges for inferior competitors and increases the species coexistence. It requires a higher degree of intraspecific versus interespecific aggregation in a pair of competing species. Ives proposal (Ives, 1988) to estimate the realative strength of aggregation effect and competition within and between species is based in the assumption that a female lays a single egg during a visit. In order to develop a method of analysis that will help to see how the real world might map onto theoretical possibilities, this research was developed to estimate the clutch size on D. phalerata, a dominant specie in the drosophilid fungal guild, under laboratory conditions. Cluth size here was defined as the number of eggs laid per female per visit. Experiments were conducted with different combinations of number of patches (pieces of mushoroom), number of females, and observation interval, with control of females (maturation, nutrition, temperature and light of the room) and patch quality. The flies were filmed on the patches for a fixed interval of time to record number of visits. The number of eggs laid in each patch was counted after each observation interval. The clutch size for D. phalerata was clearly greater than one, around 9 eggs per female visit, but follows a negative binomial distribution with k value about 0.4. The number of eggs laid was positively correlated to time and number of visits, but the oviposition behaviour presented some complexity. The was a slight tendency that one previously visited patch could be revisited more often than expected. However the was no evidence for non-random (aggregate) oviposition behaviour across patches. It was not possible to distinguish visiting behaviour from oviposition behaviour, and, in this case, more specific (manipulative) experiments will be necessary.

Session 09 - ETHOLOGY

[1781] LIVING ON A HAIRY SURFACE: MOVEMENT AND FEEDING BEHAVIOR OF GRATIANA SPADICEA (COL:CHRYSOMELIDAE: CASSIDINAE) ON ITS HOST PLANT SOLANUM SISYMBRIIFOLIUM (SOLANACEAE)

<u>L. Medeiros</u>¹ & G.R.P. Moreira², ¹ - DeBQ - UNIJUI - CP 560 - Ijuí, RS - CEP: 98700 000 / PG em Entomologia UFPR/Curitiba, PR. Email: lenicem@main.unijui.tche.br. ² -Depto de Zoologia - UFRGS. Av. Paulo Gama, 40, RS. CEP: 90046-900

Many plant attributes are involved with their adequability to herbivorous insects. The trichomes can directly act on movement and feeding of these insects. Both larvae and adults of Gratiana spadicea are associated with only one host plant, Solanum sisymbriifolium, whose leaves bear simple and stellate trichomes, which can be glandular and non glandular. We performed some behavioral tests and anatomic studies to determine whether the trichomes of S. sisymbriifolium act as a barrier to G. spadicea movement and feeding. Optical and scanning electron microscopy studies showed that the legs of G. spadicea larvae present a heavily sclerotized and hooked, apical podite (the tarsungulus), which is involved with the larvae attachment. At the first three instars, it is hooked on the stellate trichome rays (near 80% of the cases) during movement of the first three instars. Fifth instar larvae insert the tarsungulus tip directly into the leaf epidermis (71,9% of the cases). Speed tests performed with first and fifth larval instars showed that they are not able to move on smooth surfaces. When stellate trichomes were removed, the speed of first instars larvae was enhanced, but it did not change for the fifth instar larvae. The legs of the first larval instar are shorter than the central ray of the trichomes, so they cannot reach the leaf epidermis from which they feed upon. Neither larvae nor adults ingest the trichomes, which are removed from the leaf. First and second instars macerate the trichome rays to get access to the leaf epidermis. The remaining instars and adults remove the trichomes entirely. Feeding choice trails that were performed, where leaf discs with variable trichome densities were offered, showed that both larvae and adults preferred shaved compared to high density S. sisymbriifolium leaves. The mean distance between the stellate trichomes on discs with low trichome density was 0,53 mm, providing enough space for the first instars larvae (mean head width = 0,4 mm) to feed, without removing the trichome rays. The data suggest that S. sisymbriifolium stellate trichomes function as a barrier to the movement and feeding of G. spadicea, mainly to the larvae at the first instars. On the other hand, such a barrier is overcome by G. spadicea morphological and behavioral adaptations, represented respectively by hooked apical podites and remotion of the stellate trichomes.

Index terms: plant trichomes, plant physical defenses, behavioral adaptations

[1782] OVIPOSITION BEHAVIOR OF *CONOTRACHELUS HUMEROPICTUS* (COLEOPTERA: CURCULIONIDAE).

<u>C.M.D'A. Lopes</u>¹ and N.M. Silva²,¹IDAM, Rua Paraíba, Conj. Celetrazon, Rua 4, Casa 5, Adrianópolis, Manaus, AM, Brazil, 69057-000, E-mail consuelo@inpa.gov.br. ² Fac. de Ciências Agrárias, Univ. do Amazonas, Campus Univ., Manaus, AM, Brazil, 69077-000, E-mail neliton@argo.com.br.

Conotrachelus humeropictus is the major pest of cupuaçu fruit (Theobroma grandiflorum), causing 57.7% losses. The female lay egg endophitically in young fruit. The larvae feed on the fruit pulp, placenta, and lately on seeds. Limited information is available of the biology of this pest. This research was conducted to evaluate the oviposition behavior of C. humeropictus. The study took place at Training and Capacity Center (CENTRER-AM/EMATER), at Route AM-010, km29, Amazon, Brazil. After two months of fruit development cages were installed in 0.5 hectare of cupuaçu orchard. Each fruit were exposed to one male and one female. The treatments consisted of two periods: 6:00-18:00 h, and 18:00 to 6:00 h (next day) and 8 repetitions. The statistical analysis consisted of mean comparation test at 5% level. No statistical difference was observed for oviposition during, the periods evaluated, means of 1.068±0.479 (day hours), and 0.975± 0.219 (night hours). The majority of the oviposition occurred at the middle of the fruit for both periods. The females made several punctures in the fruit to feed, thus after ovipositing. The perforations were predominately grouped, though, single perforations were observed. Index terms: cupuaçu fruit borer, cupuaçu pest, Sterculiaceae.

[1783] CHARACTERISTICS OF COURTSHIP SONGS IN SEVERAL JAPANESE GREEN LACEWINGS (CHRYSOPIDAE) AND THE CROSSING EXPERIMENTS BETWEEN SOME STRAINS WITH DIFFERENT SONGS

K. Niiiima & Y. Suzuki, Lab. Entomology, Fac. Agriculture, Tamagawa Univ., Machida, Tokyo, Japan, 194-8610, E-mail nkeiko@agr. tamagawa. ac. Jp.

Green lacewings communicate by exchanging substrate-borne signals during courtship behaviors. Characteristics of these courtship songs in several Japanese species including some genus were described. The waveform, fundamental frequency and length and interval of volley are compared between species. Each species has specific signals and intraspecific reproductive isolation was considered to be achieved by this specific difference. These songs were produced by abdomen vibrating or jerking in many cases. But Brinckochrysa kintoki has a developed file-like structure in 2nd sternite and it is considered to be used for producing songs. Recently, foreign strains of *Chrysoperla* carnea are introduced into Japan for biological control of aphids. The songs of this widespreading species showed different characteristics depending on their habitat. Especially, the song of German strain is different from that of Japanese strain. So some crossing experiments between Japan strain and foreign strain were conducted. In a petridish(+9cm), most lacewings succeeded in mating between same strains in an hour, while none of them succeeded between Japan and German strain. The male selected same strain female by choice. When a pair of different strain was kept in a small cage for several days, they crossed at low ratio. The calling phenotypes of the F1 hybrids exhibited intermediate and they could cross easily each other. In a small cage (25 cm3) with a plant infested by aphids, mating ratio between Japanese and German strains was very low (0-10%) in 24 hours. These results suggested that the possibility of crossing between native and foreign strain seemed to be low in the fields.

Index terms: acoustic communication, reproductive isolation, waveform, Chrysoperla carnea, Brinckochrysa kintoki

[1784] WILL BE CERATITIS CAPITATA COMPETING WITH ANASTREPIIA FRATERCULUS?

D.R.S. de Oliveira¹ & <u>M.C.G. Pansera-de-Araújo¹</u>, ¹Dept. of Biology and Chemistry, Univ. Reg. do Noroeste do Estado do RS, R. S. Francisco, 501, Ijui, RS, Brazil. CEP. 98700-000. E-mail pansera@main.unijui.tche.br.

The South American fruit fly, Anastrepha fraterculus and Ceratitis capitata, an introduced specie, are highly polyphagous and known to attack several cultivated and wild fruits. These two species caused severe internal and external damages to orchards. The objective of this paper was verify the incidence and the viability of A. fraterculus and Ceratitis capitata in cultivated and wild fruits. The fruit flies were collected in the town of Ijui/RS from fruits of Psidium catleianum; Crysophyllum gonocarpum; Eugenia uniflora; Prunus persica; Psidium guajava; Prunus sp; Campomanesia xanthocarpa, in two years (1998 and 1999). The fruits were kept in plastic containers with sterilized garden soil and after 15 d the pupae were collected. Then, the pupae from each fruit were transferred to separate screen wooden cages (25x25x25cm) where the adult flies emerged and were provided with food and water sources through cotton wicks. The adults were counted and the viability pupae-adult verified. In the first year (1998), all the adults emerged were A. fraterculus with a differential viability and longevity fruit dependent ($\chi^2 = 17,632$; gl=6). In the second year (1999), only A. fraterculus emerged from the wild fruits while A. fraterculus and C. capitata infested the cultivated species (Prunus persica, Prunus domestica). The specie C. capitata infested 90% of Prunus persica, and 15% of Prunus domestica, and showed a high rate of pupae-adult viability (from 56% to 74%). The less viability pupae-adults were from A. fraterculus emerged of Campomanesia xanthocarpa (47%). The inviability causes were parasitoids (Brachonidae and Ichneumonidae). The occurrence of two or more species occupying niches in a definite space, interacting among them, exploiting a set of quality resources and ecological conditions, define a community. This knowledge of the community structure and the viability pupae-adults is relevant to decide how to manage the agroecosystems.

Index terms: Community; niche, viability, parasitoids

[1785] DISTRIBUTION OF SCAPTOCORIS CASTANEA POPULATION IN THE SOIL PROFILE

L. J. Oliveira¹, A. B. Malaguido² & S. De Angelis³, ¹Soybean National Research Center/ Embrapa Soja - C.P. 231, 86001-970-Londrina, PR. Brazil. e-mail: lenita@cnpso.embrapa.br, ² Fundação MT, C.P. 79, 78705-040 -Rondonópolis-MT-Brazil, ³ UNESP-Botucatu, SP- Brazil.

During the last five soybean growing seasons, the populations of brown root stink bug, Scaptocoris castanea (Hemiptera: Cydnidae) have increased, specially in the Central Region of Brazil. This bug is poliphagous, sucking roots of cotton, soybean, corn, rice, beans, pasture, as well as weeds, delaying growing or killing the plants. Surveys were carried out during one year to record S. castanea distribution in the soil profile, in three areas close to each other in Sapezal county, MT, Brazil. Every week, soil samples (50cm x 25cm x 120cm deep) were randomly removed and nymphs and adults were counted. The insects were returned to the soil shortly after sampling counting at different layers (0-10 cm, 10-20 cm, 20-30 cm, 30-40 cm, and 40-50 cm, 50-60cm, 60-70cm, 70-80cm, 80-90cm, 90-100cm, 100-110cm and 110-120cm depth). The population increased during Summer (December to March) and decreased in the colder months when adults and nymphs were deeper in the, probably in diapause, inside chambers. Adults and nymphs could be found in the soil around the year, but adults predominantly from December to early March; last instar nymphs were more abundant from May to August. In the colder months, more than 60% of population, specially older nymphs, were concentrated below 30 cm, in the soil seeking for more stable environmental conditions to survive the until the establishment of the Summer crops. From May to early October, nymphs were found until 120 cm depth in the soil. At the end of spring and during the summer, the population was concentrated at 10 to 30 cm, near the plant roots. During the hot and rainy months, the population concentrated above 20 cm, where the amount of roots is greater. Adults were more abundant in December-February and the flights were more frequent and intense from February to March. S. castanea active stages were capable of moving relatively large vertical distances to avoid temporary adverse conditions by going deeper into the soil. This ability must be considered in the choice of dates for sampling, as on hot days and in dry periods, the population may be underestimated if a superficial soil sample layer is sampled.

Index terms: Hemiptera, Cydnidae, soil insect, fluctuation, soybean

[1786] THE PREDATORY BEHAVIOR OF ZELUS LEUCOGRAMMUS, (HEMIPTERA: REDUVIDAE) IN CERRADO-SAVANNA, BRAZIL

<u>C. M. Paro, K. Del-Claro & F. R. Oliveira</u>, Univ. Fed. Uberlândia, Inst. Biology, PG-Ecology, CP 593, Zip: 38400-902, Uberlândia, MG, Brazil. e-mail: cmparo@yahoo.com

Although Reduviidae is one of the most common and diverse taxa of Heteroptera there are few informations about its behavior in natural environments. In this study we investigated the predation behavior of Zelus leucogrammus, a Brazilian Reduviidae poited out as potentially interesting to biological control, in natural conditions. We made 6 hours of direct observations in the field (60 sessions, 6 minutes each session, between July, 1997 and March 1999). The study site is a savanna field in the Gloria's farm, Uberlândia, Minas Gerais state, Brazil. Z. leucogrammus presents 5 nymph instars and are bivoltine. These predators insects possess morphologic adaptations, (trichomes and adhesive substance in its legs), that qualifie them to capture fast and flying preys. During the capture behavior, the predator's body is tilted about 75° in relation to the substratum, with the first pair of legs returned upward and moved away 45° approximately. It stays in this position until the capture of the prey. It was observed that the principal prey of Z leucogramus is Enchenopa brasilienses (Hemiptera: Membracidae) that jumps to avoid the attack. In the predation act, if there is the possibility of a new capture, Z. leucogramus arrests the died prey in the adhesive trichomes on the front legs, so that it can capture a new prey. This behavior of conduce a dead prey in the leg, is also presented during food dispute with other individuals or during the escape of predators.

Index terms: Zelus leucogrammus, Reduviidae, biological control, predatory behavior, cerrado-savanna.

[1787] SEX RATIO VS. FOUNDRESS NUMBER IN POLLINATING FIG WASP, PEGOSCAPUS CF. TONDUZI (HYMENOPTERA: AGAONIDAE), IN FICUS EXIMIA (MORACEAE)

<u>R. A. S. Pereira</u>¹ & A. P. Prado¹, ¹Dept. de Parasitologia, Univ. Est. de Campinas, C.P. 6109, CEP 13083-970, Campinas-SP, Brasil, E-mail: rodrigo@unicamp.br

Pollinating fig wasps females enter the syconium (inflorescence) of Ficus, pollinate, lay eggs in the ovary of some pistillate florets and die. When the syconium ripens, the wasp offspring emerge and mate inside. Generally, a few numbers of females (foundresses) enter the syconium, increasing the population level of inbreeding and the local mate competition (LMC). In order to study the foundress number effect over the offspring sex ratio; 25, 37 and 40 syconia of three individuals of F. eximia were sampled in Campinas/SP (22°54'S, 47°03'W), Brazil, during April to June 1999. Near the offspring emergency phase syconia were open to count the number of foundresses. Then, each syconium was closed and placed separated in plastic flasks so all the insects could emerge. Foudresses number vs. offspring sex ratio were analysed graphically and compared with three quantitative models for predicting haplodiploid sex ratio. In each of the three samples the proportion of males rise with increasing foundress number. However, observed data were more female biased the values predicted by models. Present data suggest that foundresses adjust their offspring sex ratio according to the intensity of the LMC. In two samples were observed 22 and 48% of syconia lacking foundresses, but with wasp offspring and seeds, indicating that these syconia were colonised and foundresses reemerged after. This fact is known in fig wasps, but disregarded in previous sex ratio studies based on observational data. Foundresses re-emergence possibly affects analysis decreasing the precision of the foundress number estimate. The experimental study controlling foundresses number may be a way to avoid re-emergence problems, but with the disadvantage of manipulating wasps, what could affect results (Support: Fapesp). Index terms: Ficus, fig wasp, Agaonidae, sex ratio, local mate competition.

[1788] MALE AGGRESSION IN POLLINATING (*PEGOSCAPUS CF. TONDUZI*) AND NON-POLLINATING (*IDARNES* SPP.) FIG WASPS (IIYMENOPTERA: AGAONIDAE), ASSOCIATED TO *FICUS EXIMIA* (MORACEAE)

R. A. S. Pereira¹ & A. P. Prado¹, ¹Dept. de Parasitologia, Univ. Est. de Campinas, C.P. 6109, CEP 13083-970, Campinas-SP, Brasil, E-mail: rodrigo@unicamp.br

Pollinating fig wasps females enter the syconium (inflorescence) of *Ficus*, pollinate, lay eggs in the ovary of some pistillate florets and die. Non-pollinating fig wasps females do not enter the syconium and lay eggs in the ovary of florets from outside through the syconium wall. When the syconium ripens, the wasp offspring emerge and mate inside. The pollinating species (*P. ef. tonduzi*) and the non-pollinating genus *Idames* show wingless males. Males of *Idames* spp. are aggressive during mating phase, on the contrary of pollinating species. To study the extent of injury on *P. ef. tonduzi* and *Idames* spp. males due to aggressive fighting around 25 syconia of three individuals of *F. eximia* were sampled in Campinas/SP (22°54'S, 47°03'W), Brazil, during April to June 1999. Syconia near the offspring emergency phase were placed individually in plastic flasks so all the insects could emerge. Wasps were frozen and males were inspected for injury. The extent of injury on each male was assessed by adding up points according to a sequence of scores (one to eight) proposed by Murray (Anim. Behav. 35:488-506. 1987), ranked by the importance of each type of injury. The extent of injury by wasp or "lifetime extent of injury" (LEI) and the percentage of the extent of injury by wasp or "lifetime higher in *Idames* spp. than in *P. ef. tonduzi*, according to table below.

Severe injuries, with scores ≥ 8 , took place in 13% of individuals of *ldarnes* spp. (median = 9; maximum score = 10,5). In *P*, cf. *tonduzi* was observed two severe injuries (scores 8 e 9) out 936 individuals observed. These data indicate an absence of aggression among males of pollinating species, suggesting that injuries were accidental due to syconia manipulate in laboratory. It is suggested on literature that males' aggressive behaviour evolve in high local mate competition situations, but in *P*, cf. *tonduzi* the absence of life history of this species (Support: Fapesp).

Index terms: Ficus, fig wasp, Agaonidae, male aggression, local mate competition.

[1789] ETOLOGICAL ASPECTS OF ORYZOPHAGUS ORYZAE (COLEOPTERA; **CURCULIONIDAE) IN WATER- SEEDED RICE**

H. F. Prando¹, D. R. Sosa-Gómez² & G. H. Rosado Neto³, 'EEI-Epagri, Cx. Postal 277, 8301-970, Itajaí SC. E-mail: híprando@zaz.com.br; ²Embrapa Soja sosa@cnpso.embrapa.br; ³Zoologia/Entomologia UFPR E-mail: pgento@ufpr.br E-mail:

In most water-seeded rice cultivation in Southern Brazil, the main insect pest is Oryzophagus oryzae. However, there are few works devoted to the etological study of this species. With the purpose of investigating the behavior of this species in water-seed rice cultivation, the present work was conducted in Itajaí Experiment Station- EPAGRI- Itajaí, SC, Brazil, in the 1997/98 and 1998/99 growing periods. The rice cultivar tested was Epagri 108. The adult was evaluated for feeding and oviposition behaviors. The larvae were observed from egg eclosion up to their introduction into the soil. The survival period of first instar larvae in the absence of food was also estimated. The predatory insects of the first instar O. oryzae larvae were observed at laboratory. Adults O. oryzae feed lengthwise among the veins of leaf parenchyma cuticle, leaving whitish stripes on the leaves. The leaf injuries vary from 2 - 40 mm long to about 1 mm wide. The average injured area amounts to 51.24 mm² per female, and 15.52 mm² per male, in a 24- hour period. In the waterseeded rice, the adults feed on the seed epicotyl and radicle, injuring 1.06 seedlings/couple/day. They can feed under water and may remain up to 11 days under distilled water. The oviposition takes place on leaf sheaths. The female selects the oviposition site, makes a scission with jaws, rotates 180^{9} C, introduces the ovipositor into the scission and lays one egg at a time into the aerenchyma. After eclosion the larvae remain for 1-1.5 days feeding on the inside part of the leaf, open circular orifices and leave. They make their way through the water and into the soil by gravity, and then towards the roots. The first instar larvae open galleries inside the roots, while the subsequent instars perforate and cut the roots. They live strictly in aquatic medium as free ectophytic larvae. However, first instar larvae are endophytic, having only a short ectophytic stage, that goes from their going out of the leaf up to entering the root. They move slowly, do not present natatory appendices and can only survive in still waters, mud and waterlogged soil. Most predatory insects from first instar larvae, collected on rice plants in the water, belong to at least three species of the Dytiscidae family. One of this species consume in average six larvae of O. oryzae per hour, under laboratory conditions. Index terms: rice weevil, behavior, natural enemies, Dytiscidae, damage.

[1791] SEASONAL VARIATION AND EFFECTS OF LARVAL FEEDING RESOURCES ON HELICONIUS ERATO (LEPIDOPTERA: NYMPHALIDAE) ADULT BODY SIZE

D. Rodrigues¹ & G. R. P. Moreira², ¹ CPG Ecologia, Inst. Biociências, Univ. Federal do Rio Grande do Sul. Av. Bento Gonçalves, 9500, Prédio 43422. Porto Alegre, RS, BR. Cep. 91.540-000 Cx. Postal 15007, E-mail drodrig@vortex.ufrgs.br; ²Depto. de Zoologia, Inst. de Biociências, Univ. Federal do Rio Grande do Sul. Av. Paulo Gama, 40. Porto Alegre, RS, BR. Cep. 90.046-900, E-mail grpm@if.ufrgs.br. 1 Financial support: CAPES

Adult body size, one of the most important life history component, varies strongly within and between Heliconius erato populations. In this study, it is determined whether such a variation is temperature related or caused by temporal changes in hostplants (Passifloraceae) used by the larval stage. The study area was located in the Barba Negra Forest, Barra do Ribeiro County, Rio Grande do Sul State. A H. erato phyllis population was sampled every 45 days from March 1997 to October 1998, to assess temporal variation in adult body size and on hostplants (Passiflora misera and Passiflora suberosa) used by the larval stage. Effects of P. misera and P. subcrosa on larval growth and adult size were determined in laboratory (25 ± 1 °C, 14L: 10D), when consumption rates were experimentally altered. Also, the effects of these hostplants species on growth rate and size were tested under winter (15 °C) and summer (25°C) temperatures. The field data showed that adults where larvae feed only upon P. suberosa are smaller than those fed on P. misera. The adults emerge with a larger size during the summer compared to other seasons. The larvae feed selectivily on P. misera even when the dominant passion vinc in a given place is P. subcrosa. They only change hostplant, from P. misera to P. subcrosa, during fall and winter, a period in which P. misera vines are completely defoliated. The feeding trials carried out in laboratory showed that there is a strong correlation between larval consumption rates of these two passion vines and adult size. They also confirmed that the adults emerge at a larger size when their larvae are reared on P. misera compared to those fed upon *P. suberosa*. There is no influence either of winter or summer temperatures on *H. erato phyllis* adult size determination. Thus, the temporal variation on H. erato phyllis adult size in a given place is primarily determined by the type, corresponding availability and quality of hostplants used by the larval stage.

Index terms: host-plant selection, heliconian butterflies, passion vines, temperature.

[1790] EGG HATCHING IN AEDES CASPIUS MOSOUITOES

D.M. Roberts¹, ¹Dept. of Biology, Sultan Qaboos Univ., P.O.Box 36, Al-Khod 123, Sultanate of Oman.

Acdes caspius larvae were collected from salt marsh pools on Masirah Island in Oman and reared to adult. Eggs laid by the females on damp pottery (nullipars were autogenous; parous were blood-fed) were used in the experiments. Single eggs of Acdes caspius, when undisturbed had a very low rate of hatching (0.8+0.5%), but when the water was agitated daily (by tapping the container for 30s), the hatching rate of 23.8+5.2% was significantly higher (F-ratio = 15.5, p<0.001). When reared in batches of 50, the hatching rate of agitated eggs became very much greater (undisturbed = 3.6+2.1%, agitated = 78.4+5.6%; F-ratio = 102, p<0.0001). Furthermore, when the undisturbed eggs that had failed to hatch after 14 days were then agitated daily, hatching increased from 3.6+2.1% to 17.2+ 3.7%. Mechanical disturbance of the eggs thus has a major effect on egg hatching. However, the increased hatching among eggs kept in batches of 50, compared with solitary eggs, showed that other factors (possibly chemical) also stimulate hatching. To investigate the age at which eggs became sensitive to water agitation, different batches of 50 eggs were agitated for 30s at either 4, 5, 6, 7, 9 or 11d after egg-laying. Hatching started on the 4th day, reached a maximum on the 5th day and then declined. Eggs which were flooded with water for 3d, dried out for 2d, then reflooded a 2^{nd} and a 3^{rd} time, had a very low hatching (18.8+6.2%) compared with continuously flooded eggs agitated every day. Increased hatching due to reflooding observed by other workers may therefore be the result of agitation during reflooding.

Index terms: Mechanical stimulation, flooding, Oman

[1792] GUSTATORY RESPONSE AND NUTRITIONAL SUITABILITY OF INDIVIDUAL NECTAR SUGARS FOR PIERIS BRASSICAE

I. Romeis & F. L. Wäckers, Institute of Plant Sciences, Applied Entomology, Swiss Federal Institute of Technology (ETH), Clausiusstr. 25/NW, 8092 Zürich, Switzerland, email: waeckers@cto.nioo.knaw.nl.

Most Lepidoptera feed during the adult stage on carbohydrate-rich food sources, primarily floral nectar. This adult feeding generally increases their longevity and fecundity. However, nectars are very complex food sources and little is known about the effects of individual nectar compounds on the gustatory response and the nutritional suitability for a nectar feeder. We have studied these effects for the large cabbage white, P. brassicae, using 0.5M solutions of the three main nectar sugars: sucrose, fructose and glucose. In no-choice experiments, food deprived *P. brassicae* females showed a gustatory response after tarsal or proboscis contact to sucrose and fructose only. They failed to respond to glucose. All three sugars tested increased longevity significantly in comparison to water fed control insects. Sucrose yielded the strongest effect, followed by fructose and glucose. Both lifetime fecundity and the daily oviposition rate were increased by a glucose diet. While fructose had no effect on fecundity, oviposition was almost totally suppressed in sucrose fed females. Out of 10 females kept on a sucrose diet, six laid no eggs at all, while four females produced only a few infertile eggs. Our results indicate that there is no absolute correlation between the gustatory response of *P. brassicae* females and the sugars nutritional suitability with respect to different important fitness-parameters. Index terms: Fecundity, food ecology, lepidoptera, longevity

Session 09 – ETHOLOGY

[1793] VARIABILITY IN THE BEHAVIOURAL RESPONSE OF THE ONION FLY TO N-DIPROPYL DISULFIDE

J. Romeis, D. Ebbinghaus & J. Scherkenbeck, BAYER AG, ZF-WFB, Agricultural Research Centre, Building 6220, 40789 Monheim, Germany.

The onion fly, *Delia antiqua*, is a specialist herbivore attacking only onions and closely related *Allium* species. *N*-dipropyl disulfide (DPDS) is the major headspace component of cut onions. A number of laboratory and field studies have shown that onion flies are attracted to this volatile plant kairomone. However, the insects' response was found to be highly variable. Using behavioural bioassays we found that DPDS is attractive to female onion flies but does not stimulate oviposition. The response of female onion flies to DPDS was strongly concentration dependent. The physiological state of the flies (i.e. mating status, egg load, age) also affected their responsiveness to this compound. Mated females and females with a high egg load responded significantly more strongly to DPDS than unmated females or females which had oviposited on cut onions prior to the experiment. The response of both sexes of onion flies to DPDS varied with age but females were always more attracted to this kairomone than males. The responsiveness of males reached a maximum at an age of 6-7 days after which it declined. The responsiveness of females of females of 21 days after which the experiment.

Index terms: Behaviour, Delia antiqua, diptera, kairomone, olfaction

[1795] A NEW RECORD AND BREEDING HOST PLANT FOR A SPECIES OF THE D. FLAVOPILOSA GROUP (DROSOPHILIDAE, DROSOPHILA)

R. C. O. Santos¹ & M.B. Martins², ¹Univ. Federal do Para, P. O. Box 479, Belem, CA 66075-900, **BR**, E-mail rcos@ufpa.br ²Dept. of Zoology, Museu Paraense Emílio Goeldi, P. O. Box 399, Belem, CA 66040-170, BR, E-mail marlucia@museu-goeldi.br.

Drosophilidae has at least 8 anthophilic genera. As many as 100 flower species have already been identified as being used for breeding by Drosophila species. The flavopilosa group of Drosophila, with 12 Neotropical species, represents a good example of specialization by these flies for this type of resource. The *flavopilosa* group bred and fed preferentially in flowers of the Solanaceae. They all present morphological and reproductive characters associated with flower utilization. Presently, living flowers of 12 species of Cestrum and one species of Sessea (Santos, unpublished data), both genera of Solanaceae, are known as breeding resources for these flies. However, the breeding sites remain unknown for 5 of the 12 species of the flavopilosa group. In Brazil, geographical distribution data for these species are scarce. Only 6 species have been registered in the South and Southeast regions of Brazil, which are the most intensely collected in the country. In 1998, an inventory of Amazonian flower drosophilids was initiated. As result of this work, for the first time, a natural breeding site for Drosophila melina (flavopilosa group) was recorded in Belém, Pará. Forty-five individuals (29 males and 16 females) of these files were reared in the laboratory from 2,397 living flowers of *Cestrum lacvigatum*, collected between March and May 1998 at the Museu Goeldi Research Campus (12° 706" S 48 ° 26'43" W). The adults took between 10 and 13 days to emerge. The previous records of Drosophila melina are from Santa Lucia, B.W.I., Panama and Colombia, without any information regarding natural breeding sites.

Index terms: Cestrum laevigatum, breeding site, living flowers, Amazonian region

[1794] A SILK-NEST WEAVING ANT *CAMPONOTUS SENEX* (HYMENOPTERA: FORMICINAE) IN A BRAZILIAN SAVANNA

<u>J. C. Santos</u>¹ & K. Del-Claro¹, ¹Inst. de Biologia, Univ. Fed. Uberlândia – Uberlândia, MG, CP 593, Cep 38400-902, Brazil. e-mail: jcsantosbio@hotmail.com

Camponotus (Myrmobrachys) senex, occurs in most forested areas of South and Central America and it is one of the six species of the very large and cosmopolitan genus Camponotus known to incorporate larval silk in nest construction. There are few information in literature about biology and ecology of the major part of the species of Camponotus and in this sense must be regarded as an evolutionary advanced form. In this study we investigated the nest construction behavior (N = 6) of C. senex in field (Gloria's farm – UFU – cerrado vegetation) and laboratory (Laboratório de Ecologia Comportamental e de Interações - LECI/UFU). More than a hundred hours of "ad libitum" observation (all occurrence sample, and also by a VHS film) revealed that workers conduce larvae between its mandibles and when stimulated by antennal stroking of workers, the larvae swing their heads back and forth while expelling silk threads. The weaving proceeds, a second group of workers gather sand particles, bits of detritus, and plant fragments and insert them into the fresh silk sheets. A third group of workers bite into the loose silk, specially at the points of contact with leaf surface tightening and smoothing the sheet as a whole. The nests have oval shape having until 65cm in diameter $(45,5 \pm 20,29; X \pm 1 \text{ SD}; N = 4)$ and until 716,1g in weigh $(364,62 \pm 311,89; X \pm 1 \text{ SD}; N = 4)$ = 4), but it depends of host plant and building material. A nest (21 cm in diameter) consisted of approximately 32.000 workers and one queen. Another nest (44 cm in diameter) owned 30 queens and more than 50.000 workers. Workers can take guard of the host plant against intruders and potentially can benefit the plant by the removal of herbivores.

Index Terms: Camponotus, silk-nest, cerrado, weaving-ant, ant.

[1796] THE ENERGETICS OF NECTAR FEEDING IN THE ANT CAMPONOTUS RUFIPES

P. E. Schilman & F. Roces, Theodor-Boveri-Institut, Dept. of Behavioural Physiology and Sociobiology (Zoology II), Biocenter, Univ. of Würzburg, Am Hubland, D-97074 Würzburg, Germany, E-mail schilman@biozentrum.uni-wuerzburg.de.

Forager animals are often assumed to be designed by natural selection so as to maximise the rate of food intake. This implies that animals must be able to evaluate the quality of a food source not only by assessing its energy content, but also by considering the time and energy invested in food intake. Ants trained to visit artificial feeders, providing continuous flows of nectar, appear therefore to be appropriate model systems to address the questions how animals assess rates of food intake, how this assessment controls foraging decisions, and how sugar requirements of the colony modify the individual foraging behaviour. For that, the time spent by a forager at the nest and at the feeder, as well as the amounts collected were recorded under controlled conditions in the laboratory. The results showed that: I) the sugar starvation of the colony modified the amount of nectar collected by an individual forager as well as the time spent in the nest between collecting visits, and 2) the forager crop load increased and the visit-time decreased with increasing nectar flow-rates, i.e., even though ants spent more time at the feeder, they collected less nectar. This means that ants do not stop drinking after a fixed time nor after a given crop load has been reached, but both factors are important in their decisions. The fact that the forager behaviour is modified by both the sugar starvation of the colony and the nectar flow-rates is important in relation to the foraging strategies of the whole colony. The forager does not collect nectar for it own sustemance but for colony members. It is noteworthy that for low flow-rates, ants do not fill the crop completely (just by drinking loager at the source), so they do not appear to try to maximise their energy gain per trip. One hypothesis to explain these unexpected results could be that the energy expenditure exceeds the energy gain while foraging. That seems not to be the case, because our measurements on the energy expenditure while foraging and the carbohydrate reserves in the hemolymph, obtained by recording of CO2-liberation and HPLC techniques, showed that the energy budget is not the limiting factor. Considering the time investment as the relevant variable, two alternative hypotheses could be advanced to explain partial crop loads: 1) shorter time at the food source would decrease the probability of risk predation at the source; 2) timesaving at the expense of reduced nectar loading would result in a higher probability of information exchange between workers in the nest, thus allowing nestmates to exploit more profitable resources in benefit of the whole colony. Further experiments may allow to discern between the decision-making systems in ants favoured by natural selection. Index terms: foraging, metabolism, crop load, flow-rates, time.

[1797] THIRTEEN HOUR COURTSHIP IN VINEGAROONS: A PRESCRIPTION FOR FEMALE CHOICE AND MALE INVESTMENT

J. O. Schmidt, Southwestern Biol. Inst., 1961 W. Brichta Dr., Tucson, AZ 85745, USA, E-mail ponerine@dakotacom.net

The vinegaroon, Mastigoproctus giganteus, is the largest living member in the small ancestral arachnid order Uropygida. These animals, best known for their ability to spray concentrated acetic acid solutions, are nocturnal, secretive, rarely encountered, and difficult to maintain in captivity. Although almost nothing is known about their reproduction, life-history strategies, or behaviors, they are generally assumed to have simple behaviors. During this investigation it became apparent that the courtship and reproductive behaviors of vinegaroons are far from simple. To the contrary, they possess one of the most complex and elaborate courtship systems reported from arthropods: a system ideally suited for both males and females to evaluate potential partners and make reproductive decisions based on investments, potential reproductive fitness, and costs. The courtship averages 13 hours (SD=2, n=48) and involves four distinct and cooperative phases: chase and grapple; dancing; generating; and pressing. If any of these phases fails, insemination does not occur. Female reproductive costs include producing, incubating, and initial rearing of offspring. Male costs are the generation of a complex spermatophore. In addition, both sexes incur considerable time costs during the courtship, time which otherwise could be invested in foraging or other activities. Over 200 courtships were staged in the laboratory with variables manipulated to determine the effect of an individual's mating status, size, recency of mating, age, time of season, and physical defects on female choice and male investment. Virgin females are generally more receptive than previously mated females, very small males are accepted by females, though they appear to be at a slight disadvantage to large males, and both males and females are able to mate during their second and third adult summer seasons and during any part of the season. Females exert their choice most frequently by attempting to block male advances during the crucial chase and grapple phase during which the male must grab the female's sensory legs and hold them in his chelicerae. Females sometimes will attempt to break courtship by refusing to allow the male to advance from the dancing to the (spermatophore) generating phase, or by refusing to accept the male spermatophore during the transition between the generating and pressing (spermatophore into the gonopore) phases. Males exhibit choice by refusing to court females, a behavior that most frequently occurs within 24 hr of a previous mating. Both sexes are heavily armed and can easily injure or kill each other; however, the importance of this risk factor is not easily evaluated, as only one individual was ever killed during a courtship trial, and that occurred when two females were placed together.

Index terms: Mastigoproctus giganteus, whip-tail scorpion, spermatophore

[1798] LEK ATTRACTIVENESS IN CERATITIS CAPITATA

Todd E. Shelly, United States Department of Agriculture, Animal and Plant Health Inspection Service, Plant Protection & Quarantine, Hawaii Plant Protection Center, P. O. Box 1040, Waimanalo, Hawaii 96795, E-mail tshelly@lava.net; Hawaiian Evolutionary Biology Program, University of Hawaii, 3050 Maile Way, Honolulu, Hawaii 96822, USA, E-mail tshelly@hawaii.edu.

I tested the null hypothesis that females of the Mediterranean fruit fly, Ceratitis capitata, were equally likely to visit leks composed of males with high versus low mating success. In laboratory trials, the observed distribution of mating among males differed significantly from that expected by chance, owing primarily to the higher than expected numbers of individuals with low (mated 0-1 days over 6 consecutive observation days) or high (mated 4 or more days mating scores. [In reference to these scores, I termed these two groups as 'low' and 'high' maters, respectively.] In the field, greater numbers of female sightings were made at artificial leks of high maters than low maters. This result apparently reflected a greater calling propensity among high maters. Slopes of female sightings versus calling level did not differ significantly between leks of low and high maters, suggesting that the observed relationship between calling activity and female sightings was independent of male mating status. Following the same protocol, I conducted a second experiment to examine whether males used the signals of conspecific males to locate lek sites and, if so, whether signal attractiveness varied with male mating ability. Attraction of males to calling conspecifics was far weaker than that observed for females, and over five different trials a total of only seven male sightings were made at any of the established leks.

Index terms: Ceratitis capitata, lek, pheromone.

[1799] INDIVIDUAL MATERIAL COLLECTION AND FORAGING TRIP DURATION IN MISCHOCYTTARUS DREWSENI (HYMENOPTERA, VESPIDAE)

E.R. Silva & E.Giannotti, Universidade Estadual Paulista – UNESP – Instituto de Biociências Departamento de Zoologia – Av. 24A, cp. 199, Rio Claro, SP., Brazil. e-mail: érsilva@rc.unesp.br

The objective of this work is to verify the individual specialization of workers of Mischocyttarus drewseni in the collection of nectar, wood pulp, prey and water and determine the duration of the foraging trips. In order to do so, 132 hours of observation were made on 12 colonies in post-emergence stage in the Rio Claro campus of Unesp. The foragers were marked with automotive paint in the mesosomal region, allowing the identification of each individual wasp, making it possible to distinguish their foraging habits and verify the time of departure and arrival on the nest, thus determining the duration of the collection trips. From 32 individuals observed, 21.8% collected only nectar, 46.8% collected two of the four sampled items, mainly nectar and prey, 28.1% collected three of the items, specially nectar, prey and wood pulp and 3% collected all four items. The duration of the trips varied according to the material collected. Nectar collections lasted an average of 24.3±19.8 min and prey collections 22.8±17.7 min, while the wood pulp and water collections had an average duration of 8.3±3.4 min and 2.1±0.7 min, respectively. This way we were able to demonstrate that there is no individual specialization of foragers during the collection of materials, since great part of the wasps are apt to collect the majority of the items, a characteristic of the less derived groups of social vespids. It was also established that the collection of food resources has a longer duration when compared to the collection of other items.

Index Terms: Mischocyttarus drewseni, social wasp, foraging activity

[1800] FEEDING PREFERENCE OF *PHTHIA PICTA* (HEMIPTERA: COREIDAE) BY FRUITS OF THREE CULTIVARS OF TOMATO.

<u>R. A. da Silva</u>¹, G. S. Carvalho¹, R. F. P. da Silva¹ & P. C. Bogorni², ¹Dept. Fitossanidade, Univ. Fed. do Rio Grande do Sul, P.O. Box 776, Porto Alegre, RS 90001-970, BRAZIL, E-mail: ricadaime@zipmail.com.br; ²Depto. de Entomologia, ESALQ/USP, Piracicaba, SP, Brazil.

Phthia picta is considerate one of the most important pests of the tomato culture (Lycopersicon esculentum), becoming difficult to produce fruits with commercial quality. The damage happens because of the puncture that nymphs and adults make in the fruits for feeding, prejudicing its development and making orifices that facilitate the entrance of other insects and microorganism. This study was carried out in the Laboratório de Entomologia, Departamento de Fitossanidade, Faculdade de Agronomia, UFRGS, Porto Alegre, RS, aiming at the evaluation of the feeding preference of adults of P. picta among fruits of three cultivars of tomato (Empire, Santa Clara and Carmen) and the "fidelity" of this bugs to Empire cultivar. The assays were developed using a free choice test, disposing one green fruit of each cultivar in a cylindrical vat of glass (15cm of diameter x 10cm of height) covered with voil. It was used adults of the second laboratory generation, 10 insects (group A) for an assay of feeding preference and 6 insects (group B) for an assay of "fidelity". To group A were offered, in the same time, fruits of three cultivars during 18 days before the first evaluation; to group B was offered a fruit of Empire cultivar since the first nymphal stage. It were carried out four repetitions for each assay, with three days of interval. Each repetition consisted to submit the groups A and B for a period of 24 hours without food, after to offer fruits of the three cultivars and to observe the behavior of the insects. For each insect feeding in the period of evaluation (each 5 minutes in the first hour and each 15 minutes of the first until the fourth hour) was attributed one point for the corresponding cultivar. In the intervals among repetitions were offered a fruit of each cultivar to group A and a fruit of Empire to group B. The results showed that the insects of group A preferred to feed on Empire (69% of the points). In the group B, 84% of the points were registered to Empire, indicating the "fidelity" of the bugs for this cultivar. Index terms: Lycopersicon esculentum, insecta, bug, puncture.
[1801] RANDOM MATING SECONDARILY DERIVED FROM LMC (LOCAL MATE COMPETITION) IN A GALL APHID, *NEOTHORACAPHIS YANONIS*

<u>Y. Tosaka¹</u>, T.Nishida¹ & N.Ohsaki¹, ¹Lab. of Insect Ecology, Graduate School of Agriculture, Kyoto Univ., Kyoto, 606-8502, JAPAN, E-mail juza@kais.kyoto-u.ac.jp

We examined a hypothesis that equal sex allocation observed in a gall aphid, Neothoracaphid vanonis was secondarily derived from LMC in the ancestral state. N. yanonis has five generations a year, with the fundatrix, i.e., the overwintered generation, forming a gall on a leaf surface of Distylium racemosum. The first generation shift to Quercus serrata, the secondary host and there reproduce parthenogenetically for a few generations before the third generation return again to D. racemosum. The third generation produced male and female nymphs, which disperse, develop to adults, and then mate. The numerical sex ratio of the nymphs at birth was female biased (1:2), but the males were just twice larger than females, resulting in equal investment for either sex as predicted by Fisherian theory. Observations on the mating system suggested random mating to occur because (1) multiple mothers laid nymphs within a single leaf, (2) newly hatched nymphs. particularly female nymphs dispersed from the natal leaf, and (3) reproductive adults were also highly dispersing. In spite of the suggested random mating, dissection of mother aphids revealed that almost all (97%) mothers produced two sons though the clutch size varied from 2 to 10, with the average of 6. The constant male production has been traditionally regarded as the evidence of LMC under varying resource condition (Ymaguchi, 1985). However, we found that constant male production occurs even under random mating. This suggestion that LMC might be once common in the native habitat. Thus, we tentatively conclude that the present random mating in N. yanonis may have derived from LMC in the ancestral state.

Index terms: Fisherian theory, sex ratio, constant male production.

[1803] INTRASEXUAL COMPETITION FOR VIRGIN FEMALES, AND MATURATION STRATEGY IN A FOLIAGE SPIDER CHIRACANTHIUM JAPONICUM (ARANEAE: CLUBIONIDAE)

M. Toyama. Parsimmon and Grape Research Center, National Institute of Fruit Tree Science, 338-1 Mitsu, Akitsu, Hiroshima 739-2494, Japan, E-mail tym@akt.affrc.go.jp.

Chiracanthium inponicum is a foliage spider and commonly found in Japan in open fields. This spider shows sexual differences in body shape and maturation timing; males have larger chelicelae and longer legs than females, and they mature usually before females, i.e. protandry. It is supposed that males compete for mating with virgin females and intrasexual selection acts on these sexual dimorphic traits in males through the competition because they show prematuration mate guarding. To examine male-male reproductive interaction and measure selection acting on adult-male traits in a natural population, I followed marked and released mature males for three consecutive generations from 1994 to 96 in the wild. As expected, replacements of guarding males, where in a general way larger males replaced relatively small prior residences, often occurred. The mating number in marked males was ranged from 0 to 5, and selection favored males with larger body size and early maturation. Although chelicerae and 1stlegs were used in male-male contests, I could not find selection acting on them, perhaps because of the large variation in male body size and the low occurrence ratio of direct male-male competition. This study also found a positive relationship between body size at maturity and the time of maturation in males in contrast to negative correlations are observed in most other spiders, and two peaks in frequency distributions of these male characters respectively. In addition, in these distributions and the distribution of the time of female maturation there were large differences among years and sites. This dynamics of male size at maturity and maturing timing in this spider may be explained by an alternative strategy where each individual spider decides maturation to maximize mating success expected under it's own growth conditions.

Index terms: Chiracanthium japonicum, protandry, sexual dimorphism, intrasexual selection, alternative reproductive strategy

[1802] AGING AND TOMATO LEAFLET POSITIONS INFLUENCE ON OVIPOSITION OF *BEMISIA TABACI* BIOTYPE "B" (HEMIPTERA: ALEYRODIDAE)

L. C. Toscano^{1,3} & A. L. B. Júnior¹, ¹ Depto. Fitossanidade, Univ. Estadual Paulista (UNESP), Via de Acesso Prof. Paulo Donato Castellane, s/n. Jaboticabal, São Paulo, Brasil. 14870-000. Itoscano@fcav.unesp.br; aboicajr@fcav.unesp.br.

The experiment was aimed to evaluate the influence of aging and leaflets positions of tomato on oviposition of Bemisia tabaci Biotype "B", using the free choice test, at a greenhouse (2x3x2m). There were utilized Bruna VFN (Agroflora) hybrid. At 30, 45 and 60 days of age, each plant was artificially infested with 100 adult-whiteflies. After 24 hours, two complete leaves were collected one from superior part and other inferior part, and it was determined the number of eggs/cm². It was adopted the complete randomized block design, 3x2x3 (3 = three different ages; 2 = height of the part collected-inferior and superior; 3 = leaflet positions in relation to the steam-basis, middle and apex) Factorial designing with 6 repetitions per treatment. At 30 day, the plants showed to be more preferred to oviposition (2.52 eggs/cm²) than at 45 (0.77 eggs/cm²) and 60 days (0.35 eggs/cm²). In the superior part, the favorite positions to oviposition were the apex and the middle (3.03 and 1.70 eggs/cm², respectively), being lower the preference to the basis (0.20 eggs/cm²). However, in the inferior part the preferential position was the basis (1.49) in relation to middle and apex (0.30 and 0.54 eggs/cm², respectively). It might eggs/cm be concluded that 30-day tomato plants showed to be more preferred e to oviposition of whitefly and for an effective sampling, there should be collected leaflets from apex and middle from the superior part and from basis when collected from inferior part. Index terms: Insecta, Lycopersicon esculentum, whitefly, sampling

(1804) DAILY PERIODICITY OF MATING- AND OVIPOSITING- BEHAVIOR IN DIAMONDBACK MOTH

II. Uematsu¹, K. Yoshikawa¹ & K. Nakata¹, ¹Laboratory of Applied Entomology, Faculty of Agriculture, Miyazaki University, Miyazaki, 889-2192, Japan, □E-mail a0a401u@cc.miyazaki-u.ac.jp.

A pair of newly emerged diamondback moth, Plutella xylostella, was introduced to a test tube (30 X 200 mm) with host plant, cabbage or Japanese radish. The test tubes were placed outdoors for three days. Behavior of the insects and number of eggs deposited on the host plant were noted once an hour to clarify the daily periodicity of mating- and ovipositing-behavior. Studies were made in May, June, September, October, November, December and January. Diamondback moth mated actively after the sunset, i.e., the peak was from 9 p.m. to 0 a.m. and from 7 to 10 p.m. in May-June and September-October populations, respectively. In winter season, they mated not only after sunset but also in daytime. Mean number of mating behavior per a female in the three days was 1.8 (maximum 5). Duration of mating lasted 3 hr or more in cooler seasons, although it was shorter than 2 hr in warmer seasons. Ovipositonal behaviors were most frequently observed before and after sunset in warmer seasons. In winter, however, the insect tended to lay eggs in daytime. There was a positive correlation between night temperature and proportion of number of eggs deposited in the night (Ng / TE), (here, NE: Number of eggs deposited in the night, TE Total number of eggs deposited in the night and daytime of the next day). When the night temperature was higher than 10 C, NE/TE was greater than 0.5. When the night temperature fell below 5 C, no eggs were deposited in the night. The temperature lower than 7 C seemed to suppress the oviposition in the night. Index terms: Plutella xylostella, reproductive behavior, winter, warm seasons

[1805] OVIPOSITION BEHAVIOR OF NEOMEGALOTOMUS PARVUS

<u>M. U. Ventura</u>¹ & A. R. Panizzi², ¹Departamento de Agronomia, Universidade Estadual de Londrina, Caixa Postal 6001, Londrina, PR 86051-970, BRASIL. E-mail mventura@uel.br ²Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA), Caixa postal 231, Londrina, PR 86001-970, BRASIL.

This research deals with *Neomegalotomus parvus* behaviors related to choosing the crevices on pigeon pea, *Cajanus cajan* (L.) Millsp., pods to lay eggs. Blocking of antenna, tarsi, eyes, or abdomen, and all structures simultaneously, did not affect the site of the pod (crevices) chosen to lay eggs. Oviposition occurred mainly in the afternoon. Most eggs being laid from 4-6 P.M. Females behaviors were observed. Females move antennae alternately up and down. Dabbing/antennation is accomplished, first with antenna and then with antenna and labial tip. The ovipositor is exposed and swept over the surface of the pod, leading oviposition. Eggs are held together with an adhesive substance. Mechanoreceptors were observed on the ovipositor.

Index terms: Heteroptera, Alydidae, oviposition site selection, oviposition cicardian rhythm.

[1807] HOST LOCATION AND OVIPOSITION IN THE ORUSSIDAE (HYMENOPTERA), A BASAL PARASITIC WASP FAMILY

L. Vilhelmsen¹, N. Isodoro², F. Bin², H. H. Basibuyuk³ & D. L. J. Quicke⁴, ¹Zoological Museum, University of Copenhagen, Universitetsparken 15, DK-2100 Copenhagen, Denmark; ²Institute of Agricultural Entomology, Perugia University, Borgo XX Giugno, 06121 Perugia, Italy; ³Department of Biology, Cumhuriyet University, 58140, Sivas, Turkey; ⁴Center for Population Biology, Unit of Parasitoid Systematics, CABI Bioscience UK Centre (Ascot), Department of Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, and Department of Entomology, The Natural History Museum, London SW7 5BD, UK

Anatomical studies and behavioral observations indicate that Orussidae use vibrational sounding to detect suitable oviposition sites. During host location, vibrations generated by tapping the tips of the antennae against the wood are picked up by the basitarsal pads on the fore legs, transmitted along the basitarsi to the tibia and through haemolymph to the subgenual organs, where they are transduced into nerve impulses. The apical antennomeres are distinctly shaped and have the cuticle thickened distally. The external wall of the fore tibiae have thin-walled areas distally on their posterior parts. Internally, large subgenual organs are situated opposite the thin-walled areas; each organ consists of 300-400 scolopidial units suspended between a lateral cuticular spine, a ventral sheet, and a median ridge. The fore basitarsi have weakly sclerotised basitarsal lines proximally and membraneous basitarsal pads distally. The ovipositor is several times the length of the body of the wasp. When at rest, it extends all the way into the prothorax, where it is coiled before extending posteriorly to lie between the 3rd valvulae distally. The ovipositor lies in a membraneous ovipositor sac attached posteriorly to the proximal parts of the ovipositor apparatus and the posterior margin of S7. In the ovipositor apparatus, the anterior parts of the 2nd valvifers are displaced and expanded anterodorsally, inverting the 1st valvifers and the base of the ovipositor. When in use, the ovipositor is extended and retracted by median apodemes situated on the anterior margins of abdominal sternites 3-7. Longitudinal muscles between the apodemes allow the latter to grip the ovipositor in troughs between them. The ovipositor extends from the abdomen from the distal tip of S7; an internal trough on \$7 serves to guide the ovipositor into the wood. Despite the alterations observed in the ovipositor apparatus of Orussidae, the musculature is almost complete and the mode of operation presumably not much different from that of other Hymenoptera.

Index terms: Vibrational sounding, subgenual organ, internalized ovipositor, evolution of parasitism

[1806] FEEDING BEHAVIOR OF NEOMEGALOTOMUS PARVUS

<u>M. U. Ventura</u>¹ & A. R. Panizzi², ¹Departamento de Agronomia, Universidade Estadual de Londrina, Caixa Postal 6001, Londrina, PR 86051-970, BRASIL. E-mail mventura@uel.br ²Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA), Caixa postal 231, Londrina, PR 86001-970, BRASIL.

Laboratory studies with Neomegalotomus parvus nymphs in multiple-choice tests indicated that seeds of pigeon pea, lablab, and soybean were visited first than seeds of common bean. Percent dabbing/antennation resulting in probing and percent probing resulting in feeding was higher on common bean (97%) and pigeon pea (87%) seeds than on lablab (55%), soybean (50%) or rice. (5%) seeds. In tests using 10 nymphs/petri dish, a higher number of flanges was deposited on seeds of pigeon pea (41) than on common bean, lablab, soybean (< 11) or rice (0). After two, four and five days, nymphs located seeds of pigeon pea preferentially than seeds of the other foods tested. In tests with 1 nymph/dish, no significant differences were found in the number of flanges deposited on seeds of pigeon pea, common bean and lablab (ca. 30); < than 5 flanges were deposited on soybean and none on rice seeds. In no-choice tests, the average duration of a feeding session and the longest feeding session was greater on lablab and, to a some extent on common beans than on pigeon pea, soybean or rice seeds. The number of feeding sessions was greater on seeds of common bean, pigeon pea and soybean compared to those on lablab or rice. Tests with N. parvus adults, indicated that pigeon pea seeds were located faster, followed by common bean, soybean and rice. When pods were used, dabbing/antennation time was shorter on pigeon pea than on soybean, and probing time was longer on soybean than on pigeon pea or common bean. On pigeon pea, 100% of the insects probed the food, while on common bean and soybean pods, and on rice panicles these values dropped to 71.8%, 46.0%, and 10.5%, respectively. Adults showed similar feeding time on pigeon pea, common bean and soybean pods, and did not feed on rice panicles. Electronic microscopy analysis indicated two apical lobes with 12 peg sensilla on the labium tip. Sensilla tips stained with silver nitrate solution indicated permeability of the cuticle and, therefore, their relationship with taste. Index terms: Heteroptera, Alydidae, food preference, food selection

[1808] THE DIFFERENCE OF ADULT ECLOSION RHYTHM BETWEEN DIAPAUSE AND NON-DIAPAUSE PUPAE IN THE ONION FLY, DELIA ANTIOUA

<u>Y. Watari</u>, Lab. of Biotechnology, Ashiya Univ., Rokurokuso-cho 13-22, Ashiya, Hyogo 659-8511, Japan, E-mail ywatari@ashiya-u.ac.jp

Influence of pupal diapause on adult eclosion rhythm of *Delia antiqua* was investigated. When diapause and non-diapause pupae were exposed to various LD cycles (photoperiods) at 15, 20 and 25°C, both emerged as adult closely to light-on, but the phase of adult eclosion varied according to the length of the photoperiod and temperature. In short photoperiods (LD 2:22, 4:20, 8:16 and 12:12), the adult eclosion reached a peak before light-on, but after light-on in long photoperiods (LD 16:8 and 20:4). The peak of eclosion after light-off was also delayed at lower temperatures. In each LD cycle and temperature, moreover, there was a significant difference in the phase of adult eclosion between diapause and non-diapause pupae; the eclosion peak of the former was always earlier than the latter after light-off, thus suggesting carry-over effect of pupal diapause. When diapause and non-diapause pupae were transferred to constant darkness (DD) after having experienced LD 12:12 at 15, 20 and 25°C, both showed circadian rhythmicity in the adult eclosion. Although the free-running periods increased as temperature decreased, the non-diapause pupae always that longer free-running period than the diapause counterparts. This strongly suggests that the observed difference of adult eclosion phase between diapause and non-diapause pupae at LD cycles is due to the difference of their free-running periods.

Index terms: circadian rhythmicity, photoperiod, temperature.

[1809] LEAF AREA CONSUMPTION OF Urbanus esmeraldus (LEPIDOPTERA: HESPERIIDAE) IN Centrosema pubescens, Clitoria fairchildiana AND ALTERNATE FEEDING

J. G. N. Wendt¹ & A. G. Carvalho¹, 1Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: wendt@ufrrj.br and acacio@ufrri.br.

The lepidopterouses, in a general way, are a reflex of what they consume and this fact evidence the importance for the organism. This way the quality and the amount of food consumed in the larval phase affect the growth, time of development and weight directly. This work had as purpose to study the leaf area consumption in the five larval instars of Urbanus esmeraldus (Lepidoptera: Hesperiidae) in Centrosema pubescens, Clitoria fairchildiana and alternate feeding, with Centrosema pubescens and Clitoria fairchildiana. These Leguninosae are considered of extreme importance for the replanting of degraded areas and fixation of nitrogen. The study was driven in the Laboratory of Forest Entomology of the Institute of Forests of the Universidade Federal Rural do Rio de Janeiro in 1998. The medium temperature during the conduction of the experiment was of 23,74 $^{\circ}$ C ± 1.43 °C, while the relative humidity of the air was of 74,35% ± 13,7%. The leaf area consumption of the caterpillars, in cm², in the five larval instars for the treatment C. pubescens was of 0,540; 1,212; 6,837; 27,761 and 123,880. The caterpillars fed with C. fairchildiana the leaf area consumption it was of 0,106; 1,565; 5,649; 24,553 and 111,600 and in the alternate feeding it was of 0,646; 1,904; 6,066; 27,064 and 138,980. The leaf area consumed by the caterpillars of first instar, in *C. fairchildiana*, was inferior to the other treatments presenting statistical difference (Tuckey 5%). However, the consumption in the fifth instar in the alternate feeding was superior statistically to the others. Index terms: Defoliate, Degraded areas

[1810] CIRCADIAN TEMPERATURE PATTERNS IN TWO CECIDOMYIID GALLS OF MACHILUS THUNBERGII (LAURACEAE)

Chi-Ming Yang¹, Wen-Yang Jen¹ & <u>M. M. Yang²</u>, ¹ Institute of Botany, Academia Sinica, Nankang, Taipei, Taiwan 115, R.O.C.; ² Dept. of Entomology, Nat. Chung Hsing Univ., 250 Kuo Kuang Rd., Taichung, Taiwan 402, R.O.C. E-mail: mmyang@dragon.nchu.edu.tw.

The temperature of two Daphnephia cecidomyiid galls of Machilus thunbergii leaf was recorded with a copper-thermocouple being plugged into the gall chamber and were compared with those of the air and soil, and relative humidity. They are oval-pointed and obovate galls and distributed in the northwestern and southeastern sides of Datun Mt. range in the Yangmingshan Mt. National Park at northern Taiwan. From the macroscopic view, the temperature of gall inside always follows that of the air outside. From the microscopic view, however, a general circadian temperature pattern was observed under whatever temperature condition. While the air temperature risen between midnight to midday, the gall temperature was always higher than the former until the maximal; then while the air temperature fell from midday to midnight, the gall temperature was always lower than the former until the minimal. In addition, the discrepancy between the gall and air temperature was gradually amplified during the rising period, and that gradually narrowed down during the falling period. Therefore, two circadian transition points existed at around midday and midnight each day. However, the above circadian rhythm disappeared during the cold wave period. In such weather condition, the temperature of the gall chamber is always lower than that of the air. It is apparent that the gall wall plays no role as a temperature insulator at all for the insect living inside. We propose that the circadian rhythm of gall chamber temperature is a function of the circadian behavior of the insect residing inside the gall. Further studies are necessary for identifying the behavior contributed to the gall temperature fluctuation. Index terms: circadian thythm, Daphnephia, Taiwan

[1811] INSECTS IN THE TROPICAL LAND-USE MOSAIC – THE IMPACT OF AGRICULTURAL AND FOREST DEVELOPMENT

<u>A. D. Watt</u>¹, L. Gormley¹, P. Zborowski², N. E. Stork³ & A. Gillison⁴, ¹Centre for Ecology and Hydrology, Banchory Research Station, Hill of Brathens, Glassel, Banchory AB31 4BY, Scotland, UK E-mail adw@ceh.ac.uk; ²PO Box 867, Kurunda, QLD 4872, Australia; ³Cooperative Research Centre for Tropical Rainforest Ecology and Management (Rainforest CRC), James Cook University, Cairns Campus, P.O. Box 6811, Cairns Qld 4870, Australia; ⁴Center for International Forestry Research, PO. Box 120,Yungaburra 4872, Queensland, Australia.

There is an urgent need to quantify the effects deforestation and land use change on the diversity of arthropods in tropical forest areas. This paper will summarise recent research in Latin America, West Africa and South-East Asia on the impact of land use mosaics, or 'disturbance gradients', on a range of insect groups, particularly ants, butterflies and beetles. Studies on these gradients have focussed on uncleared forest, logged forest, forest plantations with both native and non-native tree species, rubber plantations of different types and a range of agricultural land uses. In each cased the diversity, species composition and, in some cases, the trophic structure of the insect development can be very harmful to biodiversity, there are many opportunities for minimising the negative impacts of such development.

Index terms: ants, butterflies, beetles, biodiversity, deforestation.

[1813] GROUND BEETLE DIVERSITY AND ASSEMBLAGES FROM FORESTS IN FLANDERS: A BASELINE STUDY

<u>K. Desender</u>¹, D. De Bakker¹, V. Versteirt¹, B. De Vos², D. Van Den Meersschaut ²& K. Vandekerkhove², ¹ Dept. Entomology, RBINSc, Vautierstr. 29, B-1000 Brussels, Belgium, E-mail: kdesender@kbinirsnb.be; ² Inst. Forestry and Game Management, AMINAL, Gaverstraat 4, B-9500 Geraardsbergen.

Most woodlands in Flanders nowadays are highly fragmented or degraded, mainly due to excessive human interference in the past. Forests now cover less than 10% of the total surface only, but are relatively well known concerning their historical ecology. During recent years, several efforts have been directed towards increasing our knowledge on distribution, ecology and population genetics of forest organisms, in particular invertebrates. Within the context of effects of forest fragmentation, or forest quality in general, several regional projects and impulse programmes have been launched. One of these is an inter-institutional baseline study on the occurrence and bio-indicative values of terrestrial invertebrates in a large number of Flemish forests. Carabid beetles were identified from 56 forest stands, distributed in 40 forests within the region of Flanders (Belgium), and sampled by means of pitfall trapping during a complete year cycle (1997-1998). More than 30.000 individuals from some 120 ground beetle species were obtained. Beetle diversity (per sampling site) is higher in humid valley forest, but decreases for larger forest complexes (decreased edge effect?), as can be deduced from multiple regression analyses. In previous studies, we obtained already analogous results and came to the conclusion that large and ancient forests in Flanders showed a low total species richness, but a much higher number of typical stenotopic forest ground bettes as compared to smaller woods. Multivariate analyses (classification, indirect and direct gradient analyses) of the quantitative beetle data for the 56 sampled forest plots show that carabid beetle assemblages are highly structured. About five more or less well defined ground beetle communities can be distinguished in this dataset. These include (1) stenotopic species from large historical forests on somewhat higher elevation, species from (2) shady forest plots ou rather heavy soil, (3) humid valley forests on rich and heavy soil, (4) humid to wet marshy forest on poor soil and (5) dry forests on sandy soil, mainly pine woods. Each of these assemblages is characterized by a number of ecological indicators, several of which are illustrated and discussed, with notes on their distribution and dispersal power. These results serve as a necessary baseline for future site-assessment studies, investigations on the influence of forest management practices and studies aimed at elucidating the influence of single enrvironmental or historical factors on the recent distribution of forest carabids in the region of Flanders.

Index terms: Carabidae, ecological indicators, fragmentation.

[1814] ENTOMOFAUNA AS A BIOINDICATOR OF THE IMPACTS OF SILVICULTURAL OPERATIONS

A. J. Laranjeiro¹, E. Berti Filho², R. C. Sartório³, S. Silveira Neto², ¹Equilíbrio Proteção Florestal, Piracicaba/SP, Brasil; ²Departamento de Entomologia – ESALQ/USP, Piracicaba/SP, Brasil; ³Aracruz Celulose, Aracruz/ES, Brasil.

This research was carried out in order to determine and quantify the impacts of the forest management operations during one cycle of eucalypt plantation (circa 7 to 8 years), by studying the interaction among the eucalypt plantation, the underbrush and the natural reservoirs through the monitoring of the entomofauna in the plantations of Aracruz Celulose in the State of Espirito Santo, Brazil. The results obtained to date made possible the characterization of the several environments studied, the reservoir of natural woods, the plantation of clonal eucalypt and the regions bordering them, during the seasons of the year and the silvicultural phases. The main entomofaunistic parameters used to characterize the environments and silvicultural phases were frequency, abundance and diversity index, but the parameter most efficient for the monitoring was the Shannon-Wiener diversity index for morphospecies. It was possible to estimate the biodiversity index of the whole community collected by light and Malaise traps by analyzing the insects of the Order Lepidoptera captured with the light trap. The ten most abundant species associated exclusively to mature or young eucalypt plantation were identified. The study showed a positive interaction between the reservoir and the eucalypt plantations increasing the diversity of the entomofauna. The effects over eucalytp harvesting were observed on the community of insects in the three environments, but the definite patterns for the mature plantation, were recovered two years after the new planting. Index terms: eucalypt, management, entomofauna, bioindicator.

[1815] EFFECTS OF FORESTRY ON MOTH COMMUNITIES

<u>I. Okochi</u>, Insect Management Lab., Forestry and Forest Products Research Institute, Matsunosato-1, Kukisaki, Inashiki-gun, Ibaraki 305-8687, JAPAN, E-mail ohkou04@ffpri.affrc.go.jp.

Forestry may strongly affects local biodiversity through the repeated cutting and planting of single tree species. Moths are one of the largest groups that mainly depend on the leaves of plants, and species composition of many of these plants is directly affected by forestry. Therefore, the influence of forestry on forest biodiversity may be able to be monitored by changes in moth communities.

The moth communities of a primary forest in central Japan and a managed forestry area adjacent to the primary forest were compared by light trap collection on 1993, 1994, 1995, and 1998. Three plots were set in primary forest, of which two were along the stream and one on the ridge. We selected three stands as a representative of forestry areas: an open site after cutting, a remnant secondary deciduous forest, and a Sugi cedar (*Cryptomeria japonica*) plantation. The result showed that the moth communities in the forestry area were different from those in the primary forest, although the species composition fluctuated from year to year. The forestry area was rich in grassland species, while the primary forest was rich in forest species. Sugi plantation forest had the poorest species composition. This suggest that the core primary forest should be protected as a source and a refuge of the forest species, but also that the secondary forest surrounding it may have a role as a habitat for forest moth species. Open sites after clear-cutting may be habitat for grassland species.

Index terms: Moth community, Lepidoptera, biodiversity, forestry, primary forest

[1816] ENVIRONMENTAL DIVERSITY IN A *EUCALYPTUS* PLANTATION AFFECTS NUMBERS OF *SARSINA VIOLASCENS* (LEPIDOPTERA: LYMANTRIDAE) ADULTS?

J. M. M. Pereira¹; T. V. Zanuncio¹; O. T. Dall'Oglio¹ & <u>J. C. Zanuncio¹</u>, Dep. de Biologia Animal, Univ. Federal de Viçosa, 36.571-000 Viçosa, MG, BRAZIL, E-mail: zanuncio@mail.ufv.br.

Since environmental heterogeneity can reduce populations of Lepidoptera pests in Eucalyptus cloesiana plantations, the objective of this research was to study the impact of strips of native vegetation within these plantations on adult numbers of Sasina violacons (Hindh-Schreffer, 1856) (Lepidoptera Lymninidae) collected with light traps installed in two Eucalyptus plantations. The first one with strips of native vegetation (system WS) while the second had no such strips (system NS). S. violascens adults were collected from October 1993 to April 1994 with two samplings for each point every 15 days. This Lepidoptera species was collected with light traps as following: trap number 1- in a area of native vegetation; trap number 2- at the border of this area; trap number 3- at 250 meters from the border of this area in a Eucalyptus plantation; trap number 4- at 500 meters from the border of this area in a strip of native vegetation (system NS) or in a plantation of Eucalyptus (system WF); trap number 5- in a plantation of Eucalyptus at 750 meters from the border of the area of native vegetation. A total of 171 and 849 individuals of this pest was collected in the system without and with strips, respectively. Adults of S. violascens were collected during the whole period in the system with strips without reaching high numbers. This shows that S. violascens are always present in systems with higher even though adults of environmental diversity, this species is controlled by biological factors in such areas. The use of strips of native vegetation within Eucalyptus plantations can reduce the number of adults of S. violascens.

Index terms: Lepidoptera Pests, Eucalyptus, Native Vegetation.

[1817] ARTHROPODS, THINNING AND INNOVATIVE HARVEST DESIGNS: ECOSYSTEM MANAGEMENT AND BOREAL BIODIVERSITY

W. J. A. Volney¹, J. R. Spence², & D. W. Langor¹; ¹ Natural Resources Canada, Canadian Forest Service, 5320-122^m Street, Edmonton, Alberta, Canada T6H 385, ² Dept. of Biological Sciences, Univ. of Alberta, CW405A Biological Sciences Bldg., Edmonton, Alberta, Canada T6G 2E9

We report impacts of forest cutting on boreal arthropod biodiversity based on two largescale field experiments located in northern Alberta, Canada. The first experiment (c. 340 ha with 4 replicates), located 1000 km N of Edmonton, was designed to compare several approaches to thinning as potential mitigation strategies for a persistent outbreak of spruce budworm. The harvest treatments, applied in 1997-98, reduced standing volumes by 25 or 50% in 3 patterns: linear strip, feathered edged strip or uniform shelterwood cuts. Responses in these thinnings were compared to those in untreated controls and standard, operational clearcuts. In addition to evaluating the impacts of these treatments on defoliation, we also collected data on impacts of these treatments on vegetation, moths, carabid beetles and saproxylic insects. Results to date suggest that reductions of stand volume have not reduced budworm populations in residual stands but spruce beetle populations temporarily increased in residual stumps. Immediate post treatment effects in the other biota assessed were associated with the degree of disturbance. The second experiment (c. 1000 ha), located c. 600 km NW of Edmonton was designed to explicitly study the trade-offs between biodiversity, more traditional measures of forestry performance, and other indicators of ecosystem function. The harvest treatments, applied in 1998-99 in a replicated experiment across for cover-types (conifer and deciduous dominated and two mixedwood types), left 10, 20, 50 and 70% of the volume as standing green trees selected compartments. Through explicit comparisons with experimental green trees selected compartments. burns, we are assessing the extent to which leaving green-tree residuals in a range of volumes delivers biodiversity outcomes similar to those resulting from natural disturbance. We have collected pre-treatment and response data about carabid and staphylinid beetles, spiders, parasitoids, moths and butterflies and saproxylic beetles, in addition to numerous data about plant biodiversity and community response. Initial results show that boreal insect communities are largely similar across cover-types within a northern mixedwood forest and that harvest can have large immediate impacts on aspects of arthropod community structure. The value of such large-scale experiments lies in simultaneous measurement of many variables in single study areas so that trade-offs between biodiversity and more traditional measures can be clearly assessed.

Index terms: forest harvest, fire, ecosystem management, residual structure, thinning, beetles, moths, spiders

[1818] EFFECTS OF A MULTI-YEAR GYPSY MOTH ERADICATION PROGRAM ON DIVERSITY OF NONTARGET FOREST CANOPY ARTHROPODS AND THEIR BIRD PREDATORS IN THE OZARK MOUNTAINS

F. M. Stephen¹, **M.P. Lih¹**, **G.W. Wallis¹**, **L.R. Nagy²**, **& K.G. Smith²**, ¹Dept. of Entomology, Univ. of Arkansas, Fayetteville AR 72701, USA, E-mail fstephen@comp.uark.edu; ²Dept. of Biological Sciences, Univ. of Arkansas, Fayetteville AR 72701. USA.

Through inadvertent transport of egg cases on a recreational vehicle, gypsy moth Lymantria dispar (L.) (Lepidoptera: Lymantriidae) recently colonized oak forests in the Ozark Mountains of Arkansas, USA. The introduction was undetected for approximately eight years. Upon discovery, an extremely rapidly reproducing population with egg mass numbers estimated to be several thousand per ha was found. In order to eradicate the infestation two aerial applications of *Bacillus thuringiensis* var. *kurstaki* were made approximately a week apart, on 10,100 ha in 1994 and on 7,150 ha in 1995. We hypothesized that the reduction in Lepidoptera larvae in the sprayed areas would potentially reduce the overall breeding success of the caterpillar-eating birds, and in particular the Hooded Warbler. Our objectives were to examine effects of eradication on (1) abundance and biomass of nontarget forest canopy arthropods; (2) structure of the breeding bird community; and (3) abundance and reproductive success of the Hooded Warbler (Wilsonia citrina), a Neotropical migratory bird that nests in the Ozarks and that utilizes caterpillars during the breeding season. Sampling of oak foliage in tree canopies in control and spray plots was conducted to estimate abundance and biomass of nontarget forest canopy arthropods in 1994, 1995 and 1996. Coincident with arthropod sampling, bird censusing at fixed-radius plots was conducted along transects in all spray and control plots to assess abundance and diversity of the bird community. The eradication sprays, in separate plots in spring of 1994 and 1995, dramatically reduced lepidopteran larval populations for four to six weeks post treatment. Lepidopteran populations remained low during the same time period one year post treatment, but appeared to be recovering by year two. The effect of spraying on the Neotropical migratory birds was evident in only a few species that were specialists on lepidopteran larvae, suggesting that Neotropical migratory birds may be adapted to fluctuations in prey availability on their breeding grounds. Index terms: Lymantria dispar, Bacillus thuringiensis, Neotropical migratory birds

[1819] INSECTS AND BOREAL FOREST MANAGEMENT

J. Niemelä Dept. of Ecology and Systematics, P.O. Box 17, FIN-00014 University of Helsinki, Finland, e-mail: jari.niemela@helsinki.fi.

Intensive forestry adversely affects biodiversity on various scales in the boreal forest, Especially in Fennoscandia, forests have lost much of their natural heterogeneity due to removal of coarse woody debris and large deciduous trees. As a consequence, many forest species are now threatened. At the scale of forest stands three types of responses to logging can be distinguished: (1) species of open habitat increase, (2) forest generalists remain largely unaffected, and (3) old-growth specialists suffer. On larger scales, forestry has homogenized landscapes. For instance, comparisons across the Finnish-Russian border show that many insects species common in the less impacted Russian forests are suffering in the intensively used Finnish forests. Adverse effects of forestry on biodiversity have prompted public criticism which has lead to a rapid development of harvesting methods, usually based on the 'natural disturbance imitation' hypothesis, intended to enhance the maintenance of biodiversity while harvesting timber. How well these methods achieve their ambitious goal is currently being investigated. A field experiment using plots of 1 ha to examine both ecological and economical-technical effects and feasibility of various 'alternative' forest harvesting techniques was started in 1995. Invertebrates and vascular plants were used as bioindicators. Results show that traditional clear-cutting has more profound ecological effects than harvesting aiming at uneven-aged forest structure or harvesting creating small openings (0.1-0.15 ha). However, costs of harvesting (time used) was higher for the uneven-aged method than for others. These results can be used to improve forest harvesting methods so that they better take biodiversity into consideration. Key words: Carabidae, biodiversity, forestry

[1821] LITTER ANT COMMUNITY IN SUBTROPICAL ARAUCARIA AND COASTAL ESCARPMENT FORESTS IN SOUTHERN BRAZIL

J. Ketterl^{1,2}, W. Engels^{1,2} & M. Verhaagh^{1,3}, ¹LPB, PUCRS, 90619-900 Porto Alegre, RS, Brazil; ²Zool. Inst., Uni. Tübingen, Auf der Morgenstelle 28, 72076 Tübingen, Germany, B-mail jochen.ketterl@student.uni-tuebingen.de; ³Staatliches Museum für Naturkunde, Erbprinzenstr. 13, 76133 Karlsruhe, Germany.

Within the Atlantic rain forest (Mata Atlântica), the montane Araucaria rain forest of Southern Brazil may be regarded as the most endangered ecosystem. After the massive forest clearance in the past decades, only a few percent of the former area are still covered with primary forest. Little is known on the flora and fauna of this unique type of tropical forest dominated by a coniferan tree, the so-called Brazilian pine Araucaria angustifolia. We studied the litter ant fauna in a fragmented Araucaria forest and a nearby coastal escarpment forest, comprising only deciduous trees, in a forest reserve of 4,500 ha located on the Serra Geral in Rio Grande do Sul. Different sampling techniques were applied, in particular Winkler extraction by which more than 80% of all ant species were obtained. The total of over 100 recorded taxa included species of the subfamilies Dolichoderinae, Ecitoninae, Formicinae, Myrmicinae, Ponerinae and Pseudomyrmecinae. The ant diversity in the litter stratum of the Araucaria forest was a little lower than that of the coastal forest with deciduous trees only and, in the Araucaria forest, most taxa were less abundant, except one eudominant Hypoponera species, representing nearly 50% of the total Winkler catch. The sample included many rare species and numerous yet unidentified and perhaps undescribed taxa. According to extrapolations, about 20% more species can be expected to occur at the sites. The results are discussed under biogeographical and environmental aspects

Index terms: litter ants, Winkler extraction, Atlantic rain forest, Araucaria angustifolia

[1820] CHANGE IN BUTTERFLY COMMUNITY WITH SECONDARY SUCCESSION OF TEMPERATE DECIDUOUS FOREST

T. Inoue, Forestry and Forest Products Research Institute - P. O. Box 16, Tsukuba Norin Kenkyu Danchi-nai, Ibaraki 305-8687, Japan, E-mail taisei@ffpri.affrc.go.jp

Transect counts of butterflies were made in the north of Ibaraki Prefecture, central Japan from April to October in 1998 and 1999. I compared butterfly communities observed in eight and eleven research sites in 1998 and 1999, respectively. Research sites were composed of grassland (1 site), cutover immediately after clear-cutting (1 site), very young (2 sites; 6-9 years old), young (2 sites; 16-21 years old) and old (2 sites; 47-51 years old) secondary forests and old-growth natural forests (3 sites; 124-175 years old). A total of 2367 individuals belonging to 73 species and that of 3285 individuals belonging to 79 species were observed during the season (14 counts) of 1998 and 1999, respectively. Species richness of butterflies was the highest in the grassland, the next highest in the cutover and very young (less than 10 years old) secondary forests, and the lowest in young (16-21 years old) and old (47-51 years old) secondary forests. Species richness in one oldgrowth natural forest that contains many gaps was relatively high (near to very young secondary forests), but those in the others that contain almost no gaps were very low. The habitat preference of each butterfly species observed was decided from the literature. Species that prefer primitive grassland were observed only in the grassland research site. Species that prefer primitive forest were very few in the grassland, cutover and very young secondary forests. The percentages of species that prefer primitive forest increased, as the forest grow older and were the highest in old secondary and old-growth natural forests. Index terms: butterfly diversity, old-growth forest, secondary forest, grassland.

[1822] ANTS AS INDICATORS OF ENVIRONMENTAL CHANGE IN LOWLAND FORESTS OF THE ALTO RIO JURUÁ, ACRE, BRAZIL

R.B.Francini¹ & A.V.L.Freitas², Museu de História Natural, FAFIS, Universidade Católica de Santos, Rua Euclides da Cunha, 247, 11065-902, Santos, SP, Brazil, E-Mail francini@unisantos.com.br, ² Museu de História Natural, Instituto de Biologia, UNICAMP, CP 6109, Campinas, SP, 13083-970, Brazil, E-mail: baku@atribuna.com.br. Financial support: CIFOR, BSP

Among conservation biologists, there has been considerable recent interest in the identification of good indicators of the state of ecological systems, that can be readily incorporated into land monitoring and assessment programs. The ants are good candidates for use as indicators, since they are diverse and dominant in biomass and, have fundamental importance in ecosystem function. Along the upper Juruá River, south of Marechal Taumaturgo, AC, 130 hours of field work in 1999 with 8 series of standardized sardine baits (80 samples from 8 places) gave 70 morphospecies of ants. The species accumulation curves for the eight places showed some stabilization, but the combined curve for the 80 samples did not reach an asymptote. The richest sites (up to 25 species) were in the uplands with the poorest (6 species) were the seasonally flooded areas of Foz Analysis included similarity matrices using the Morisita index and the do Breu. clustering. The poorest places were secondary environments and igapós (where part of the ant assemblage is eliminated during the rainy periods), and the richest places were the forests with low levels of disturbance. A contingency table between the similarity of the places and their linear distance indicated a high significantly difference. Therefore, other factors, natural and/or anthropic should explain this difference. These results show that ants can be a excellent group of organisms to environmental monitoring, but with limited use for non-specialist people (local populations), due to difficulty in separating species without the aid of special equipment (local people recognize only 21 "kinds" of ants) and special training. Nevertheless, the recognition of a locally rich soil fauna (with many species) using fixed baits (for example sardine) could be a good basis for environmental monitoring by trained biologists. The abundance of some larger predator species (large Ponerinae and ground-swarming ants) could also be interpreted as indicative of better preserved areas, but medium to long term monitoring on the part of a team of specialists would be necessary to support a proposal of use of those organisms as indicators. Observations of these two categories of ants in a hunter's log book could help in future comparisons.

Index terms: anthropic impact, bio-indicators, ant assemblages.

[1823] INTRODUCTION AND RELEASE OF RHYSSINES TO CONTROL SIREX NOCTILIO IN BRAZIL

E.T. Iede¹, S.R.C. Penteado¹, S. Murphy², D. Haugen³ & W. Reis Filho⁴, ¹Embrapa Florestas, Caixa Postal 319, CEP 83411-000, Colombo, PR, BR, iedeet@cnpf.embrapa.br; susete@cnpf.embrapa.br; ²CABI – Bioscience, Silwood Park, Buckhurst Road, Ascot, Berkshire SL5 7TA United Kingdom, s.murphy@cabi.org; ³USDA-Forest Service, Saint Paul, Minnesota, USA, hauge017@tc.umn.edu; ⁴Epagri, Caixa postal 319, CEP 83411-000, Colombo-PR-BR, wilson@cnpf.embrapa.br

An integrated pest management program of Sirex noctilio in Brazil was initiated after the detection of S. noctilio in 1988. The program is based on monitoring, improved silvicultural management and in the introduction of the parasitic nematode, *Deladenus* The program is being complemented by the introduction of Megarhyssa siricidicola. nortoni and Rhyssa persuasoria (Hym.: Ichneumonidae), both imported from Tasmania, Australia. Importations were made in 1996 and 1997, through a cooperative project of Embrapa Forestry, the International Institute of Biological Control (CABI-Bioscience) and the USDA Forest Service. In the 1996 shipments, 77 M. nortoni arrived alive in Brazil. They were kept under quarantine in chambers with controlled humidity and temperature, where 1.8m long, 0.25cm diameter Pinus taeda billets with S. noctilio larvae were offered to them. Billets were collected by the end of August, about 45-60 days before the parasitoids arrived and kept in a cold chamber at 12C, to synchronize the life cycle of S. noctilio with that of the parasitoids. In 1997, only 9 females and 4 males of M. norteni and 9 females of R. persuasoria were imported. The first generation of M. norioni emerged in 1997 and resulted in 88 females and 45 males, of which 18 mated females were released in the field. The second generation of M. nortoni yielded 218 males and 101 females, of which 136 males and 97 females where released in the field. In 1999, only 50 males and 31 females emerged. The 1998 generation of *R. persuasoria* yielded 18 males and 19 females, of which 2 males and 10 females were released in the field. In 1999, 40 females and 20 males emerged. At the end of 1999, the establishment of these species at the release areas was not confirmed.

Index terms: Biological control, Pinus spp., Rhyssa persuasoria, Megarhyssa nortoni

[1825] ADVANTAGES AND LIMITATIONS IN THE USE OF PATHOGENS AS BIOCIDES FOR CONTROL OF FOREST PESTS

J.L. Madden ^{1,2} & **V.Patel**², ¹School of Agricultural Science, University of Tasmania & ² CRC Sustainable Forest Production, Hobart, Tasmania, Australia. E-mail:< johnL.madden@bigpond.com>.

Entomopathogens together with parasitoids and predators are major biological components of the 'natural control' of insects. However their individual effectiveness is unpredictable. Some potentially useful pathogens of specific insect pests have been grown successfully and demonstrated effectiveness in dosage mortality assessment under laboratory and field situations. Some have been propagated economically, formulated, packaged and applied to limit pest damage. In this sense they can be described as biocides for they replace the use of an insecticide. Emphasis on this type of use has been intensified due to both public and agency response to environmental and health concerns and problems of resistance. Today the quest for new insecticides continues because they, when used responsibly, are economical and possess important practical advantages. The positives include availability, ease in transport, handling, application and rapid cessation of pest damage. In use they are predictable in their effect and versatile as individual compounds may be used against a range of forest, agricultural and stored product pests. Thus biocides must ideally satisfy two criteria. They must share in the above advantages and be utilized in those environments that favour a better realization of their potential for economic control. These requirements will be addressed with respect to an evaluation of the potential use of spore formulations of strains of the entomopathogenic fungi, Beauveria and Metarhizium in the control of chrysomelid eucalypt defoliators. Though high rates of field infection and mortality (>90 percent) were achieved, the approach was subject to severe limitations. First the durations of the most susceptible stages, the egg and first two larval instars, were relatively short and there must be suitable prevailing weather conditions for application. Then the effectiveness of oil- spore sprays was restricted to direct contact with target stages. Later stages, though infected, continued to feed and failed to provide a significant reduction in defoliation status. However the results suggest that pathogens do have a role to play in more environmentally predictable and frequently monitored locales such as nurseries and small farm plantations. Preferably future research in this field should concentrate on enhancing those key characteristics and properties of pathogens and selecting the appropriateness of each pest situation to provide a biocide as a worthy alternative to an insecticide.

[1824] DETECTION AND CONTROL OF THE GUM TREE WEEVIL GONIPTERUS SCUTELLATUS IN CHILE (COLEOPTERA: CURCULIONIDAE)

<u>M. A. Beéche Cisternas¹, S. Rothmann T.², ¹ Servicio Agrícola y Ganadero / Defensa Agrícola – Av. Bulnes Nº 140, Santiago – Chile; ² Servicio Agrícola y Ganadero / Laboratorios Agrícolas – Av. Bulnes Nº 140, Complejo Lo Aguirre, Santiago – Chile</u>

The gum tree weevil, Gonipterus scutellatus, is one of the most important defolianting pests, in whose respect Eucalyptus globulus and E. viminalis, both cultivated for commercial purposes in Chile for the production of wood pulp - are among its most susceptible hosts. The larvae and adult of this pest are feeding from the eucalyptus foliage and may cause a significant reduction to the trees growth, including deformation of their crown and an increased susceptibility to the attack of other pests. This insect, of Australian origin, is currently present in most of the countries where eucalyptus is cultivated both in commercial and non-commercial form. In Chile, the first detection of *G. scutellatus* was performed by SAG inspectors during February 1998 in the locality Termas de Jahuel (V Region, Province of Los Andes); this resulted in the need to know the pest dissemination in the country, to determine the presence of natural enemies and to implement control actions which could reduce the potential damages in eucalyptus commercial plantations. Following the phytosanitary prospections, it could be determined that G. scutellatus is present in Chile only in the Provinces of Los Andes and San Felipe (V Region) and that no important natural enemies of the pest exist. As a result, the need was defined of introducing into the country the oothec parasitoid Anaphes nitens (Hymenoptera: Mymaridae). This biological control program was undertaken in order to supply the implementation of quarantine control actions coupled to chemical air focal controls, intended to reduce the possibility of disseminating the eucalyptus weevil in non-infested areas of the country. Thus, during October 1998 the collection of A. nitens took place in different localities of South Africa (Cape Town and Natal Provinces) where 3,232 G. scutellatus parasitized oothecs were collected and transported to Chile, being submitted to post-entry quarantine followed by their release in infested areas. The post-entry quarantine was carried out in the SAG / Lo Aguirre Laboratories and Quarantine Stations (Metropolitan Region, Chile) inside bio-climatic chambers, using for the quarantine and breeding of the parasitoid oothecs of the eucalyptus weevil collected in Chile and/or produced in the laboratory. Release of A. nitens took place in 6 localities of he Provinces of Los Andes and San Felipe, including a total of 5,715 adults. The subsequent field evaluations have demonstrated that A. nitens was successfully established in Chile and it reaches to day oothecs parasitism percentages ranging between 94 and 98% in the localities where they were released.

[1826] THE MORPHOLOGY OF THE IMMATURE STAGE OF *PHORACANTHA RECURVA* (COLEOPTERA: CERAMBYCIDAE) AND A KEY TO LARVAE OF THE SPECIES OF *PHORACANTHA* IN URUGUAY

M. Bianchi¹, E. Morelli² & A. Sínchez³, ^{1,3}Facultad de Agronomía. Departamento Forestal. Avenida Garzón 780. Montevideo Uruguay. C.P 11900 e-mail phoracantha @ yahoo. com, ². Facultad de Ciencias. Sección Entomología.Iguá 4225. Montevideo. Uruguay. C.P 11400; e-mail emorelli@ fcien.edu.uy.

During the last ten years species of the Eucalytus genus have been widely planted in Uruguay with industrial purposes. As a consequence of this, some insects pest have been detected with eventually could cause serious economic damage. Phoracantha semipunctata was detected in 1932 and Phoracantha recurva has been recently found in 1998 which have been accidently introduced. Larvae of these beetles bore trough the bark and mine along the cambium of stressed trees, usually killing its host. P. semipunctata and P. recurva larvae were reared in the laboratory on its natural host (on Eucalytus globulus ssp. globulus logs).Neonate larvae were manually transferred to logs which were kept in a controlled environment chamber (25°C and photoperiod 12 hs.). Mature larvae and pupae were removed from these logs to make its description. Diagnosis of the larvae was based on Duffy (1960), Costa, Vanin & Casani-Chen (1988) and Stehr (1991). Key to larvae of the species of Phoracantha in Uruguy: Temples with broad ferruginous cuneiform band behind the antennal bases. Supraocelar area with 7 setae, 3 of them in a straight towards at each median lobe - P. semipunctata. Temples without the broad ferruginous cuneiform band. Supraocelar area with 5 fine setae in a well - defined region. Abdominal tergite X with less abundant chaetotaxy and a pair of long setae in the border of each median lobe - P. recurva

[1827] USE OF CRISOPIDAE ON BIOLOGICAL CONTROL OF TROPICAL FOREST INSECT

[1829] POTENTIAL USE OF ASOPINAE STINKBUG BUG PREDATORS IN BRAZIL

J. C. ZANUNCIO¹ & J. B. TORRES¹, ¹DBA-Universidade Federal de Viçosa 36571-000 Viçosa, MG, Brasil. E-mail: zanuncio@mail.ufv.br; ²DEPA-Fitossanidade, Universidade Federal Rural de Peranambuco, 52171-900 Recife, PE, Brasil. E-mail: jorge@nelore.npde.ufrpe.br

Pentatomid Asopinae have been reported as potential biocontrol agents mainly against defoliator insects in natural occurrences in several crops in Brazil. Species of the genus Podisus have been more frequently found in several agroecossystems than any other related species. For this reason control programs with such predatory species against caterpillars have been developed by eucalyptus forest companies in Brazil and several measures are been used aiming to maintain these natural enemies in agricultural and forest ecosystems. Among these measures the following ones can be highlighted in Brazil. i) quantitative mass production programs of stink bugs have been continually improved with better alternative preys and rearing facilities aiming to increase efficiency and cost-effective commercial production and field delivery. Advances in rearing with artificial diets are also been obtained; ii) a second aspect refers to the use of these predators as part of IPM programs which is critical in order to reduce insecticide application. Researches in laboratory and field conditions have been showing compatibility of some insecticides with releases of stink bug in the field; iii) predator-prey relationships are been studied in laboratory and in field cages particularly with Noctuidae caterpillars in soybean, cotton, tomato and cabbage crops. Number and frequency of releases of predatory bugs have shown better results when unfed nymphs are released in the evening and continuous releases of adults for long periods at the same place are not recommended due to the impact of egg parasitoids. Finally, a better understanding of ecology and evaluation methods for these predators would contribute to enhance their use in biological control programs and to evaluate their relative importance in natural ecossystems. In addition its is necessary to have more clear systematic studies and to revise the nomenclature of these insects in order to improve joint researches between laboratories and the possibilities to publish results of researches with Asopinae .

0 [1839] PLATYPUS SULCATUS: A RATIONAL APPROACH TO ITS CONTROL IN POPULUS SPP. IN ARGENTINA

G. Mareggiani¹, A. Etiennot², <u>R. Giménez</u>³ & G. García⁴, Proyecto UBACyT, TG16. ^{1 y 4} Cátedra de Zoología Agrícola, Facultad de Agronomía, Univ. de Buenos Aires. Av. San Martín 4453, (1417), Buenos Aires, Argentina. E-mail: mareggiani@pinos.com.^{2 y 3} Cátedra de Terapéutica Vegetal, idem¹. E-mail: rgimenez@agro.uba.ar

Platypus sulcatus Chapuis (Col. Platypodidae), "ambrosia beetle", is a pest, which causes great losses on the final timber production of poplar trees (*Populus spp.*), becoming a serious danger for the regional economy in the Delta of Paraná River (Argentina). The current way to control this pest has a very high cost, not only from an economic point of view, but also due to their environmental impact. This damage is particularly important in an area ecologically sensitive as Delta of Paraná River, due to its proximity to the urban centers and sailing courses that serve as source of fish production. A better knowledge of the biological characteristics and population dynamics of P. sulcatus will be useful to evaluate management alternatives which will minimize the economic incidence on the final timber production. These studies have been carried out during two years, with traps put in the holes previously produced by the beetle. Sampling areas were selected taking into account the number of fallen trees and of holes with sap flow and larval sawdust. Every week traps were monitored to assess the date of adult sawdust and maximum adults emergence, differentiating males and females. It has been established that approximately a month before of maximum adult emergence, there was a great amount of adult sawdust in the traps. After that, in the latest days of November (the end of spring in the southern hemisphere), maximum adult emergence occurred. These results were related to climatic parameters of the area. The results here discussed together with those from the two years will be integrated to obtain a basis for the forecast of P. sulcatus, which will be useful to determine more exactly the moment for chemical control, in order to avoid indiscriminate insecticide applications.

Index terms: ambrosia beetle, wood borer, poplar

[1831] STRATEGIES TO MANAGE TERMITES IN EUCALYPTUS PLANTATIONS IN BRAZIL

C.F. Wilcken¹, Dept. Plant Production - FCA / UNESP - Campus of Botucatu - P.O. box 237 - 18603-970, Botucatu - SP - Brazil. E-mail: cwilcken@fca.unesp.br.

The termites have great importance to forest ecosystems, as much decomposition agents as pests. The termite pests can affect root system of eucalyptus young plants or destroying the heartwood of trees. Syntermes spp. and Cornitermes spp are species that attack young plants and Coptotermes testaceus attacks the tree trunk. Plant mortality caused by young plant termites vary of 10 - 70 %. The control strategy is the chemical barrier in soil, around root system of plants. Today, the control can be made with fipronil (phenilpyrazol), applying the insecticide in the seedling before planting. New products are in test, mainly pyrethroids and neonicotinoids. Nevertheless, it is necessary reduce the treated area, because the termite attack in the field occurs in spots, due to aggregate distribution. Monitoring systems to termite infestations have been studied, using cardboard traps distributed in soil. Early results indicated that is possible to develop sampling techniques economically feasible and avoid unnecessary insecticide applications. Index terms: Forest pest, damage, control, monitoring

[1833] THE UNITED STATES RESPONSE TO TWO RECENT INTRODUCTIONS: ANOPLOPHORA GLABRIPENNIS (CERAMBYCIDAE) AND TOMICUS PINIPERDA (SCOLYTIDAE)

R. A. Hnack & T. M. Poland, US Dept. Agriculture, Forest Service, North Central Research Station, 1407 S. Harrison Rd., East Lansing, MI 48823, USA; E-mail: rhaack @fs.fed.us

Two recently introduced tree-feeding insects in the US include the Asian cerambycid Anoplophora glabripennis and the Eurasian scolytid Tomicus piniperda. Both insects likely arrived in the US on infested solid wood packing material (e.g., crating, pallets, or dunnage) associated with international cargo. Established populations of A. glabripennis were first discovered in New York City in 1996 and then in Chicago in 1998. All infestations have been in urban areas. Because of the limited number and size of infestations, the US Department of Agriculture (USDA) is attempting to eradicate this insect by cutting and chipping all trees with evidence of attack, i.e., exit holes or oviposition pits. All infested areas are under quarantine. As of January 2000, more than 4000 infested trees have been cut in New York and more than 1000 in Chicago. Maples (Acer spp.) are the most commonly infested trees, but elms (Ulmus spp.) and horsechesnut (Aesculus hippocastanum) are also readily attacked. USDA and university entomologists have begun several research programs in the US and China that are aimed at A. glabripennis life history, dispersal, chemical ecology, chemical control, entomopathogens, biological control, host range, trapping, and acoustic detection of larvae in wood. Established populations of T. piniperda, the pine shoot beetle, were first discovered in Ohio in 1992, and within one month it was found in 5 additional US states. As of January, 2000, T. piniperda is known to occur in 271 counties in 11 US states and in 33 counties in 2 Canadian provinces. Because T. piniperda populations were already so widespread when discovered in 1992, the USDA made no effort to eradicate this beetle. Nevertheless, since 1992, the USDA has imposed a federal quarantine on the movement of pine Christmas trees, ornamental nursery trees, and logs from infested to uninfested areas in the US. The quarantine requires that pine material be treated or pass inspection before being moved. In addition, a "National Compliance Management Program" was developed for Christmas-tree and nursery managers, which allows easier movement of pine trees if managers follow approved cultural and chemical controls . Since 1992, several state, biology, behavior, and control. This paper will discuss the US experience with A. glabripennis and T. piniperda, including quarantine issues and research programs. Index terms: exotic insect, eradication, quarantine

[1832] CERTIFICATION OF EXPORTED CHILEAN FOREST PRODUCTS. ADVANCES IN THE MANAGEMENT OF ENTOMOLOGICAL RISKS

D. Lanfranco, H. Peredo & Sandra Ide, Inst. de Silvicultura, Univ. Austral de Chile, Casilia 567, Valdivia, CHILE, E-mail certisan@uach.cl.

Chile is a country that largely exports primary forest products such as logs, lumber or chips. Currently around 40 foreign countries import these products which must be qualified in terms of sanitary requirements. These forest products (78%) come from radiata pine plantations, (9%) from eucalyptus plantations and (13%) from native forests. Considering the dependence on external markets, Chile has been diversifying markets and products, ensuring the high quality of them and fulfiling international sanitary/environmental regulations. Between 1999-2001 a group of forest pathologists and entomologists are studying the sanitary risks in all the levels of the productive process, including the storing and shipping procedures. This presentation focuses on the advances of entomological risks. The general research objective is to develop guidelines, techniques and procedures for the international sanitary certification of primary forest products: (1) To define the key biological aspects of the insect-tree interactions, (2) Select management and control criteria at each step of the productive, transformative and exportation process, (3) Create a plan of technological transference during the development of the project and(4) Establish sanitary certification protocols. Preliminary results indicate that the highest risks are during the process of harvest, wood manufacture, storage in the sawmills, and pre-embark storage in ports. Several forest management and silvicultural practices avoid, as proactive measures, the incidence of some defoliators, bark beetles or wood borers. However the thinning, pruning and harvesting in the forest along with the manufacture of primary products in sawmills, attract mainly bark beetles. The same problem occurs during storage time in ports. Several bark beetles species (native or introduced) can damage the logs causing holes and galeries or perhaps introducing blue stain fungi spores with the concomitant wood biodeterioration. Complementary research is centralized in basic biological and population dynamic indicators of bark beetles and their possible fungal associates. A brief review of risk levels in steps of the productive flow is presented, including a list of the main hosts per exported tree species and their significance. Some final comments identify future trends in forest health and productivity, primary Chilean products, new markets for enhancing international trade, pesticides in final shipments with environmentally inocuous chemicals, minimizing risks of infection and infestation in all phases of the productive process, and ensuring the compliance with all international sanitary standards.

[1835] DIFFERENTIAL COLONIZATION POTENTIAL AMONG WOOD-BORING BEETLES LEADS TO HIGH PROPORTIONS OF INBREEDING SPECIES ON TROPICAL ISLANDS

B. H. Jordal¹, R. A. Beaver² & L. R. Kirkendall¹, ¹Department of Zoology, University of Bergen, allegt. 41, N-5007 Bergen, Norway, E-mail: bjarte.jordal@zoo.uib.no; ²161/2 Mu 5, Soi Wat Pranon, T. Donkaew, A. Maerim, Chiangmai, 50180, Thailand.

Parthenogenesis and regular close inbreeding are important characteristics of colonizing plant and animals. Inbreeding in wood-boring species in the weevil families Scolytinae and Platypodidae is most frequent in tropical latitudes, especially on small islands. In order to study the relationship between colonization success, island attributes and mating system in these beetles, we analysed the relative proportions of inbreeders and outbreeders for 45 Old World tropical islands plus two adjacent mainland sites, and scored islands for size, distance from nearest source population, and maximum altitude. We applied stepwise regression to isolate the best predictor(s) among the three variables. The numbers of woodborer species decreased with decreasing island size, as expected. Elevation, on the other hand, did not contribute much to explain species numbers, neither did the degree of isolation. Numbers of outbreeding species decreased more rapidly with island size than did those of inbreeders (had significantly steeper slopes). Comparing species with similar ecology (ambrosia beetles) showed that this difference was due to differential success in colonization, rather than differences in resource utilization or sampling biases. This conclusion was further supported by analyses of data from eight small isolated islands, which suggested that outbreeding species have a higher degree of endemism and that inbreeding species are generally more widespread. A wide distribution might indicate high colonization potential. Recently established small populations necessarily go through a period of severe inbreeding, which should affect outbreeding species much more than inbreeding ones. In addition, non-genetic ecological and behavioural ('Allee') effects are also expected to reduce the the success of outbreeding colonists much more than that of inbreeders: compared with inbreeders, inbred lineages of outbreeders are expected to have slower growth rates, have greater difficulties with mate-location, and be vulnerable to random extinction over a longer period. Hence, it is no surprise that inbreeders are indeed more common on isolated tropical islands.

Index terms: island biogeography, Allee effect, inbreeding, Platypodidae, Scolytinae

[1836] RECORDS OF CONIFER APHIDS FROM ARGENTINA (HOMOPTERA, APHIDIDAE)

M. A. Delfino¹ & A. Binazzi², ¹ Cat. de Entomologia, Univ. Nac. de Córdoba, Av. Velez Sarsfield 299, 5000-Córdoba, Argentina, E-mail Erro! Indicador não definido. 2. Istituto Sperimentale per la Zoologia Agraria, Sezione di Entomologia Forestale, Via Lanciola 12A, 50125 Firenze, Italy, E-mail abinazzi@dada.it.

Planted forests of exotic Coniferae are present in many areas of Argentina. During the twentieth century many European and American species of *Pinus* were introduced into various parts of this country. Most of the damages caused to trees by aphids seem to result directly from their feeding, either by removing of sap or wounding of tissues, or at least in some cases by the toxic effect of saliva. Economic damage to some Coniferae by sporadic outbreaks of aphids has been observed in Argentina. Most of the aphid species living on either native or exotic Coniferae in Argentina belong to Cinara (Lachninae), a very large genus resulting from a highly successful adaptative radiation on Coniferae of the families Pinaceae and Cupressaceae. All Cinara species live without host alternation on the twigs, shoots or needles, branches, trunks and, sometimes, roots of their host conifers living holocyclic and/or anholocyclic. The following species were identified from Argentina: Cinara acutirostris, C. maghrebica, C. maritimae, C. pinivora on Pinus, C. costata on Picea, C. fresai, C. juniperi, and C. tujafilina on species of Cupressaceae. Also the genus Eulachnus, with long-bodied, narrow individuals living on needles of pines, was found in Argentina with only two species, E. rileyi and E. tauricus; the former is widespread all over the world being the most polyphagous entity of this genus, the latter is originally linked to various Mediterranean pines (mainly black pines); only a few species of this genus are strictly monophagous, i.e., some European ones; individuals of *Eulachnus* are often cryptic when feeding, but very active when disturbed. In the South of Argentina also Elatobium abietinum (Aphidinae) was collected on the needles of Picea spp.; spring colonies on this host plant cause discoloration and loss of old needles, sometimes involving serious defoliation. C. acutirostris, C. juniperi and C. pinivora are mentioned for the first time in South America. It seems likely that C. acutirostris was introduced into Argentina from Europe where it lives commonly on *Pinus nigra* and *P. pinea* while *C. pinivora* comes from North America where it feeds on pines of subsections Australes and Contortae (eastern USA and Canada). Some of the mentioned conifer aphid species are attended regularly by ants, i.e., C. acutirostris and C. maritimae. On the other hand, a few of them, i.e., C. acutirostris, C. fresai and E. rileyi, produce, with their outbreaks, a large amount of honeydew leading to much developing of sooty mould fungi. Index terms: Aphids, Coniferae, Argentina

[1837] THE EXOTIC FOREST PEST INFORMATION SYSTEM FOR NORTH AMERICA

J. E. Macías-Sámano, El Colegio de la Frontera Sur, ECOSUR, Carret. Antiguo Aeropuerto Km 2.5, 39700 Tapachula, Chiapas, México, E-mail: jmacias@tapecosur.edu.mx

This system (EFPISNA) is a joint project of the member organizations of the Insect and Diseases Study Group of the North American Forestry Commission, FAO. These organizations are the Canadian Forest Service, the Canadian Food Inspection Agency, Secretaría del Medio Ambiente, Recursos Naturales y Pesca (SEMARNAP) Mexico, the USDA Forest Service, and the USDA Animal and Plant Health Inspection Service. The web site (www.exoticpests.org) is being provided and maintained by the NSF Center for Integrated Pest Management at North Carolina State University. Other cooperating universities and research centers are Michigan State University, El Colegio de la Frontera Sur, and Universidad Autonoma Chapingo. The objective of this effort is to identify exotic insects, mites and pathogens with potential to cause significant damage to North American forest resources. The database contains background information for each identified pest and is intended to serve as a resource for regulatory and forest protection agencies in North America. Each pest in the database is assumed to be able to maintain a population in North America, and to cause either economic or environmental damage following introduction. To categorize the risk posed by each pest, an evaluation sheet is provided, which ranks pest risk using these three criteria. Although emphasis in the pest risk assessment model developed for this project is on potential establishment and impact, information pathways for introduction and means of dispersal is provided in the "Pest Fact Sheet". It is anticipated that this information will prove useful for the assessment and management of introduced pests, wood products and other commodities from offshore sources. Experts from around the world prepare records for EFPISNA. Each pest record will contain full authorship information, and will be peer reviewed before being added to the database. Information may be submitted to the EFPISNA in English, French, or Spanish. An Evaluation Worksheet and a Pest Fact Sheet are required for each evaluated spanish. An Evaluation worksheet and a rest Part oner are required for each evaluated pest at the time of submission. A data entry program for entering and storing database records has been developed for EFPISNA. We highly encourage prospective authors to download and use the program, which may be obtained by retrieving it from our web site. Currently this program is only available in an English language version, but we expect to have French and Spanish versions soon. Authors are encouraged to submit suitable hard copy or digital photographs or drawings to accompany submitted test. Space has been reserved for up to four graphics per data sheet, representing the organism's appearances, a distribution map, life cycle, and photos of damage.

[1838] AN OVERVIEW OF BIOTECHNOLOGICAL APPROACHES TO BIOLOGICAL AND BIORATIONAL CONTROL OF FOREST INSECT PESTS

A. Retnakaran¹, Q.-L. Feng¹, B. M. Arif¹ and S.R. Palli^{1,2}, 'Great Lakes Forestry Centre, Canadian Forest Service, P.O. Box 490, Sault Ste. Marie, Ontario, Canada, P6A 5M7; ²Rohm and Haas Research Laboratories, 727 Norristown Road, Spring House, Pennsylvania, 19477, USA; E-mail: aretnak@nrcan.gc.ca

The earliest recorded use of a chemical, sulfur, for insect control appears in the writings of Homer before 1000 BC. The use of inorganics as first generation pesticides was replaced with powerful organo-chlorines led by DDT as their second generation replacements. The adverse environmental effects of many of these broad-spectrum insecticides was dramatically brought to light in the "Silent Spring" (Rachel Carson 1962) and this spawned the advent of Biorationals under the banner of third generation pesticides (Carol Williams 1967). Since then numerous specialized pest control agents such as benzoyl ureas, hormone analogs, avermeetins, azadirachtin, chloronicotinyls, arylpyrroles etc have been introduced. Concomitantly, traditional biological control based on parasite and predator release was being augmented with microbial control. Biological control which is generally perceived as environmentally benign has its best success story with B.t. The advent of Biotechnology has opened a new area where tailor made pesticides that are target specific can be designed. A panoramic outline of the genesis of pest management from the past to the present will be presented.

Index terms: Organochlorines, Benzoyl ureas, Hormone analogs, Avermectins, Azadirachtin, Chloronicotinyls, arylpyrroles, B.t.

[1839] PREDATORS AND PARASITOIDS FOR CONTROLLING INSECT PESTS OF FORESTS

<u>J.-C. Grégoire</u>¹ & M. Kenis², ¹Laboratoire de Biologie animale et cellulaire, CP160/12, Université Libre de Bruxelles, 50 av. FD Roosevelt, B-1050, Bruxelles Belgium, E-mail jegregoi@ulb.ac.be; ²CABI Bioscience Centre Switzerland, 1, Rue des Grillons, 2800 Delemont, Switzerland, E-mail m.kenis@cabi-bioscience.ch.

Biological control methods using parasitoids and predators can be divided into three categories: the augmentation of local or exotic natural enemies by inoculative or inundative releases at critical times, the conservation of local natural enemies by modification of management practices favoring the natural enemies in the target area, and the importation of exotic natural enemies for permanent establishment, a strategy often referred to as classical biological control. The use of parasitoids and predators in augmentative biological control programmes against forest pests is hampered by several constraints, among which the high costs related to mass production and application to large areas. Nevertheless, augmentative releases would be particularly suitable in urban landscapes. The conservation of natural enemies, e.g. through modifications of cultural practices or selective insecticide timing, is still a rather neglected strategy in forest pest management. However, the increasing limitations in the use of chemicals and biopesticides in forest environment will undoubtedly favor conservation strategies. The conservation of natural enemies also shows much promises in agroforestry (i.e. the use of forest trees in agricultural systems), particularly in developing countries. Until now, most biological control programmes in forestry focused on the introduction and establishment of exotic natural enemies into new areas to control an invasive pest. There are numerous spectacular successes worldwide showing unbeatable cost/benefit ratios. Although, in most cases, the motivation was purely, or mainly, economic, classical biological control is also increasingly used to protect biodiversity, as shown in St Helena where the coccinellid Hyperaspis pantherina, predator of the scale insect Orthezia insignis, saved the endemic gunwood, Commidendium robustum from extinction. Although classical biological control has been recently criticized for its possible side effects on non-target organisms, it still represents the safest and most efficient management method against invasive pests. The long life span, size and complexity of forest ecosystems provide favourable ground for both naturally occurring and man-manipulated biological control. However, they also complicate assessment of the impact of native or introduced parasitoids and predators, and implementation of biocontrol programmes. This review attempts to draw a link between cases studies of relationships between native forest pests and native natural enemies and the effective or potential use of these predators and parasitoids in biological control programmes

Index terms: biological control, parasitoids, predators

[1840] THE ROLE OF *BACILLUS THURINGIENSIS* IN FOREST PEST MANAGEMENT: ITS CURRENT STATUS AND FUTURE PROSPECTS

J. A. Elek & N. Beveridge¹, ¹Forestry Tasmania, GPO Box 207 and Cooperative Research Centre for Sustainable Production Forestry, GPO Box 251-12, Hobart, Tasmania, Australia 7001, Email: Jane.Elek@forestrytas.com.au.

It is almost 100 years since a bacillus was isolated from a silkworm which was later named Bacillus thuringiensis Berlinger (Bt). The first commercial insecticide was developed to control the flour moth in the 1930s. Its mode of action and different strains mean that Bt can target specific groups of insect pests with minimal effect on natural enemies and the environment. However, it was not until the 1980s, when there was growing resistance by both insects and environmentally-aware people to the large-scale use of broad-spectrum insecticides, that it became cost effective to use the new, more expensive, biological insecticide. In 1980, insecticides based on the strain, Bacillus thuringiensis var. kurstaki (Btk), that specifically targets lepidoptera, were sprayed on 20% of the area managed for invasion of the gypsy moth (Lymantria dispar) in USA. By 1999 this had reached 79% (81,651 ha) of the total area treated for gypsy moth. In Canada in 1980, Btk-based insecticides were used on only 4% of the area treated for spruce budworm (Choristoneura fumiferana) but by 1995 this had increased to 100% (139,618 ha). Achieving this widespread use of Bt-based insecticides has not been easy. They not only target specific insect groups, but also require many other specific biological and physical parameters for successful control. This achievement is the result of considerable research into their mode of action and optimum requirements which lead to developing effective formulations and methods of application for Btk-insecticides. There is still similar work to be done on other strains and insect pests. We have been testing B. t. var. tenebrionis (Btt) for its activity against the chrysomelids Chrysophtharta bimaculata and C. agricola, defoliators of eucalypts. The Btt insecticide caused higher mortality and suppression of feeding of younger instars that was not proportional to body size, peaking at 4 d after treatment, and prolonged development time by several days. Its activity was also affected by the host Eucalyptus but not the chrysomelid species. It had no effect on the two major coleopteran predators. The future use of Bt-inssecticides will be affected by adoption of new technology. For example, in 1999 a virus and pheromone lure were used on about 20% of the area managed for gypsy moth in USA. However, a wide range of agricultural crops now have been engineered to incorporate several Bt genes, and the Btt gene has been engineered into eucalypts in Australian laboratories. Thus, Bt should continue to have an important role in managing forest insect pests, both as insecticides and perhaps as Btengineered tree crops.

Index terms: Bt, biological control, Chrysophtharta bimaculata, Chrysomelidae

[1841] TEBUFENOZIDE: AN EFFECTIVE AND SELECTIVE CONTROL AGENT FOR CATERPILLAR PESTS IN FORESTRY

G. R. Carlson¹, S. Dodo² & J. A. Nakano³, ¹Rohm and Haas Research Laboratories, 727 Norristown Rd, Spring House, PA 19477-0904, USA, E-mail rsagrc@rohmhaas.com; ²Rohm and Haas Quimica Ltda Fazenda Experimental, Caixa Postal 66, Paulínia SP, Brazil, E-mail: shizuo_dodo@rohmhaas.com; ³Av. Prof. Mário Werneck, 2.027 apt 1002, Bairro Burits, Belo Horizonte MG, Brazil, E-mail: Jose-akira-nakano@rohmhaas.com.

Insecticides for use in forestry must be effective, target selective and environmentally benign. Tebufenozide possesses all three attributes. It has been used successfully to control many of the key lepidopterous pests of forests in North America (*Choristoneura fumiferana*, *Lymantria dispar*), South America (*Thyrinteina arnobia*, *Rhyacionia buoliana*) and Europe (*Lymantria monacha*, *Thaumetopea pytiocampa*). Most of the beneficial attributes of tebufenozide result directly from its novel "ecdysonoid" mode of action. This presentation will briefly describe the mode of action and general biological properties of tebufenozide, and will summarize results of some recent lab and/or field tests.

Index terms: tebufenozide, Thyrinteina arnobia, Rhyacionia buoliana

[1842] BIORATIONAL AGENTS – MECHANISM AND IMPORTANCE IN INTEGRATED PEST MANAGEMENT (IPM) AND INSECTICIDE RESISTANCE MANAGEMENT (IRM) PROGRAMS

L. Ishanya & A. R. Horowitz, Dept. of Entomology, Agricultural Research Organization, The Voicani Center, Bet Dagan 50250, Israel, Fax: +972-3-968 3835, E-mail: vpisha@netvision.net.il,

In recent years, insect control by broad-spectrum insecticides has come under assault and scrutiny because of their undesirable effects on human health and the environment. Furthermore the rapidly developing resistance to conventional insecticides provides the impetus to study new alternatives and more ecologically acceptable methods as part of IPM and IRM programs. One of these approaches is the development of novel compounds affecting developmental processes in insects, such as chitin synthesis inhibitors, juvenile hormone mimics, and ecdysone agonists. In addition extensive efforts have been made to develop compounds acting selectively on some groups of insects by inhibiting or enhancing biochemical sites such as respiration (diafenthiuron), the nicotinyl acetyl choline receptors (imidacloprid and acetamiprid), and salivary glands of sucking pests (pymetrozine). Among the most recent novel insecticides with selective properties are the novaluron, thiamethoxam and spinosad. Novaluron (Rimon) is a novel benzoylphenyl urea that acts by both ingestion and contact. As such it is a powerful suppressor of lepidopteran larvae such as Spodoptera littoralis and Helicoverpa armigera (by ingestion) and of whiteflics such as *Bemisia tabaci* and *Trialeurodes vaporatiorum* (by contact). Thiamethoxam (Actara) is a novel neonicotinoid acts specifically on aphids and whiteflies and spinosad (Tracer) acts on diversity of insect species and is considered an important agent for controlling the western flower thrips. The above compounds will be discussed in relation to their modes of action and their importance in IPM and IRM programs in various agricultural systems.

Key words: Selective insecticides, benzoylphenyl ureas, juvenile hormone mimics, ecdysone agonists, biocontrol agents.

[1843] GENETIC ENGINEERING OF GENES THAT CONFERS INSECT RESISTANCE TO TREES

L. Jouanin, Biologie cellulaire, INRA 78026 Versailles Cedex, FRANCE, Email: jouanin@versailles.inra.fr

Trees are the target of many different phytophogous insects. Genetic engineering offers new possibilities of introducing insect resistance into trees. Several strategies have been considered to obtain such plants using genes which have demonstrated previously their interests in annual crops. The introduced genes are mainly genes of bacterial origin such as the *Bacillus thuringiensis* delta-endotoxins or genes of plant origin such as proteinase inhibitors or lectins. Poplar is often used as a model tree to demonstrate the interest of the strategy but insecticidal genes have also been expressed in many other trees including conifers. A review of the obtained results and of the pespectives will be presented. Index terms : Transgenic trees, entomotoxic proteins, poplar, conifer. [1845] BIOLOGICAL CONTROL OF FOREST PESTS USING INSECT SPECIFIC VIRUSES

S. R. Palli^{1,2}, T. R. Ladd¹, Q. L. Feng¹, W. Tomkins¹, M. Primavera¹, S. S. Sohi¹, B. M. Arif¹ & A. Retnakaran¹, ¹Great Lakes Forestry Centre, Canadian Forest Service, P. O. Box 490, 1219 Queen Street East, Sault Ste. Marie, Ontario, Canada, P6A 5M7; ²Rohm and Haas Research Laboratories, 727 Norristown Rd. Spring House, PA 19477, USA. Email: RAHSUB@ROHMHAAS.com.

Insect specific viruses especially baculoviruses are being developed as environmentally friendly alternatives to chemical insecticides. Virus control of insect pests is attractive because it is lasting, highly selective and effective. However, to compete against chemical insecticides, they have to be fast acting and cheaper to produce. The advent of recombinant DNA technology has made it possible to make these viruses fast acting by inserting genes from different sources. We have engineered several genes such as *Choristoneura* hormone receptor 3 (CHR7, an ecdysone induced transcription factor), *Choristoneura* hormone receptor 75 (CHR75, an ecdysone induced transcription factor), *Choristoneura* hormone receptor 75 (CHR75, an ecdysone induced transcription factor), *Choristoneura* normone receptor 75 (CHR75, an ecdysone induced transcription factor), *Choristoneura* nulticapsid nucleopolyhedrovirus (CfMNPV). All the genes were expressed under the control of CfMNPV polyhedrin promoter. The recombinant viruses were plaque purified, amplified and used in bioassays to determine LD50, ST50 and FT50 values for 4th instar C. *fumiferana* larvae. All the recombinant virus expressing CHR3 in sense orientation is the best recombinant virus we have produced so far. All three, LD50, ST50 and FT50 values for this virus were significantly better than the values for the wild-type or egt'viruses.

Index terms: baculovirus, *Choristoneura fumiferana*, ecdysone, juvenile hormone esterase, AaiT

[1844] INSECT PATHOGENIC FUNGI AS RESOURCE OF GENES FOR INSECT PEST CONTROL

St. R. Leger

ABSTRACT NOT RECEIVED

[1846] MODEL ORGANISM GENETICS AND GENOMICS: TOOLS FOR TARGET DEVELOPMENT IN PEST CONTROL

<u>S. Thibault & J. Margolis</u>, Exclixis, Inc. 260 Littlefield Ave. South San Francisco, CA USA, E-mail thibault@exelixis.com;

The pharmaceutical and agricultural industries are moving increasingly toward target based screening as their primary discovery engine for novel bioactive small molecules. Screening, of course, requires new targets and confidence that altering the activity of these targets in vivo will have the desired outcome, be it curing a disease or controlling a crop pest. Exelixis utilizes the power of genetic, genomic, and informatic technologies to rapidly identify and validate novel targets by using modulation of gene activity as a surrogate for chemical inhibition or activation of protein function. Transposon technology is one of the foundations of Exelixis' technology platform, providing a rapid method to deliver transgenes and modify the genome of both laboratory models and pest species. The power of *Drosophila* and *C. elegans* genetics makes them a fascile system for insecticide target discovery. Ideal targets are essential for viability, selective and specific to pest species, dosage sensitive, and lead to rapid knockdown when disrupted. Genes that kill an organism when knocked out or overexpressed represent first-stage validated targets for pesticide development. Historically, P element screens have tagged approximately 10% of letter al loci in *Drosophila*. Efforts are ongoing at Exclisits to saturate the number of transposon-tagged genes in *Drosophila* using P. Screens underway with second generation transposons may uncover a complementary set of loci. Exelixis is also committed to develop representative non-drosophilid insects and plant pathogenic nematodes as additional model genetic systems. Increasingly reverse genetic tools such as EST projects, large insert genomic libraries and RNA-mediated gene interference are enabling genetic entry points in species that lack a history of classical genetic analysis. Development of biotechnology tools used in target discovery for Lepidoptera, Coleoptera, and nematodes will be discussed.

[1847] A NEW VIRAL PRODUCT "INF-LD" USED IN THE CONTROL OF POPULATIONS DENSITY OF LYMANTRIA DISPAR AND EUPROCTIS CHRYSORRHOEA

M. Ciuhrii¹, G. Mihalache², T. Manole¹, P. Cosconea¹, C. Ciornei³, I. Voicescu, M. Iamandei¹, ¹Research Institute for Plant Protection-Bucharest, Bd. Ion Ionescu de la Brad, 8, sect. 1, Bucharest; Romania; ²Research Institute for Forestry-Bucharest; ³Department of Plant Protection-Bacau: Department of Plant Protection-Pitesti, Romania.

On the Romanian territory, every year many surfaces with forests and orchards could be infested with Lymantria dispar and Euproctis chrysorrhoea which are both damaging of deciduous forests. We choose any specific parts of forest suitable for producing the infection of epizootics. Only the infected larvae were collected after peculiar symptoms of NPV. In the laboratory the larvae were selected once again and after that the viruses were isolated, purified and are conditioning as follows:

Formulation	powder
Colour	white-yellow
Humidity(U%)	5-6%
Biological activity	80-94% host mortality
Nucleocapsid concentration	72 x 1011
SPVC concentration(inclusions)	5.6 x 10 🗆
The polyvirions presence(q2; q3)	60%
The alien microflora concentration	2×10^{2}
PH	7.0- 7.2
Resistance to light	60 hours
Homogeneity(in water)	60 s
Adherence	85-90 %
The period of storage	5 years
The dosage at ha	20 g

The viral product is advisable for treatments at the egg stage before the larvae are hatching strongly connected with eggs density. When the laying eggs density were at 1,3-1,8 per tree the treatment was made with hand-made sprayers in the belts with 5-m width. The distance between belts was of 400 m. In the cases when laying eggs density was smaller the distance between belts are corresponding widest at 600-800 m. In 1999 on the Romania territory 22,000 ha were treated and the effects were good, the population of L. dispar weren't in increasing. In the same year the effect of "Inf-Ld" effectiveness appear in the treatments against E. chrysorrhoea.

Index terms: Lymantria dispar, Euproctis chrysorrhoea, viral product, biological control, NPV.

[1848] PRELIMINARY STUDIES ON THE APPLICATION OF STEINERNEMATID NEMATODES AGAINST OVERWINTERING LARVAE OF PINE PROCESSIONARY CATERPILLAR, THAUMETOPOEA PITYOCAMPA DEN. ET SCHIFF. (LEPIDOPTERA: THAUMETOPOEIDAE)

O. Triggiani & <u>E. Tarasco</u>, Di.Bi.C.AF.A. - Dipartimento di Biologia e Chimica Agro-Forestale ed Ambientale, Università di Bari, via Amendola 165/A 70126 Bari Italia Email: eustachio.tarasco@agr.uniba.it.

Pine processionary caterpillar *Thaumetopoea pityocampa* (Lepidoptera: Thaumetopoeidae) is a very dangerous lepidopterous spread in the mediterranean area. A preliminary survey was conducted with 4 different strains of Steinernematid entomopathogenic mematodes in the nests of pine processionary caterpillars in a *Pinus silvestris* reafforestation (Gravina in Puglia - 550 m a.s.l.) of Apulia Region (Southern Italy). Three different strains of *Steinernema feltiae* (2 indigenous, from Apulia Region pine woods, and 1 from Germany) and 1.8. *kraussei* strain from Northern Italy were used; 300.000 Infective Juveniles (JJs) in a gel suspension were injected in the nests on January and February. The percentage of larval mortality was evaluated at 10 day intervals during 2 months. The results of this preliminary experiment pointed out:

- the ability of Steinernematid nematodes to control the processionary caterpillars;

- the persistence in the nests of IJs for more than 20 days from treatment;

the possibility of nematodes to complete their life cycle in the larvae of T. pityocampa;
no negative effects were observed on Prhyse caudata (Diptera: Tachinidae), the most important natural antagonist of T. pityocampa larvae.

Index terms: Steinernema, entomopathogenic nematodes, microbial control

[1849] OCCURRENCE OF HYMENOPTERA PARASITOIDS IN LARVAE OF PHORACANTHA SEMIPUNCTATA (COLEOPTERA: CERAMBYCIDAE)

G. T. Ribeiro & J. C. Zanuncio, Dept^a. de Biologia Animal, Univ. Fed. Viçosa, 36571-000, Viçosa, MG, Brasil, E-mail zanuncio@mail.ufv.br.

The importance of wood boring insects specially those of the Coeloptera order has been increasing in Brazil because wood from reforested areas in this country are been used for many products besides sawlog for export. Species of Cerambycidae are very important because most of them are wood borrers of tree species. *Phoracantha semipunctata* (Colcoptera: Cerambycidae) is one of the most important species of this group in the world because it damages Eucalyptus. This pest was recorded in the States of Rio Grande do Sul in Eucalyptus grandis, especially in recently cut and wood stored at small sawmills; in São Paulo in Eucalyptus citriodora; in Espírito Santo in a hybrid of Eucalyptus urophylla and E. grandis; in Bahia in Eucalyptus pellita, Eucalyptus cloeziana, Eucalyptus camaldulensis, E. urophylla and in a hybrid of E urophylla and E. grandis; in Minas Gerais in the area of Savannah in Eucalyptus spp. Tunneling in the subcortical region where its larvae feed during its development represents the damage by this insect. During the last instar larvae of this pest drill into the log where it prepares a pupal chamber. P. semipunctata can attack standing logs with bark in the field and also stored at the mill. Attacks by this pest represent an important problem because perforations in Eucalyptus wood make them unfeasible for export. Damage by this pest include the death of plants and wood depreciation. The incidence of P. semipunctata was registered in areas of E. urophylla in the northeast of Bahia where a high number of Eucalyptus trees were attacked after a fire. Many empty pupae of parasitoids were observed in larvae of P. semipuncinia. Alive pupae of this parasitoid were observed in alive pupae of this pest. These pupae were maintained in laboratory for emergence of the parasitoids which were sent to specialists for identification. They were identified as Liobracon sp. and Leluthia cf. Monitoring of wood piles in the Northeast of Bahia showed that about 50.0% of the pupae of P. semipunctata were killed by parasitoids, probably of the genus Leluthia. Another search in Eucalyptus logs after five months of cutting showed that approximately 45.5% of pupae of P. semipuctata were dead with the presence of empty cocoons of parasitoids, which was probably also of the genus Leluthia.

Key words: Phoracantha; parasitoids; biological control.

[1850] INFLUENCE OF NATURAL ENEMIES ON THE POPULATIONS OF TWO STOLAINI SPECIES (COLEOPTERA: CHRYSOMELIDAE: CASSIDINAE) IN A BRAZILIAN TROPICAL FOREST

<u>F.N. Sá</u>l & J. Vasconcellos-Neto^t, ¹ Universidade Estadual de Campinas - Inst. Biologia -Depto. Zoologia. Campinas, SP, Brasil, 13083-970. E-mail: fnsa@obelix.unicamp.br.

Natural enemies of Chrysomelidae are represented by organisms of many different taxa that can cause heavy impact on them. In this work, we followed populations of *Stolus* chalybea and S. areolata for two years, looking for natural enemies and investigating their influence on mortality of those Cassidinae populations. For the three studied species, we observed highest mortality rates during egg phase (87.5%, 66.98% and 65.65% for S. areolata, S. chalybea and A. phaeopoda respectively) provided by hymenopteran parasitoids, predation and infection by fungi. We obtained eight parasitoid species accounting for S. chalybea eggs (with total parasitism rate of 51.93%) and two accounting for S. areolata (with total parasitism rate of 28.57%). Larvae were harmed by predators like spiders and Pentatomidae hemiterans and by two Tachinidae species parasitizing them. Tachinidae parasitism rates was of 46.15% for S. areolata and 19.39% for S. chalybea. Larvae in earlier stages showed highier mortality than more mature larvae of the same species. We obtained the parasite nematode Hexamermis sp. (Memithidae) in adults of S. chalybea and we also observed some acari on their elytrum, but we could not be sure if they were acting as parasites or comensals. Adults of this Cassidinae species were also sometimes observed attached to spider webs. A one-year census on Bidens segetum and Mikania cordifolia, host plants of Stolas chalybea and S. areolata respectively, revealed, by significant positve correlations, that the abundance and richness of potential predators was synchronous with the abundance of the eggs and larvae of the beetles, sometimes showing a lag period in response. Ants, spiders and heteropterans were the most frequent predators found on host plants. We believe that this result may suggest the influence of the populations of invertebrate predators which forage on Cassidinae host plants their populations.

[1851] OVERVIEW OF MECHANISMS OF RESISTANCE IN TREES TO INSECTS

S. Larsson, Dept. of Entomology, Swedish University of Agricultural Sciences, Box 7044, SE-750 07 Uppsala, Sweden, E-mail Stig.Larsson@entom.slu.se

Plant resistance to insects has been defined as the "relative amount of heritable qualities possessed by the plant which influence the ultimate degree of damage done by the insect" (Painter 1951). Although other definitions of resistance are favored by some researchers, this plant-centered definition is most often cited in the literature and will be used in my talk. Painter's definition focuses on plant damage. A resistant plant can be less damaged than another, more susceptible, plant by 1) being less attractive to insects, 2) causing higher insect mortality, or 3) being more tolerant to the same amount of damage. Most often, published data on tree resistance to forest insects refer to the second category. In cases where tree resistance is thought to contribute to insect population dynamics it is highly relevant to investigate intraspecific variation in insect performance, such as mortality. It is important, however, to recognize that such data refer to responses at the level of the individual. Whether populations also respond depends on the strength of the effect, in relation to other population processes. It is also important to recognize that performance data may say more about a specific tree/insect interaction than about the tree's resistance in general. Insects from different feeding guilds often perform differently on dissimilar tree phenotypes because members of different guilds respond to different key traits in the plant (nutrients, secondary metabolites, physical characteristics, phenology). In my talk I will discuss the complexity of the resistance concept. I will emphasize the importance of clarifying whether the context in which resistance is used is tree- or insectoriented.

Index terms: Individual performance, population dynamics, feeding guild

[1852] MECHANISMS OF RESISTANCE IN TREES TO DEFOLIATORS

K. M. Clancy, USDA Forest Service Research, Rocky Mountain Research Station, 2500 S. Pine Knoll Dr., Flagstaff, AZ 86001-6381 USA E-mail: kclancy@fs.fed.us.

I will discuss 10 mechanisms known to be important in resistance of trees to insect defoliators, with appropriate examples from the literature and my own work with the western spruce budworm (*Choristoneura occidentalis*) and Douglas-fir (*Psuedotsuga menziesii*). The mechanisms I will emphasize are: 1) Phenological asynchrony between host trees and insect herbivores; 2) Host tree tolerance of defoliation, and the role of host tree vigor; 3) Host tree compensatory photosynthesis and growth in response to defoliation; 4) Toughness of leaves and needles; 5) Low nutritive quality of foliage; 6) Defensive compounds (or allelochemicals) in foliage; 7) Three-trophic-level interactions among the trees, their insect herbivores, and natural enemies of the herbivores (i.e., predators, parasites, pathogens); 8) Host tree microbial mutualists such as mycorrhizae and fungal endophytes; 9) Induced defenses in host trees; and 10) Induced susceptibility in host trees.

Index terms: phenology, tolerance, compensation, foliar chemistry, mutualists

[1853] MECHANISMS OF RESISTANCE IN TREES TO SHOOT INSECTS

R. L Alfaro¹, E. S. Tomlin², R. McIntosh³, J. Borden⁴ & J. King⁵, ¹Research Scientist, Pacific Forestry Centre, Victoria, BC. Canada; ²Research Scientist, Biology Dept., University of North Carolina, Greens borough, N.C., USA; ³Insect and Disease Specialist, Saskatchewan Environment; Prince Albert, Saskatchewan. Canada; ⁴Dept. Biological Sciences, Simon Fraser University. Burnaby, BC. Canada; ⁵Geneticist, BC Ministry of Forests, Victoria, BC. Canada.

This paper provides a summary of the resistance mechanisms to shoot insects that we have uncovered either by examination of the literature or by detailed work on the white pine weevil, *Pissodes strobi*, a shoot insect affecting spruce and pine in North America. The review indicates that conifers rely on a combination of defense mechanisms to fend off herbivores which feed on their shoots. These range from defense strategies in which the host provides improper nutrition to the attacker, for example by being in the wrong phenology state at the time of feeding, to constitutive defenses, such as resin canals and sclereids, to inducible defenses, which are activated in response to the attack. The latter include the manufacture and mobilization of defensive chemicals to the site of wounding, and the production of traumatic resin in conifers in response to insect and fungal attack...

[1854] MECHANISMS OF RESISTANCE TO WOOD BORERS

T. D. Paine, Dept. of Entomology, Univ. of California, Riverside, CA, USA 92521

Wood boring insects can include a wide taxonomic range including the Coleoptera, Lepidoptera, and Hymenoptera. In many groups, the larval stages feed in the inner bark and outer layers of xylem tissues of their host plants, and pupation may occur in cells constructed within the wood. The adult insects are entirely free-living. However, there are several groups of wood-boring beetles in which the adults excavate oviposition galleries in the wood of the host. As a broad generalization, many of the wood-borers colonize weakened, stressed, dead, or dying host plants. The insects are frequently part of a guild of secondarily invading scavengers of host material weakened by environmental factors, disease, or other insect activity. The resistance mechanisms (induced and preformed defenses that are under some living control) thought to be important against phloem feeders and other primary colonizers may become critical factors if the woodborers colonize relatively healthy trees. However, the resistance mechanisms against phloem feeders not critical factors if the insects are colonizing dead and dying trees. The physical factors that are associated with the bark or wood (e.g., lignin or moisture) can remain and may affect the survival of wood-borer larvae. In Australia, Eucalyptus resistance to infection and invasion has been associated with induced production of a phenolic resin. However, there may be differences in tree colonization patterns of woodborers in Australia compared to exotic environments in North America, South America, Africa, and in the Mediterranean basin where colonization of water stressed trees appears In California, Eucalyptus resistance to Phoracantha to be critical. semipunctata colonization appears to be independent of the induced response, but rather is a function of a physical factor. If the water content of the outer bark is greater than 55%, then the larvae are virtually incapable of penetrating that barrier. Induced reactions are present, but appear not to be a key factor because of the temporal lag in response. Index terms: Host resistance, Eucalyptus, Phoracantha semipunctata,

[1855] MECHANISMS OF RESISTANCE IN TREES TO BARK BEETLES

<u>F. Lieutier</u>, Laboratoire de Biologie des Ligneux. Univ. d'Orléans. B.P. 6759. F-45067 ORLEANS CEDEX 2. France. E-mail : francois.lieutier@univ-orleans.fr.

As in most phytophagous insects, the living host plays an essential role in the population dynamics of bark beetles. It is not surprising, in these conditions, that taking the host effect into consideration in the development of bark beetle research has lead, since the beginning of the 70ies, to a considerable amount of knowledge in bark beetle biology. Two basic resistance mechanisms have been recognized in conifers of which the relative importance depends essentially on the beetle behavior. The classical model of tree-bark beetle relationships is based on the involvement of a third partner, a moderately phytopathogenic fungus, which needs to be mass inoculated (that is above a certain threshold of density) to the tree by the beetles to weaken host resistance and kill the tree. Based on this model, different beetle strategies have been proposed to explain the between species variations in these relations and the beetle behaviors. The physical, histological and chemical phenomena involved have been intensively studied. A presentation of these results is given. However, when trying to understand the mechanisms in details, it appears that numerous aspects of conifer resistance to bark beetles are still unknown. The exact role of the associated fungi in beetle population establishment and in tree death is unclear, although it is the basis of the classical model. The role of the beetle itself is also not really understood and may have been under-estimated. How the tree defense reaction works when the threshold level of attack density is going to be reached and how this threshold is overcome have almost never been investigated. Tree resistance to beetle-fungus attacks has been mainly studied in the phloem although the beetle both at the phloem and the sapwood levels often inoculates the fungus. Sapwood resistance may have an essential role in containing fungus development and consequently in beetle establishment How environmental factors interfere in the beetle-fungus-tree relationships is a very complex and difficult topic which has been approached, except in few cases, only relatively recently. The effects of the resistance mechanisms on the aggressors are still poorly understood. The reasons for these lacks are analysed and suggestions for research development are presented. Although various tracks are suggested, they all correspond to a re-focusing of the approaches on the insect aspects and on experimental situations close to the threshold of attack density. Finally, the topics the most susceptible to give practical applications in the field of tree resistance and in the present context are presented Index terms : Conifer, review, research prospect

[1856] MECHANISMS OF RESISTANCE IN TREES TO GALL-FORMING INSECTS

G. Wilson Fernandes, ML Faria, TG Cornelissen, MM Espirito Santo, D Negreiros, FMC Castro. ¹Ecologia Evolutiva de Herbívoros Tropicais, DBG/Universidade Federal de Minas Gerais, CP 486, 30161-970 Belo Horizonte, MG Brazil, Email gwilson@icb.ufmg.br

Plants posses a wide spectrum of traits that generally affects the colonization and success of gall-forming herbivores. These include plant secondary chemistry and physical barriers, behavior (e.g., phenology), and genetics. We have studied the relationships between two species of wild congeneric dioecious shrubs of the genus *Baccharis* which are highly species-rich on gall-forming insects in southeastern Brazil. Approximately 40 new species of galling insects are known to attack these two host plant species in the area. We report on a two year field experiment in which 160 plants (80 males and 80 females) were equally divided into four treatments to evaluate the influence of plant quality on galling abundance, richness, and performance. The treatments were plant fertilization (NPK), irrigation, irrigation and fertilization, stress, and control. Plant Sex had no effect on the gall community. Irrigation and fertilization were found to negatively influence all the parameters evaluated, while stress had a negative effect on them. Galls were mostly common on control plants. Plant module senescence also negatively influence gall success, a parameter not generally studied in galling insect studies. Furthermore, plant diminishing galling success. [1857] THE BIOCHEMICAL MECHANISM FOR THE RESISTANCE OF RED MAPLE TREES TO FOREST TENT CATERPILLAR FEEDING

<u>B. V. Helson¹</u>, M. M. Abou-Zaid¹, J.T. Arnason² & C. Nozzolillo², ¹Canadian Forest Service, Natural Resources Canada, P. O. Box 490, Sault Ste Marie, ON P6A 5M7, CANADA, E-mail bhelson@nrcan.gc.ca; ²Ottawa-Carleton Institute of Biology, University of Ottawa, Ottawa, ON K1N 6N5, CANADA.

We have demonstrated experimentally that forest tent caterpillar (FTC) larvae do not feed on red maple leaves but will feed readily on sugar maple leaves. An ethanolic extract of red maple leaves applied to aspen leaf disks also deterred the feeding of larvae which suggested that the mechanism is biochemical in nature. Fractions of the red maple extract containing the highest concentrations of phenolic compounds were most deterrent. The red maple extract and phenolic fractions were consistently more deterrent than the comparable extract and fractions of sugar maple. These results suggested that phenolic compounds present in red maple could be involved in the resistance of red maple to feeding by FTC larvae. The major phenolic compounds in red maple and sugar maple were isolated and identified. Six of the the compounds present in red maple leaves were available and obtained commercially. When these compounds were assayed in choice leaf-disk tests at 283 µg/cm², methyl gallate and gallic acid significantly deterred the feeding of FTC larvae while the other 4 compounds which were flavonol glycosides did not. These findings indicated that only certain phenolic compounds in red maple are involved in the mechanism for resistance. In order to determine which specific compounds could be responsible, 10 more phenolic compounds from red maple leaves were extracted and purified in large enough quantities to test their antifeedant effects on forest tent caterpillar larvae. Five more gallate compounds including ethyl m-digallate, ethyl gallate, 1-galloylrhamnose, 1-galloyl-glucose and m-digallate also exhibited significant antifeedant activity. Gallates may be responsible for protecting red maple from feeding by FTC. Ethyl digallate in particular could be a major factor because it is the most common gallate compound in red maple leaves. It has not been detected in sugar maple which FTC larvae cat readily. Furthermore, ethyl digallate is also abundant in silver maple leaves which are also not eaten by FTC larvae.

Index terms: Malacosoma disstria, antifeedant, ethyl m-digallate, phenolics, gallates, sugar maple

[1858] OVERVIEW OF TREE RESISTANCE DEPLOYMENT APPROACHES

D. J. Robison, Department of Forestry, North Carolina State University, 3118 Jordan Hall, Box 8008, Raleigh, NC 27695-8008 USA, E-mail: dan_robison@ncsu.edu

The intensification of forest plantation systems is tightly coupled with tree genetic improvement and the deployment of increasingly limited genetic diversity. This presents substantial challenges with respect to pest management in these systems. In natural forests and traditional low-intensity plantations there are large amounts of genetic diversity among individual trees, whereas in more intensive systems the buffering or resiliency of the trees against pest depravations can be compromised. This buffering is due to large ranges in the variation and apparency of phenotypic host plant resistance characters, and their ability to limit pest population expansion and restrict pest biotype evolution. In intensive systems relatively few genetic families or specifics clones are deployed. These, by design, exhibit limited phenotypic variation and are cultured with weed management and fertilization. Together these can create perennial systems that are prone to large damaging pest populations. Simultaneously, the intensity of management and use of genetically improved planting stock represents an investment that must be secured and is likely to have a lower economic injury threshold than more traditional forest systems. Deploying these systems over large areas in an ecologically simplistic manner will lead to instability. What is required for ecological and production stability/sustainability is ecological complexity imposed through the careful screening and deployment of genotypes. Perennial clonal systems in nature contain a diversity of genotypes and can be very stable and productive over very long periods of time. Such systems can provide clues for forestry deployment, as does genetic interaction modeling between crops and pests. Selecting specific genotypes for temporal and spatial deployment on the basis of productivity and pest management is a new management tool in forestry that requires substantial development. The current level of understanding and theoretical basis for this development is discussed in this paper.

Index terms: clonal forestry, host plant resistance, planting designs, landscape diversity

[1859] DEPLOYMENT OF TREE RESISTANCE TO INSECTS IN SHORT-ROTATION BIOMASS PLANTATIONS

J. D. McMillin¹, D. R. Coyle², R. B. Hall³ & E. R. Hart^{3,4}, ¹USDA Forest Service, Forest Health Management, Rapid City, SD 57702, USA, E-mail jmcmilli/r2_blackhills@fs.fed.us; ²USDA Forest Service, SRI, New Ellenton, SC 29072, USA; ³Dept. of Forestry, Iowa State Univ., Ames, IA 50011, USA; ⁴Dept. of Entomology, Iowa State Univ., Ames, IA 50011, USA.

Insect herbivores have potential to cause economic impact on short rotation biomass plantations. Host plant resistance is a fundamental component of integrated pest management (IPM) to control insect herbivores in short rotation woody crop production. Operational biomass plantations currently are using a limited number of clones that probably exhibit modest host plant resistance to insects and may be promoting insect adaptation to resistance. Further complicating the development of deployment strategies for host plant resistance is the fact that different insect species prefer different clones; a seemingly resistant clone to one insect is susceptible to a complex of other insects. However, based on a review of the literature, examples of host plant resistance to forest insects include antibiosis, antixenosis, and tolerance. Approaches to incorporating host plant resistance into short rotation woody crop systems include tree breeding, genetic engineering, clonal deployment, and IPM development. Iowa State University and other researchers have investigated chemical and physical attributes that may affect the susceptibility of some select Populus clones and potential resistant traits of other clones. Recent evidence suggests that the ratio of long-chain fatty alcohols and a quinone compound in hybrid Populus influences Chrysomela scripta adult and larval feeding preference and performance. There have been several recent attempts to use genetic engineering to insert resistance genes, including Bacillus thuringiensis and protease inhibitor genes, into Populus clones. However, environmental and societal concerns may affect the operational status of these genetically engineered clones. Deployment strategies of host plant resistance include creating monoclonal stands, mosaics of monoclonal blocks that contain varying resistance traits, mosaics of clonal rows, and single tree and small groups of trees. Each of these planting strategies has benefits and costs in terms of maximizing plantation efficiency and minimizing pest damage. Future strategies using IPM for the control of insect pests of short rotation Populus systems will include a combination of host plant resistance, genetic engineering, biorational sprays, planting design strategies, and biological control. The use of all these strategies will help to maintain and conserve host plant resistance and genetically improved clones for longer-term use. Research needed to reach this integrated approach includes further identification of host plant resistance, large-scale testing of different deployment schemes, and further examination of the impact that natural enemies have on Populus insect pests. Index terms: Chrysomela scripta, clonal forestry, host plant resistance, Populus

[1860] HORTICULTURAL STRATEGIES FOR DEPLOYMENT OF TREE RESISTANCE TO INSECTS

D. A. Herms. Dept. Eutomology, The Ohio State Univ., Ohio Agric. Res. Dev. Cen., 1680 Madison Ave., Wooster, OH 44691 USA, email: herms.2@osu.edu.

Historically, insect resistance has received little consideration in the selection, use, and management of trees in urban forests and ornamental landscapes. Deployment of pest resistant has been constrained by a lack of long-term research. Furthermore, few studies have addressed the role of cultural practices in IPM programs. Plant defense theory offers potential in both arenas. Biogeography theory predicts that patterns of resistance will correspond with historical selection pressures exerted by key pests. For example, we found that native North American birches are highly resistant to bronze birch borer, with which they share an evolutionary history. Conversely, the exotic species that are planted almost exclusively are highly susceptible: Fertilization is frequently touted as an important component of IPM programs for ornamental plants. However, theory predicts that fertilization will decrease the resistance to trees growing on highly disturbed, infertile soils characteristic of many urban sites. Experimental data from our work and the literature is consistent with these predictions, and will be reviewed.

Index terms: plant defense theory, growth-differentiation balance, cultural management, IPM

[1861] RESISTANCE OF YOUNG AND MATURE BALSAM FIR TREES TO SPRUCE BUDWORM AS AFFECTED BY STAND THINNING : SHORT AND LONG TERM EFFECTS

É. Bauce, M. Charest & R. Bérubé, Département des Sciences du Bois et de la Forêt, Faculté de Foresterie et de Géomatique, Université Laval, Ste-Foy, Québec, G1K 7P4 CANADA, E-mail eric.bauce@sbf.ulaval.ca.

The impact of stand thinning on the resistance of young and mature balsam fir, Abies balsamea, trees to spruce budworm, Choristoneura fumiferana, the most important insect pest of the North American boreal forest, has been monitored and estimated for 8 years. Both field and laboratory experiments were conducted to reveal the ecophysiological processes involved at host tree and insect levels after the sylvicultural intervention. The density of young stands was reduced from 15000 stems/ha to 2500 stems/ha while the density of mature stand was reduced by removing 25% of the stand basal area. Both young and mature thinned stands suffered heavier defoliation by the insect one year after the treatment. In young stand the increased defoliation (24%) was related to high insect survival due to a reduction in foliar polyphenolics. In mature stands increase in defoliation (+45%) was related to high insect food consumption rate due to a reduction in foliar monoterpenes. These results were supported by laboratory rearing experiments. Because trees were more defoliated and did not produced much foliage one year after stand thinning, the amount of residual foliage after insect defoliation, an index of host tree resistance, was 75% and 38% lower in mature and young thinned stand respectively compared with control stands. These results indicate that stand thinning should be avoided during spruce budworm outbreaks. However, such negative impacts of stand thinning diminished gradually over time. In fact, two years after the treatments there was an increase in foliage production that exceeded the increase in defoliation in thinned stands. Moreover, five years after the thinning treatment, mature trees had 6 times more residual foliage after insect defoliation than control trees, Even after eight years, mature trees in thinned stand had 48% more residual foliage than control trees, indicating that thinning had a lasting effect in reducing host vulnerability to further attacks by the insect. Similarly, three years after the thinning treatment, young trees had 6 times more residual foliage than control trees. Even after five years, they maintained 104% more residual foliage than control trees. Our results suggest that stand thinning could be an efficient tool to reduce balsam fir tree vulnerability to spruce budworm as long as thinning is conducted few year prior to budworm outbreak so that treated trees can pass through their short period of high vulnerability before budworm's attack.

Index terms : Choristoneura fumiferana, vulnerability, polyphenolics, terpenes

[1862] POSSIBILITIES TO UTILIZE TREE RESISTANCE TO INSECTS IN FOREST PEST MANAGEMENT IN CENTRAL AND WESTERN EUROPE

C.M.Heidger (1) and F.Lieutier (2), (1) Hochschule Zittau/Goerlitz (FH) Univ.of applied Sciences, Dept.of Ecology and Environmental Protection, P.O.Box 261, D-02755 Zittau, Germany. (2) Univ. Orléans, Laboratoire de Biologie des Ligneux, B.P. 6759, F.-45067 Orléans Cedex, France.

The most relevant forest trees in Central and Western Europe are Norway spruce (Picea abies), Scots pine (Pinus sylvestris), maritime pine (Pinus pinaster), beech (Fagus sylvatica) and oak (Quercus petraeae, Q. robur). They are attacked by several pests among which the most agressive belong to the bark beetles, weevils and Lepidoptera and, to a lesser extend, aphids and scale insects. Trees have developed resistance mechanisms against all of these insects and the existence of more or less long periods without damage proves, that these natural mechanisms are efficient most of the time. In Central an Western Europe several investigations in this field have been undertaken for the above insects, revealing different kinds of mechanisms, which range from avoiding the pest to the induced systemic defence. These mechanisms depend on the damage location in the host and the feeding behaviour of the pest (defoliator, sap-sucking, phloem feeders,...). However, very few attempts have been made for a practical use of these mechanisms in forest pest management. Two main possibilities can be considered: tree breeding for genetic resistance by taking into account resistance criteria in genetic improvement programs, or enhancement of the defence mechanisms and resistance level of the trees by silvicultural practices. The paper presents all these aspects through examples of research on Central and Western European forest pests, while insisting on the possibilities open to utilize natural resistance in forest pest management for each of them. Index terms: resistance breeding, genetic selection, silvicultural methods.

[1863] DEPLOYMENT OF TREE RESISTANCE TO PESTS IN ASIA

N. Kamata, Lab. of Ecology, Fac. of Sciences, Kanazawa Univ., Kakuma, Kanazawa, Ishikawa 920-1192, Japan, E-mail: kamatan@kenroku.kanazawa-u.ac.jp

In NE Asia, many trials to deploy tree resistance to pests have been done. In China, selection had been the main method of tree breeding until the early 1980s. Later, breeding by crossing became popular for trees belonging to the genus Pinus, Salix, and Larix. In China, the influence of Lysenkoism prevented the progress of tree breeding by 1960s. The main purpose of tree breeding in China has been to breed fast growing trees to recover vegetation. Because such fast growing trees tend to be infested by pests, many plantations of popular and willows are susceptible to insect attack. Amongst them the Asian longhorn beetle, Anoplophora glabripennis, is the most serious pest, which sometimes kills trees. Projects to breed beetle-resistant tress have started. In S Korea, a forest rehabilitation program started after the Korean War. Many native pine trees have been planted but damaged badly by the pine needle gall midge, *Theodiplosis japonicus*. Recently, the salicylic acid concentration in the pine needle has been proved to be the important determinant of resistance against T. japonicus: Needles of susceptible species had a low concentration of salicylic acid under the phenolic compound-free conditions while needles of resistant species against this insect contained a higher concentration of salicylic acid. The Korean Forest Research Institute first tried to select the resistant strain but failed. Effective production of insect-resistant pines can be obtained through hybrids by crossing between susceptible and resistant species by increasing internal salicylic acid contents of the needles. In Japan, selection for larch and poplar resistant against hares and voles has been successful. Selection for Cryptomeria japonica resistant against Sugi bark borer, Senanotus japonicus, and against Cryptomeria bark midge, Reeseliella odai, has been carried out. The pine wilt disease caused by pine wood nematode, Bursaphelenchus xylophilus, is the most harmful pest in the NE Asian countries. There is a relationship between species-level susceptibility and phylogenic classification: pine species belonging to the subsection Australes are the most resistant, followed by the subsection Contortae. Pines belonging to the subsections Ponderosae and Oocarpae are susceptible. The subsection Sylvestres contains both resistant and susceptible species. After inoculation of PWN, the nematodes increased in number and spread rapidly in the susceptible pine trees, but not in the resistant trees. Responses of resistant pine species, wound periderm formation and occlusion of cortical resin canal, trapped the nematode within damaged tissue. The insensitivity of xylem parenchyma to the PWN also acts as a defensive factor of resistant pine species. In Japan, the national project to select resistant pine trees started in 1978, which was successful for P. densiflora. However, because P. thunbergii, which is an important species to protect seashore, is much more susceptible to PWN than P. densiflora and proved to be difficult to select resistant trees, the international hybridization project of P. thumbergii x P. massoniana was started in 1983 by introducing 20 liters/year of P. massoniana pollen from China.

[1864] USING RESISTANCE IN TROPICAL PLANTATIONS

<u>J.R. Cobbinah¹</u> & M.R. Wagner², ¹Forestry Research Institute of Ghana, UST Box 63, Kumasi, Ghana. ²School of Forestry, Northern Arizona University, P. O. Box 15018, Flagstaff, AZ 86011-5018, U.S.A.

The major factor limiting the establishment of indigenous species plantations in subsaharan Africa is insect pests. Earlier efforts at establishing commercial plantations of valuable timber species such as Iroko, Obeche, Mansonia, Mahoganies, Emire, Aucounnea have all been hampered by insect pests that in many cases had not been previously encountered in the natural forest. Even small trial plots and nursery blocks of these species have not been spared. Whiles chemical control has shown promise in the control of major pests of Mansonia, Emire, Afrormosia and Obeche, this strategy has proved ineffective against pests limiting the establishment of Iroko, Mahoganies and Ceiba. However, from both economic and environmental stand points chemical control appears not to be a feasible option in commercial plantation in this region. While the humid tropical forest is highly diverse and contains wide array of organisms at different tropic levels including potential natural enemies of the major insect pests, very low natural enemy fauna have been encountered in the commercial monocultural plantations. Results of recent studies on Iroko and Mahoganies however, indicate that there is considerable variability in susceptibility within and among provenances and progenies of forest tree species to pests and that tree resistance would be the centrepiece of IPM for major pests of forest plantations in Africa in the future. In Iroko as much as 12-fold differences in attack rates have been recorded on resistant and susceptible individuals. Selection of lines with reduced susceptibilities or high recuperative ability followed by clonal multiplication of these individuals have resulted in genetic gain of about 35%. Present findings suggest that success in plantation establishment would depend largely on the deployment of genetic resistance in IPM programmes.

[1865] INHERITANCE PATTERN OF RESISTANCE TRAITS IN HYBRID WILLOWS: EFFECTS ON HERBIVORES AND PATHOGENS

I. Hiältén, Department of Animal Ecology, Swedish University of Agricultural Sciences, S-901 83 Umeå, Sweden. E-mail joakim.hjalten@szooek.slu.se.

It is generally accepted that hybridization has been important for plant evolution. However, in recent years there has also been and increased interest for the role of hybridization in plant-animal interaction. Herbivore response to hybrid plants depends on both inheritance patterns of resistance traits and the response of specific herbivores to these characters. For insect herbivore plant phenolics plays and important role for food plant selection, acting both as attractants for specialist herbivores and as repellents for generalists. The aim with this study was to determine the inheritance pattern of plant phenolics in hybrid willows and the response of specific herbivores (galling sawflies) and parasitic fungi Melampsora sp. to these changes. To control the plant material used and minimize the influence of environmental variation F1 hybrids and parental species were produced by hand-pollination of willows in the field. In addition, the plants were potted and kept in an experimental field under controlled conditions. Three willow species were used, Salix caprea were crossed with both S. repens and S. phylicifolia. These species hybridize naturally. The inheritance patterns of plant phenolics can best be described as additive, that is hybrid plants had intermediate concentrations of phenolics compared to the parental species. However, the response of herbivores and Melampsora rust did not follow the same pattern. The densities of galling sawflies on hybrid plants were generally similar to the densities on the most susceptible parent. By contrast, hybridization resulted in a breakdown in the resistant of F1 hybrids to Melampsora rust. However, a reconstitution of resistance occurred in backcrosses, suggesting an additive inheritance of resistance traits. Potential mechanism for the response of herbivores and Melampsora rust to hybrid plant is discussed.

Index terms: Willows, hybrids, resistance, galling sawflies, melampsora rust

[1866] ENVIRONMENTAL EFFECTS ON RESISTANCE OF YOUNG SPRUCE TO INSECTS AND FUNGI

D. Wainhouse, Entomology Dept. Forest Research, Alice Holt Lodge, Wrecclesham, Farnham, Surrey, GU10 4LH, UK. E-mail d.wainhouse@forestry.gov.uk.

When the supply of mineral nutrients is limiting, application of fertilizer usually increases tree growth. This 'carbon-demanding' response to fertilisation can reduce resources allocated to carbon-based defences as predicted by resource-availability models of plant defence. Such effects on the expression of quantitative defences have been commonly observed in trees although their influence on herbivores has been less commonly measured. Experiments are briefly described in which young plants of Sitka spruce were grown under two light and nitrogen regimes to determine effects on growth, quantitative defences (resin and polyphenols) and nutritional status (sugars and nitrogen) of both above and below ground parts of the tree. Concentrations of resin, polyphenols and carbohydrates were higher in low nitrogen treatments as predicted by resource- availability models of defence and the changes were similar in all parts of the trees including tissues formed prior to experimental treatments. However, these changes did not appear to be the result of a direct trade-off with growth but reflected treatment-induced variation in the root/shoot ratio. Production of quantitative secondary chemicals may, therefore, be part of an integrated response of the trees to environmental stress. Bioassays with Elatobium abietinum, Gilpinia hercyniae and the facultatively pathogenic fungus Phacidium coniferarum however, showed changes in the concentration of carbon-based secondary chemicals alone were of only limited value in predicting susceptibility of spruce to insect and fungal attack.

[1867] ECOLOGY AND MANAGEMENT OF DEFOLIATING PESTS OF CONIFERS IN NORTHERN BRITAIN

<u>A. D. Watt</u>¹, B. J. Hicks¹, H. F. Evans² & S. E. Hartley¹, ¹Centre for Ecology and Hydrology, Banchory Research Station, Hill of Brathens, Glassel, Banchory AB31 4BY, Scotland, United Kingdom E-mail adw@cch.ac.uk; ²Forest Research, Alice Holt Lodge, Wrecclesham, Farnham, Surrey GU10 4LH, United Kingdom.

The main forest trees in the UK are North American conifers, Sitka spruce and lodgepole pine. Both tree species have been attacked by a range of native insects and outbreaks of one of these, pine beauty moth (*Panolis flammea*), has occurred regularly on lodgepole pine since 1977, while remaining an innocuous insect on Scots pine. Over approximately the same period, another insect pest, the winter moth (*Operophtera brumata*), has emerged as a pest of Sitka spruce and heather. This paper will summarise recent research carried out on these insect pests, particularly recent work on the impact of fungal pathogens on pine beauty moth and the evolution of host-specific races in both species. Index terms: pine beauty moth, winter moth, fungal pathogens, host-specific races. [1869] NEW BACILLUS THURINGIENSIS PRODUCTS AND THE FUTURE OF BACILLUS THURINGIENSIS PRODUCTS IN THE NEW MILLENNIUM

R. A. Fusco, Valent BioSciences Corporation, HC 63, Box 56, Mifflintown, PA 17059, USA, E-mail: robert.fusco@valent.com.

During the past 30 years, much technological advancement has been made in the development of microbial pesticides for use in forest insect control programs. Advances in fermentation technology, formulations, and application technology have been significant and have made *Bacillus thuringiensis subsp. Kurstaki* the preferred pesticide for controlling North American lepidopteran forest pest insects. These advancements include the fermentation of higher potency Btk formulations, increased formulation stability (both physical and biological), enhanced persistence of Btk preparations on target foliage, enhancement of activity in Btk preparations to specific pests, transconjugants, and genetic engineering technologies including bioencapsulation and Bt transgenic forest plantations. Methods to achieve aerial application objectives include temperature-driven simulation models of insect and plant development for predicting optimal spray lines, Differential Global Positioning Systems (DGPS) for aircraft guidance, Aircraft Integrated Meteorological Measurement System (AIMS) and the use of ELISA based Accurate Deposit Assessment Methodology (ADAM) kits. Microbial pest control in forestry with Btk and other microbials will be an exciting commercial challenge in the new millennium. Some of the current and future issues regarding the use of microbial pesticides will be presented.

Index terms: Bacillus thuringiensis subsp. Kurstaki, microbial control, technological advancements, Accurate Deposit Assessment Methology.

[1868] OUTBREAKS OF FOREST DEFOLIATING INSECTS AND FOREST DAMAGE IN JAPAN

N. Kamata, Lab. of Ecology, Fac. of Sciences, Kanazawa Univ., Kakuma, Kanazawa, Ishikawa 920-1192, Japan, E-mail: kamatan@kenroku.kanazawa-u.ac.jp

In Japan, various kinds of forest-defoliating insects sometimes reach the outbreak level and cause serious defoliation. Defoliated trees sometimes die after severe defoliation. In 1984, there was an episode killing more than $10,000 \text{ m}^3$ of beech trees after the *Syntypistis punctatella* outbreak in 1982. The mortality was more than 50%. The percentage of *Cryptomera japonica* that had died from the heavy defoliation by *Calliteara argentata* ranged from 6.5 to 58.2%. However, the tree mortality caused by insect defoliation is low because the climate in Japan is moist. Evergreen conifers sometimes die from insect defoliation but deciduous broad leaved trees seldom die. Amongst the forest-defoliating insects in Japan, *Dendrolimus spectabilis* has been studied the most intensively, because many pine trees died from pine wilt disease caused by the pine wood nematode, which has been proved to be the main cause of pine motality in 1970. Until then, defoliation caused by *D. speciabilis* was supposed to be one of the greatest causes weakening pine trees to induce secondary beetles attacks. Outbreaks of *D. speciabilis* frequently occurred from 1950s to the early 70s. Chemical and biotic insecticides were deployed to control this insect during these periods. The outbreaks of *D. spectabilis* have decreased in recent years according with the maturation of vast areas of pine stands planted after World War II. On the contrary, insect defoliation in larch plantation has become more frequent with stand maturation. Ptycholomoides acriferana, Spilonota eremitana, Cryptoblabes loxiella, Coleophora obducta, and larch sawflies, Pachynematus itoi and Pristiphora erichsoni are the main outbreak species. Especially, outbreaks of a larch sawfly, Pristiphora erichsoni, have been prevalent. It is specific that outbreak of P. erichsoni continues 4-6 years in the same stands. No density-dependent mortality factors seemed to be effective in this system. Host plant deterioration and/or outbreak of rodents that is driven by masting are the main factors to terminate the outbreak. In natural fir forests and larch plantations, *Lymantria fumida* periodically reaches the outbreak level and defoliates trees completely. A chemical insecticide (BHC) and biotic insecticide (mixture of NPV and CPV) were sprayed against this insect outbreak in the 1960s. In the 60s and 70s, many trial virus applications against outbreaks of forest-defoliating insects were done in Japan under the leadership of FFPRI, which included; D. spectabilis, D. superaus, Euproctis subflava, L. dispar, L funida, and Hyphantria cunea. Because silviculture in Japan declined rapidly with economic development, insecticide application against forest defoliators was no longer cost-efficient and was stopped in mid-1970s. The research budget and interests of forest entomologists shifted to pine will disease caused by pine wood nematode and many wood boring insects that spoiled wood quality. In spite of such circumstances, intensive population studies on *L. dispar*, *D. superans*, and *S. punctatella* have been continued. Outbreaks of these defoliators have occurred periodically and were terminated by insect diseases that operated in a density-dependent fashion. NPV and *Entomophaga maimaiga* are effective for *L. dispar*, CPV and NPV for *D. superans*, Cordyceps militaris for S. punctatella.

Index terms: Dendrolimus spectabilis, Syntypistis punctatella, insect disease, control

[1870] MASS REARING OF THE NATIVE ENDOPARASITOID CHOUIOIA CUNEA (HYMENOPTERA: EULOPHIDAE) AND ITS SUCCESSFUL USE FOR CONTROL OF THE INTRODUCED FALL WEBWORM IN CHINA

<u>Y. Zhong-ai</u>, Research Institute of Forest Ecology, Environment and Protection, Chinese Academy of Forestry, Beijing, 100091, P.R. China.

The introduced fall webworm, Hyphantria cunea, became an important pest in China, causing serious damage. Because of the severity of this damage, the native biotic agents attacking this introduced pest in China were investigated. One of them, a native endoparasitoid, Chouioia cunea Yang (Hymenoptera: Eulophidae: Tetrastichinae), is new to science. This parasitoid was found to cause considerable mortality of H. cunea pupae in some areas. The host range of this new species was investigated to find a practical substitute host for mass rearing of C. cunea. This mass-rearing technique is described along with the successful release of this parasitoid into new areas, three provinces and in the city of Tianjing. Parasitism by C. cunea in the areas it was released was usually over Srews Soft. These successful release of native parasitoids in the country of introduction more frequently than was previously assumed, and classical biological control (the introduction of natural enemies of the introduced pest from the country of origin) may not always be needed.

Index terms: Hyphantria cunea, Chouioia cunea, biological control, mass rearing, release, parasitic wasp

[1871] DEVELOPMENT OF INTEGRATED MANAGEMENT OF DEFOLIATING INSECTS IN CANADA

I.S. Otvos¹, V. Nealis¹, & K. van Frankenhuyzen², ¹Natural Resources Canada, Canadian Forest Service – Victoria, 506 West Burnside Road, Victoria, B.C. V8Z 1M5 Canada, E-mail: iotvos@pfc.forestry.ca, ²Natural Resources Canada, Canadian Forest Service, Great Lakes Forestry Centre, P.O. Box 490, 1219 Queen Street East, Sault Ste. Marie, ON, P6A 5M7, Canada.

Forests in Canada cover about 453 million hectares, approximately 45% of the total landmass of the country; of this 244 million hectares is productive forest. The forests of Canada are the most important natural resource in the country; they contribute more to the economy of the country than all the other natural resource sectors combined. The protection of this valuable natural resource is of great economic importance. The development of forest insect pest control in Canada is reviewed, from the early days of organic chemical insecticides, to the development of microbial insecticides and the more recent concept of integrated management of insect pests. Broad-spectrum chemicals have been replaced by the more selective microbial insecticide for defoliators. The shift from chemical insecticides to the extensive use of Bacillus thuringiensis was gradual. Classical biological control was, and still is, used against pests of foreign origin introduced into Canada without their natural enemies. Inspection and eradication are used to prevent or delay establishment of exotic pests. There has been a shift towards more intensive forest management, this change being reflected in methods of control - attempts are made to manage insect pest problems before drastic measures are required to control them. This change is also noticeable in the way insect problems are addressed. It is recognized that insect damage and its impacts should be minimized in an ecologically sound and environmentally friendly manner. Insects are managed instead of being suppressed, and whenever possible an integrated approach is taken. In the future, attempts will be made to prevent insect outbreaks or mitigate the long-term impacts of insect disturbance on the forest. The approach will be more ecologically based and comprehensive by integrating pest dynamics, forest use, socioeconomics and environmental considerations. The control agents used to manage forest insects will likely have narrow activity ranges requirement likely to be demanded by the environmentalists and general public. This will increase the pressure to develop novel control agents (such as genetically engineered microbes or introducing insect pathogens into host trees). However, some of these novel approaches may not gain general acceptance due to public opposition. It is inevitable that some effective and safe direct control measures may have to be used on a short-term basis when insect damage is unacceptable.

Index terms: biological control, defoliators, integrated pest management

[1872] GROWTH LOSSES AND ECONOMIC CONSEQUENCES OF PINE SAWFLY DEFOLIATION

P. Lvytikäinen-Saarenmaa¹ & E. Tomppo², ¹Finnish Forest Research Inst., Rovaniemi Research Station, P.O. Box 16, FIN-96301 Rovaniemi, FINLAND, E-mail paivi.Jyytikainen-saarenmaa@metla.fi; ²Finnish Forest Research Inst., National Forest Survey, Unioninkatu 40 A, FIN-00170 Helsinki, FINLAND.

The European pine sawfly (Neodiprion sertifer) and the large pine sawfly (Diprion pini) are common forest pests in northern coniferous forests, reaching occasionally outbreak levels and defoliating wide areas of Scots pine (Pinus sylvestris) stands of all ages. Defoliated area during the latest outbreak of D. pini in 1998-99 was approximately 500 000 ha. N. sertifer is an early-season defoliator that feeds on old needles only, whereas D. pini is a late-season defoliator that feeds on new and old needles. Defoliation reduces tree growth and timber yield, but these aspects have been considered quite often less important than tree mortality. Economically significant reductions in increment occur even after a single defoliation period, and even when densities remain below those required to call upon a secondary attack by scolytid bark beetles. Defoliation by N. sertifer seldom kills trees, whereas the number of killed trees is much higher after damage by D. pini. Tree mortality after outbreak period of N. sertifer has been recorded to be approximately 4 %, and after outbreak of D. pini approximately 30 % of the total tree number in defoliated stands. However, mortality can be much higher in young stands. Volume growth can be decreased by 33 % and 85 % after moderate, and by 40 % and 99 % after heavy defoliation by N. sertifer and D. pini, respectively. Increment losses are two or three-fold higher after defoliation of D. pini compared to N. sertifer. The economic value of growth losses is possible to estimate on the basis of the proportion of tree species in a stand, structure and age of a stand, average annual increment, intensity of pine sawfly defoliation, and a value of timber. In Finland the estimated average economic value of growth losses and killed trees might reach up to 45 USD/ha for N. sertifer, and 310 USD/ha for D. pini, after a single-year outbreak. The recovery period of Scots pine after insect defoliation is partly unknown, but volume growth will re-establish at least within 10-15 years. These estimates of economical losses indicate a dramatically higher impact of pine sawflies than those revealed by the earlier few studies in Europe.

Index terms: Neodiprion sertifer, Diprion pini, Pinus sylvestris, annual increment, timber yield

[1873] MANAGEMENT VS. MITIGATION OF DAMAGE: CAN WE DO BETTER IN THE 21ST CENTURY?

<u>E. A. Cameron</u>¹, Dept. of Entomology, Penn State Univ., 501 A.S.I. Bldg., University Park, PA 16802-3508, USA E-mail: acameron@psu.edu.

'Forest pest management,' especially in North America, frequently occurs in response to short term public pressure to mitigate nuisance or perceived damage. Practices and procedures that would reduce adverse impacts over the longer term too frequently have not received the emphasis they deserve. Often we still do not understand the steps that can or might be undertaken to improve management over the lifetime of a forest. These gaps in knowledge must drive research efforts to improve management of defoliators, and to integrate economic, ecologic, aesthetic, and other values. Vast forested areas require different practices than those which are suitable for smaller, intensively-managed, areas of high value - a fact which must be borne in mind as manipulative management decisions are made. The use of chemical insecticides has diminished in recent years, in large part as a result of environmental concerns as well as of cost. Biologically-based insecticides are also costly to use, and are coming under increasing criticism as agents of environmental disruption especially with reference to their effects on non-target organisms. Biological controls, in particular with respect to exotic species, have had both successes and failures. They, too, are under increasing criticism from vocal groups that seem to desire preservation of existing fauna even at the expense of reasoned arguments for introduction of additional exotic species. Sound silvicultural practices too often have not received the support and priority that they deserve. Sustainable management, coupled with intensive public education, must be the touchstone for evolution of 21st century forest practices if forest managers are to regain the confidence and support of the general public and of public agencies. Examples such as the gypsy moth, Lymantria dispar (Lepidoptera: Lymantriidae), spruce budworms (Choristoneura spp. (Lepidoptera: Tortricidae), sawflies (Hymenoptera: Tenthredinoidea) on various coniferous and Tenthredinoidea) on various coniferous and hardwood hosts, and leafrollers and leaftiers (Lepidoptera: Tortricidae), especially on oaks (Quercus spp.), will be among those referenced as illustrative of past and possible future practices.

Index terms: Lymantria dispar, Choristoneura spp., Tenthredinoidea, silvicultural practices

[1874] IMPACT OF TIMBER HARVESTING ON INSECT HERBIVORE POPULATIONS OF *QUERCUS* IN A NORTH AMERICAN TEMPERATE DECIDUOUS FOREST

R. J. Marquis¹ & J. T. Lill¹, ¹Dept. of Biology, Univ. Missouri-St. Louis, 8001 Natural Bridge Rd., St. Louis, MO 63121-4499 EUA, E-mail robert_marquis@umsl.edu.

Tree harvesting may have significant effects on the abundance of forest organisms over and above the local effects of tree removal. The nature of such possible landscape-scale effects on insect herbivores are not well known. We have been documenting the landscape effects of timber harvest on the abundance of insect herbivores both pre- and post-harvest on two deciduous tree species (Quercus alba and Q. velutina) of a deciduous forest of the Ozark plateau of the central United States (Missouri). This study is part of larger multi-collaborator project called the Missouri Ozark Forest Ecosystem Project (MOFEP) run by the Missouri Department of Conservation. Replicate forest sites (3 each per treatment, approximately 240 ha) underwent one of three harvesting treatments in 1996: control or no harvest, even-age management or approximately 10% of stands clearcut, and unevenage management or thinning of the forest. Insects were sampled without removal both on saplings and the canopy of adult trees. Effects of timber harvest are described for three years pre-harvest and three years post-harvest. Insect abundance declined 30-70% across all treatments following harvesting compared to pretreatment levels. As in the pretreatment years, insect abundance was higher on understory plants of Q. alba on north- and east-facing slopes than on south- and west-facing slopes. Also, insect abundance was generally higher on Q. alba than on Q. velutina in both the canopy and understory (except for the first census following leaf flush), higher in the understory than in the canopy, and higher late in the season on Q. alba than early, but lower on Q. veluting later in the season than earlier. Treatment effects appeared in both the understory and canopy in the first year following cutting (1997). Treatment effects were relatively weak in the understory (occurring in only 1/4 censuses each for both species), with cutting increasing the number of insects compared to controls for both Q. alba and Q. velutina when such effects did occur. In contrast, cutting reduced the number of insects encountered in the canopy compared to control sites in both 1997 and 1998, and then finally increased the number of insects at the end of 1999. Links to changes in insectivorous bird abundance as also affected by timber harvesting will be discussed. Index terms: forest management, insect communities, landscape effects.

[1875] CONNECTION BETWEEN THE FLORA AND LEPIDOPTERA FAUNA OF AMERICAN NORTHWEST FORESTS

T. D. Schowalter, Dept. of Entomology, Oregon State Univ., Corvallis, OR 97331-2907, USA, E-mail schowalt@bcc.orst.edu.

Canopy arthropods are a poorly known component of forest ecosystems but represent the vast majority of species, some of which are capable of dramatically altering forest structure and function. Their small size, short life spans and high reproductive rates make Nevertheless. them highly sensitive to environmental gradients in time and space. relatively few studies have addressed factors affecting patterns of species abundance or community organization in forest canopies. Studies of canopy communities in the Pacific Northwestern U.S. demonstrate effects of crown position, tree species, forest age, and latitudinal or climate gradients on arthropod species abundances and community structure. Relatively few taxa show significant variation with crown height, despite the 40 m depth of foliated crowns. However, most taxa show significant variation in occurrence or abundance among tree species. Folivores, predators and detritivores generally are most abundant in older or undisturbed canopies, whereas sap-sucking species are most abundant in younger canopies. Economically important folivores (such as the western spruce budworm, Choristoneura occidentalis) and sap-suckers (such as the Cooley spruce gall adelgid, Adelges cooleyi) are most abundant in homogeneous canopies of the dominant tree species, compared to more heterogeneous canopies. Similarly, species and functional groups also vary in their representation across latitudinal or precipitation gradients in this region. Species within each functional group vary in their responses across these environmental gradients, indicating an important role of biodiversity in buffering the ecosystem from changes in ecological functions during environmental changes Index terms: Choristoneura occidentalis, Adelges cooleyi, forest, disturbance, precipitation

[1876] COMPARISON OF THE MACROLEPIDOPTERAN ASSEMBLAGES OF SALIX NIGRA AND ACER NEGUNDO: A STORY OF CATERPILLARS, PLANTS, PARASITOIDS, AND PREDATORS

P. Barbosa¹ & A. Caldas¹, ¹Dept. of Entomology, Univ. of Maryland, Plant Sciences Bldg., College Park, MD, 20742, USA, E-mail pb5@umail.umd.edu and Bldg., ac182@umail.umd.edu

Larval free-feeding macrolepidoptera of two riparian trees Salix nigra (black willow) and Acer negundo (box elder) were sampled and sorted by species and abundance. Data collected established that the majority of species in the assemblages in each tree species occurred at low abundance in each of the 5 years when larvae were sampled. On both trees, assemblages were dominated numerically by relatively few species, a pattern that has been observed for insect assemblages on plants in managed and unmanaged habitats. Absolute sampling of two macrolepidopteran assemblages on box elder and black willow was undertaken by fogging the canopy. Collections of larval Lepidoptera demonstrated that assemblages are numerically dominated by few species, i.e., scarce species constitute a large proportion of our samples. Specifically, the proportion of singleton species in these temperate habitat assemblages parallels that observed in fogging studies in tropical habitats. The similarity index calculated for the species in the two assemblages was relatively low. The latter results were compared to those obtained from absolute sampling (achieved by fogging). The patterns were the same regardless of the sampling approach. Patterns of larval parasitism among species in the macrolepidopteran assemblages also were examined.. Total parasitism of larvae on box elder was significantly higher than that of larvae on black willow. Comparisons of parasitism levels among lepidopteran families showed that in five of seven families larval parasitism on box elder was significantly higher than on black willow. For species whose larvae were found on both tree species, total parasitism was significantly higher when the larvae were on box elder than when larvae of the same species were on black willow. In comparisons of species found on both tree species, larvae in three of seven families suffered significantly higher levels of parasitism when on box elder than when on black willow. The roles of the functional/numerical responses of parasitoids, common and numerically dominant parasitoid species, and plant volatiles are considered as causal mechanisms underlying differential parasitism but are not supported by the data. Age based differential predation by birds on one of the more common macrolepidoptera species also has been observed. Behavioral observations further suggest that the ability of prey larvae to differentiate among predators and other herbivores in the habitat may serve as the basis for other examples of differential predation.

Index terms: Differential parasitism, box elder, black willow, insect assemblages scarce species.

MACROLEPIDOPTERA OF EASTERN NORTH AMERICAN [1877] DECIDUOUS FORESTS: ASSOCIATIONS WITH HOST TREES AND PARASITOIDS IN THE CENTRAL APPALACHIAN MOUNTAINS

. Strazanac & L. Butler. West Virginia University, Division of Plant and Soil Sciences, P. O. Box 6108, Morgantown, West Virginia, 26505, USA.

The macrolepidoptera associated with the eastern North American deciduous forests are an abundant and diverse group. A large portion of the more than 5,000 species (USDA 1985) of the described Lepidoptera from this region are probably associated with the Appalachian Mountains and their adjacent foothills. The foliage macrolepidopteran fauna of Appalachian deciduous forests is in large part documented. For many species, the details of their distribution, host preferences, and especially, their parasitoid relationships are not well known. Two recent studies on oak-dominated sites illustrate how limited our knowledge is of the parasitoid-host relationships. Butler (1993) reared 46 species of macrolepidopteran larvae, producing 136 primary parasitoid-host associations. Of these, 115 were not previously reported. An on going project with an extensive rearing effort of catempillars from selected hardwood trees produced 60 tachinid parasitoid associations not previously reported. In terms of the diversity of caterpillars attacked, Tachinidae can be equally effective parasitoids as Braconidae and Ichneumonidae in forest canopy environments.

Index terms: Tachinidae, Braconidae, Ichneumonidae, canopy, hardwoods

[1878] RICHNESS AND ABUNDANCE OF CATERPILLARS ON CONGENERIC PLANTS IN CERRADO AREAS OF THE DISTRITO FEDERAL

I. R. Diniz¹ & H. C. Morais², ¹ Departamento de Zoologia, ² Departamento de Ecologia, Universidade de Brasília, 70910 900, Brasília, DF, Brazil. E-mail: ivone@rudah.com.br.* Patial funding from CNPq Proc. nº 5010225/92; PIBIC/CNPq/UnB.

The richness and abundance of Lepidoptera larvae on the same host plants is compared between areas with similar vegetation (cerrado sensu stricto): Fazenda Água Limpa (FAL), Botanical Garden of Brasília (JBB) and the National Park of Brasília (PNB). The FAL and JBB study areas are 6 km apart and both are cerca 30 km from PNB. Host plants examined were Byrsonima coccolobifolia, B. verbascifoliu (Malpighiaceae), Erythroxylum deciduum, E. suberosum, E. tortuosum (Erythroxylaceae). These species are deciduous, woody shrubs, dropping their leaves at the end of the dry season and are common in the cerrado. The inventories of caterpillars were conducted within 1 ha areas and, weekly, 15 plants from each species, measuring between 0.50 and 2.50 m of height, were examined in each area. The exophytic, folivorous caterpillars were collected and separated according to morphospecies. The data were obtained between March and August of 1994, including the peak for caterpillar abundance (May-July). In general, 20% of the 4394 plants examined presented caterpillars and the richness per plant species varied between seven and 24. The variation in caterpillar richness among plant species is not related to host plant density, nor with other easily recognizable characteristics such as leaf pilosity or plant size. The proportion of plants with caterpillars, here used as an indicator of caterpillar abundance, was greater at JBB (26%) and lower at PNB (14%). For Erythroxylum spp., caterpillar abundance and the number of caterpillar species presented a positive relationship in the three areas: E tortuosum > E. deciduum > E. suberosum. This relationship between abundance and richness was completely broken for Byrsonima spp.: B. coccolobifolia (FAL = 15% and 10 spp.; JBB = 38% and 15; PNB = 16% and 23), B. verbascifolia (18% and 13; 38% and 21; 12% and 20). Two lepidopteran species (Cerconota achatina and Gonioterma exquisita - Elachistidae) are dominant on Byrsonima spp., but their frequency of occurrence varies between locales ($\chi^2 = 24.897$; p < 0.001). Erythroxylum spp. also present two dominant caterpillar species, however, with lower frequencies, which do not vary between locales. Variation in the abundance and richness of caterpillars occurs between species of Erythroxylum, whereas on Byrsonima spp. the variation occurs predominantly between locales and is related to the population variations of the dominant caterpillar species on those plants. Index terms: Elachistidae, Cerconota achatina, Gonioterma exquisita

[1879] IMPACT OF FOREST UTILIZATION ON THE ASSEMBLAGE OF LONGICORN BEETLES (COLEOPTERA: CERAMBYCIDAE) IN THE WARM-TEMPERATE FORESTS OF JAPAN

K. Maeto¹, S. Sato¹ & H. Miyata², ¹Shikoku Res. Ctr., Forestry & For. Prod. Res. Inst., 915 Asakura-Nishimachi 2, Kochi 780-8077, JAPAN, E-mail maeto@ffpri-skk.affrc.go.jp; ²Kochi Pref. Forest Tech. Ctr., 80 Ouhira, Tosayamada, Kochi Pref. 782-0078, JAPAN.

Insect diversity has been seriously affected by the reduction of temperate natural forests, due to coppicing, shifting cultivation, logging and monocultural planting, but only a little is known what insect groups or guilds depend on natural forests and thus suffer greatly from the forest utilization. Shimanto River Basin of southwest Japan was largely covered with natural or semi-natural forests dominated by evergreen broad-leaved and coniferous trees, although the traditional practice of shifting cultivation and coppicing had started several thousand years ago. In recent several decades, however, they have been rapidly cleared and mainly converted to coniferous plantations or young secondary forests. It is estimated that near-primary forests remained account for less than 0.3 % of total woodland area in the district. In order to understand the impact of such forest utilization on insect diversity, we have established 14 study plots of near-primary natural forests, naturally regenerated secondary forests (30-60 year-old) and coniferous plantations (ca. 30 year-old) in the Shimanto River Basin area. Here we report the influence of forest alterations on the assemblage of longicorn beetles (Coleoptera: Cerambycidae and Disteniidae). The beetles were sampled by the use of white and yellow collision traps attached with flower fragrance chemical (benzyl acetate) and ethanol as attractants in 1998 -1999. The assemblages were compared among plots in the correlation coefficient (tau) of species ranking and coordinated by the multi-dimensional scaling (MDS). Total number of species (general species richness) was not different among three forest types (natural forest, secondary forest and plantation). Even in coniferous plantations, the vegetation of undergrowth and naturally regenerated patches will be rich enough to keep many species of longicorn beetles. But species composition was conspicuously different among them. It is noteworthy that natural forests were characterized by the richness of the subfamily Lepturinae, especially of the genus Pidonia. The larvae of Pidonia inhabit thick bark of partly decayed or fallen trees of angiosperm. They are less host-specific and feed on various tree species, which are regenerated in secondary forests, but they require old-age trees with thick bark and humid forest floor. Our findings support the view that insects specific to natural forests strongly depend on the large and complex structure of aged forests, as well as on the taxonomic diversity of vegetation. Monitoring and management of old forest remnants and neighboring secondary forests for the conservation of biodiversity will be also discussed.

Index terms: Pidonia, biodiversity, human impact, forestry, kairomone trap

[1880] ARCHAEOLOGICAL GROUND BEETLE ASSEMBLAGES AND RECENT FOREST FAUNA IN FLANDERS: WHAT HAVE WE LOST DURING MEDIEVAL FOREST DEGRADATION AND FRAGMENTATION?

K. Desender ¹& A. Ervynck², ¹ Dept. Entomology, RBINSc, Vautierstr. 29, B-1000 Brussels, Belgium, E-mail: kdesender@kbinirsnb.be; ² Inst. Archaeological Heritage Flemish Community, Doornveld 1 box 30, B-1731 Zellik, Belgium.

In 1988, the Provincial Archaeological Museum of south-east Flanders excavated a stone well of Roman type at Velzeke (Eastern Flanders, Belgium), at the edge of a Roman site that flourished from the first to the third century AD (Van der Plaetsen, pers. comm.). The lower 3,5 m of the well's filling consisted of a deposition of organic debris that was subdivided in 11 sampling units and sieved on 0,5 mm meshes. The residues proved to be rich in zoological remains, i.e. bone, mollusc shells and the chitinous remains of insects. From the latter group, only the carabid remains were used in order to attempt a reconstruction of the former landscape around the well. Radiocarbon dating situated the existence of this fauna around 500 AD and covering a time span of more or less 150 years (Van Strydonck, pers. comm.). From each subunit, the remains of at least 100 carabids could be identified, yielding a total sample of more than 1100 ground beetles, belonging to 58 species. Most of the subunit samples (especially subunit 2 - 9) yielded a detailed carabid faunal assemblage for a woodland habitat, dominated by stenotopic and eurytopic woodland species, implying that woodland surrounded the well at that time. Extensive data on the recent carabid beetle fauna occurring in woods of Flanders were compared to the archaeological dataset of the post-Roman forest. Integration of these data reveals that during medieval forest degradation an fragmentation, most woods must have been impoverished to a high extent with respect to their stenotopic woodland beetle fauna. Typical woodland beetles show a reduced dispersal power (constant brachyptery) and appear to be powerful indicators for larger ancient woods.

Index terms: Carabidae, diversity, historical ecology, ancient woods.

[1881] SIREX NOCTILIO IN SOUTH AMERICA: DISTRIBUTION, MONITORING AND CONTROL

E.T. Iede¹, P. Klasmer² & S.R.C. Penteado¹, ¹Embrapa Florestas, Caixa Postal 319, CEP 83411-000, Colombo, Paraná, Brasil. iedeet@cnpf.embrapa.br; susete@cnpf.embrapa.br; ² Inta, Campo Forestal Gral. San Martín, C.C. 268430, El Bolsón, Pcia. de Rio Negro, Argentina. vklasmer@bariloche.inta.gov.ar.

Sirex noctilio is being monitored and/or controlled in approximately 3.9 million hectares Pinus spp. in South America's Southern Cone of which 2 million ha are in Brazil, 1.5 million ha in Chile, 0.3 million ha in Argentina, 0.1 million ha in Uruguay and 0.05 million ha in Paraguay. The woodwasp is a secondary pest in its origin region, but became a main pest of Pinus spp. in the countries where it was introduced. In South America, it was first registered in P. taeda and P. elliottii stands at the Department of Cerro Largo in Uruguay, in 1980. The insect dispersed rapidly to the existing 35,000 ha of the country. In 1993, it was first detected in the Argentinian Patagonian Andes threatening stands of little economic significance, but of strategic ecological importance. In 1985, it was detected in P. taeda stands at the Province of Entre Rios and dispersed to Corrientes (1993), Jujuy (1994), Misiones (1995) and Cordoba Provinces (1995). In Brazil, the pest was introduced in Rio Grande do Sul (1988), Santa Catarina (1989) and Paraná (1996), and attacks currently around 300,000 ha, most of it of P. taeda. Monitoring and early detection are among the main prevention measures adopted in all countries, including Chile and Paraguay where the pest is not present. Monitoring is made with trap-trees, trees that are stressed with herbicides to become attractive to the pest. In Chile, the program is complemented by a quarantine control of solid wood packing material.

In the countries where *S. noctilio* is present, control measures are similar, but enforced with different intensity. In general, forest management practices, specially thinning of overstocked stands, were intensified and natural enemies introduced. Large applications of the *Deladenus siricidicola* were made. This nematode sterilizes females and after inoculation is dispersed through the wasp eggs. Nematode inoculation is done since 1988 in Uruguay, 1989 in Brazil and 1995 in Argentina. *Ibalia leucospoides* (Hym.: Ibaliidae), a parasitode of the woodwasp eggs was accidentally introduced together with the pest and is present in the whole pest dispersion area. It has an average parasitism of 23% (ranging 4-45%) and a high capacity of establishment. In Brazil and at the Argentinian Patagonian Andes, *Megarhyssa nortoni* and *Rhyssa persuasoria* (Hym.: Ichneumonidae), ectoparasitodes of the woodwasp mature larvae are being introduced to complete the biological control program.

[1882] RISK TO SOUTH AMERICAN RADIATA PINE RESOURCES BY THE PINE SHOOT MOTH, RHYACIONIA BUOLIANA

D. Lanfranco¹, P. Klasmer², E. Botto³ & S. Ide¹, ¹Inst. de Silvicultura, Univ. Austral de Chile, Casilla 567, Valdivia, CHILE, E-mail dlanfran@uach.cl; ²INTA (E.E.A.Bariloche), CC 268430, El Bolsón-Rio Negro, ARGENTINA. ³IMYZA-CNIA-INTA, Castelar (1712), Buenos Aires, ARGENTINA.

The european pine shoot moth populations are distributed in the South American countries of Argentina, Uruguay and Chile. The most susceptible hosts are Pinus radiata, P. ponderosa, P.contorta var. latifolia and P. taeda that are extensively established. Rhyacionia buoliana (Rb), is a univoltine tortricid that attacks fresh buds and shoots, causing serious injury to the stem if the leader shoot is attacked. The impact of this pest has been monitored by following indicators such as pest density, host-pest relationships and damage, the productive objectives of the stands, and levels of pest control and pest dynamics in the light of quite diverse site conditions in Chile. Several historical data will be presented. Silvicultural, biological, chemical and pest management measures have been adopted, but each plantation represents an unique case study with variable indicators. Most of the control actions are mechanical and chemical during the first 2 or 3 years of plantation growth and later there is effective biological control with an univoltine specific internal parasitoid, Orgilus obscurator (Oo) that has been introduced into these countries. Levels of parasitism by Oo, increase with time, specially in temperate plantations areas. Parasitism rates are between 0% to 84% in Chile and 0% to 65% in southern Argentina. Few studies have been conducted about O.o behaviour: survival rates, sex proportion, fecundity, basic genetics and incidence of wildflowers. An endemic chilean egg parasitoid Trichogramma nerudai was recently and experimentally introduced to southern Argentina, as an inundative strategy. Native natural enemies in Chile (birds, spiders and insects parasitoids or predators) also enhance Rb population control. Between them, Coccygomimus fuscipes, an ichneumonflies, is commonly detected, also in Argentina. Carduelis barbata, a passerine bird, also plays a predator role principally during their reproductive periods. An unstudied but interesting spider complex may have some significance. Meanwhile, satisfactory levels of recovery in damaged trees with one or at most two stem defects are observed. This is evident in trees with several levels of crooks and not good in forked or multiforked trees. No long term studies have been conducted in the countries with Rb, nevertheless forest health and sustainability of the forest resources are commonly invoked in forestry meetings and papers. Chile and Argentina are still establishing pine plantations mainly with susceptible species to this pest. And Rb is still a serious pest in both countries.

Index terms: pine insect pests, pest management, Argentina, Chile

[1883] MANAGEMENT OF THE WHITE PINE WEEVIL IN NORTH AMERICA

Rene L Alfaro, Pacific Forestry Centre, Canadian Forest Service, Victoria, BC V8Z 1M5

The white pine weevil, Pissodes strobi Peck, is an indigenous insect of North America, and can be found in most regions of Canada and the United States. In British Columbia this insect has become a serious pest of reforestation, causing severe damage to young stands of Sitka spruce, Engelmann spruce, white spruce, and their hybrids. An Integrated Pest Management System has been proposed for *P. strobi*. This system relies on restoring ecosystem balance by reducing the conditions that lead to outbreak development. The system recommends tactics that diminish heat accumulation in the stand by encouraging growth of suitable non-host conifers as well as deciduous species such as aspen or alder. These trees render the stand cooler and shadier, reduce food supply, and probably create conditions which enhance natural enemy populations. Reduction of damage by increasing plantation density is also recommended. Central to IPM is the continuous monitoring of weevil populations and forecasting of weevil impacts on forest productivity. This can be accomplished through a computerized decision support system, which helps to evaluate the need for, and the possible benefits of a given tactic. A salient feature of the IPM system for P. strobi is the combination of tactics involving silviculture and host genetic resistance. Host genetic resistance could be utilized to allow increased reforestation with spruce species in ecosystems prone to infestation. In low hazard areas, silviculture-driven tactics such as mixed-species planting and increased planting density may be sufficient to produce a successful spruce crop. In high hazard areas, the silvicultural prescription should include the use of resistant stock. However, the deployment of resistant genotypes should take into consideration the need for avoiding the risk of insect selection leading to biotypes capable of overcoming the resistance mechanisms. For this, a component of susceptible stock should be planted along with the resistant material.

[1885] REFORESTATION PEST PROBLEMS IN TROPICAL AMERICA

<u>J. E. Macías-Sámano</u>, El Colegio de la Frontera Sur, ECOSUR, Carret. Antiguo Aeropuerto km 2.5, 39700 Tapachula, Chiapas, México, E-mail: jmacias@tapecosur.edu.mx

The concept of reforestation in America's tropics has changed, very especially because of our environmental concerns and the goal of sustaintability. Until now, reforestation was the equivalent of plantations, and dealt with very few, mostly exotic species. To great extent, major world timber companies established this pattern. Provoking an immense interest in the study of entomofauna associated with species growing in plantations, such as pines, eucalyptus, teak, mahogany and gmelina, among others. Therefore there is some information about them. However, the very nature of the tropics call for managing diversity of native species and the potential timber trees - those more likely to be adapted to local environments and those that would follow sustaintability goals- are many and poorly known. Consequently the study of the entomofauna associated to these potential timber species is in its infancy. There are very few efforts in Central and South America that try to document, in a synthetic way, the pest for these species. Published information is in small numbers and to be qualitative and anecdotal. This is partially due to the large number of potential timber species available at any particular location. An International effort is needed to develop this information that is of basic nature to establish any reforestation effort.

[1884] CHALLENGES TO PEST MANAGEMENT IN SOUTHEAST ASIS

[1886] ARTHROPODS AS BIOINDICATORS IN AN AREA UNDER REFORESTATION IN SÃO PAULO STATE, BRAZIL

<u>M. P. Pais</u>¹ & E. M. Varanda², Depto de Biologia, FFCLRP, Univ. de São Paulo, Av. Bandeirantes 3900, CEP 14040-901, Ribeirão Preto, SP, Brasil. ¹E-mail paism@usp.br; ²E-mail emvarand@ffclrp.usp.br.

Due to the high level of devastation to which ecosystems components in the Atlantic Forest have been submitted, several reforestation methods have been employed both by the public and private sectors. Among these methods, the most relevant are those concerning the successional status of plant species, such as heterogeneous reforestation. However, information lacks on methodologies that promote the faster recovery of the diversity of the flora, fauna and their interactions. An indicator that has been employed in several studies concerning the successional recovery of a forest is the insect or arthropod diversity and community structure. Arthropods are useful environmental indicators because of their small size, their continuous presence and sensitiveness to narrow environmental changes. In October 1999, we began monitoring the arthropod community in a 16.6-ha area that had been reforested December 1998 on the Ribeirão Preto campus at São Paulo University. We have collected arthropods associated with the three most abundant pioneering and climactic plants in the area every four months. Our study aims at documenting the major changes on the arthropod community structure in the first stages of reforestation and gathering information to contrast with other information referring to reforestation employing only pioneering plants. Our results have indicated a high species richness: on 240 plants, we found 223 morphospecies of insects and 16 morphospecies of spiders. In total, 3,308 organisms were collected. Guilds are distributed as follows: 42.4% of the organisms are herbivores, 15.9% are predators, 1.7% are parasitoids, 3.5% are detritivores, 32.7% are ants (retained as a distinct guild because of their various feeding activities), 2.2% are seed-eaters, wood-eaters, fungus-eaters or "tourists" and 1.6% were not assigned to guilds due to identification difficulties. Because predators, parasitoids and detritivores are abundant in more stable communities, we expect that their occurrence will increase in the next collections. The results indicate that the reforestation methodology employed promotes a high faunal recovery from the first steps following planting. (FAPESP)

[1887] USE OF STRIPS OF NATIVE VEGETATION WITHIN EUCALYPTUS PLANTATIONS AS A STRATEGY TO REDUCE LEPIDOTERA PEST POPULATIONS

J.C. Zanuncio¹, **T.V. Zanuncio¹**, **J.M.M. Pereira¹**, **A.C. Oliveira² & G.D. Freitas²**, ¹ Dep. de Biologia Animal, Univ. Federal de Viçosa. 36.571-000 Viçosa, MG, Brasil. E-mail: zanucio@medufybr, ²Mannesmann Florestal Ltda. Curvelo, Minas Gerais, Brasil.

Eucalyptus plantations are used in Brazil as a source of wood for pulp and paper and as well as to produce charcoal for metallurgy. The Eucalyptus plantations face serious problems with pests such as leaf cutting ants and lepidopterous defoliators. For this reason faunistic analyses were made aiming to evaluate the effect of "cerrado" (Brazilian savannah) native vegetation on Lepidoptera associated with Eucalyptus cloeziana plantations of the Maanesmann Florestal Ltda in Minas Gerais, Brazil, which has been proposed as a strategy for reducing pests of Eucalyptus because islands and/or strips of native vegetation can be reservoirs of natural enemies of defoliator pests. The objective was to test the hypothesis that native vegetation as strips inside Eucalyptus clossiana plantation could reduce populations of defoliator Lepidoptera. The insects were collected during one night with light traps in five sampling sites for each system of Eucalyptus cultivation (i.e. with and without strips of "cerrado") every 15 days during six months. The first trap was located 100 meters within the native vegetation reserve, the second at the border of this reserve within the Eucalyptus; the third 250 meters into the plantation, the fourth at 500 meters (which placed it in the native vegetation strip, or between two blocks of Eucalyptus in the plantation without strips) and the fifth at 750 meters into the Eucalyptus plantation. Lepidoptera were removed from light traps, sorted and counted. A total of 5,511 individuals of 459 species and 16,021 individuals of 300 species of Lepidoptera were collected in areas with and without strips of "cerrado". In the first system, a higher number of species was collected within the strips of "cerrado" vegetation, the four most frequent species accounted for ± 20% of the individuals collected; nine species were constant (present in 50% to 100% of the samples) among the 23 most important ones, four of these were accessory (present in 25 to 50% of the samples) and ten accidental (present in 0 to 25% of the samples). Diversity was higher in the intersection of the habitats and smaller within the eucalypt plantation. In the system without strips of native vegetation, a higher number of species was collected in the native vegetation; the intersection between native vegetation and eucalypt plantation was similar in species composition with a smaller number of species within the eucalypt plantation. The three most frequent species in this habitat accounted for \pm 31% of the individuals collected; nine species were constant, nine were accessory and eight were accidental. The diversity indexes were higher in the plantation with them than in the plantation without "cerrado" strips. Additional sampling is required to evaluate populations of natural enemies in the native vegetation and the role of strips in spreading these natural enemy populations throughout the Eucalyptus plantation. Lower population levels of defoliator Lepidoptera within *Eucalyptus* plantations with strips of native vegetation shows that the strategy of Mannesmann Florestal Ltda using such strips can be recommended to aiming to reduce problems with Lepidoptera pests of in Eucalyptus in Brazil.

[1888] INSECT RESISTANCE IN EUCALYPTUS GLOBULUS TO ACUTE AND CHRONIC INSECT DAMAGE IN AUSTRALIA

R.B. Floyd¹ & M. Matsuki², ¹ CSIRO Entomology & Cooperative Research Centre for Sustainable Production Forestry, GPO Box 1700, Canberra, ACT 2601, Australia. E-mail: Rob.Floyd@ento.csiro.au² CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia. E-mail: Marnoru.Matsuki@ento.csiro.au

Eucalyptus globulus occurs naturally in SE Australia and widely planted in plantations in SE and SW Australia. Previous studies showed large inter-population variation in resistance to insect herbivores. In this study, we examined relationships between growth of E. globulus and acute and chronic damage caused by insects. We defined acute damage as intense damage caused by Christmas beetles (Anoplognathus spp. Scarabaeidae: Coleoptera) occurring in two days to two week each summer and chronic damage as less intense damage by other insect species occurring over three months or longer. Seedlings from 18 populations of E. globulus were planted in a field trial, and we measured growth and insect damage for five years. There was large inter- and intra-population variation in insect damage. All but one of the 185 plants suffered acute damage by Anoplognathus spp., and up to 90% of a plant was affected in any one year. Populations of *E. globulus* from Tasmania and the Bass Strait islands, which have previously shown resistance to autumn gum moth (Mnesampela privata Geometridae: Lepidoptera) and leaf blister sawfly (Phylacteophaga froggatti: Pergidae: Hymenoptera) tended to show cross-resistance to Anoplognathus spp. Individual plants and populations that tended to suffer severe acute or chronic damage in one year tended to suffer acute or chronic damage, respectively, in the following year. Populations suffered up to 50% reduction in mean annual growth rates due to insect damage. Reduction in growth was greater in populations with inherently fast growing plants than those with inherently slow growing plants. Insect pest management implications of these observations will be discussed. Index terms: Anoplognatius spp., Scarabaeidae, between-provenance variation, defoliation.

[1889] THE CHALLENGES OF SOIL-DWELLING SCARABS AS PESTS OF EUCALYPTS

J. N. Matthiessen, CSIRO Entomology & Cooperative Research Centre for Sustainable Production Forestry, Private Bag PO, Wembley, WA 6014, Australia. E-mail: iohnm@ccmar.csiro.au.

Several soil-dwelling scarabs are highly destructive pests of the early establishment phase of eucalypt plantations in various parts of southern Australia. Most are native 'spring beetle' species of the diverse genera Heteronyx and Liparetrus, with the accidentally introduced African black beetle, Heteronychus arator, a major pest in higher-rainfall areas of south-western Australia. A critical characteristic of these pests is that they often cause the death of seedlings, which are highly vulnerable because of their small size. This necessitates re-planting. Damage takes the form of defoliation by adult 'spring beetles' severe root pruning by *Heteronyx elongatus*, and severing of stems by adult African black beetle. Challenges in dealing with such pests include: difficulties in scouting for risk assessment and management intervention because of subterranean habit or sporadic mass invasion from adjacent habitat; the potential for catastrophic damage to occur rapidly (in minutes); assessing cryptic subterranean root and stem damage as seedlings may appear healthy but succumb to physical stresses some time after damage has occurred; in the case of African black beetle, very low damaging population densities and complexities of seasonal changes in activity; patchy distribution within a plantation; cultural incompatibilities between silviculture and pest management; and environmental factors that exacerbate risk of damage. These constraints typically render reactive interventionist control strategies risky. They also work strongly against the development or application of biological approaches to control, with their general limitation of slow effect and better applicability to reducing eruptive pests below economic thresholds. Prophylactic management techniques offer the most appropriate option particularly for those scarab species that dwell in the habitat prior to planting it with eucalypts (African black beetle and *Heteronyx elongatus*). These techniques are currently insecticidal but are erratic in effect. Improvements should be possible with better targetting, and with the support of cultural modifications, subject to economic constraints. Invasive 'spring beetles' appear not amenable to prophylactic techniques and present a potentially intractable challenge. Index terms: African black beetle, Heteronychus arator, Heteronyx, Liparetrus, spring

[1890] BIOLOGICAL CONTROL OF COLEOPTERAN PESTS OF EUCALYPTUS IN CALIFORNIA

J. G. Millar¹, **L. M. Hanks² & T. D. Paine¹**, ¹Dept. of Entomology, Univ. of California, Riverside CA 92521, USA, ²Dept. of Entomology, Univ. of Illinois, Urbana IL 61801, USA.

Eucalyptus spp. were introduced into California more than 100 years ago, and are now widely distributed throughout the southern and central parts of the state. Eucalyptus trees are valued because of their fast growth rates, their tolerance of drought and poor soils, and until recently, their lack of any significant insect pests; no native insects have expanded their host ranges to include Eucalyptus to any significant extent. However, around 1980, the first serious pest of Eucalyptus, the Eucalyptus longhorned borer Phoracantha semipunctata, was introduced into the state, followed by a congeneric species, Phoracantha recurva, in 1995. These two beetle species attack stressed trees, particularly those that are drought stressed during California's long hot summers. Trees are killed in a few weeks by the destruction of the cambium layers by the developing larvae. A biological control program initiated in the early 1990's, using the egg parasitoid Avetianella longoi and several braconid parasites of the larvae, has helped to reduce tree mortality. However, during the course of this project, it became obvious that the two borer species have subtly different biologies and life histories; since its introduction four years ago, *P. recurva* has largely replaced *P. semipunctata* in southern California. Possible reasons for this rapid replacement of one species by another in a shared habitat will be discussed. In addition to these two wood-boring insects, two serious defoliating pests also have been introduced into California within the last decade. The first, the Eucalyptus snout beetle Gonipterus scutellatus, has a considerable history as a pest of Eucalyptus in other regions of the world. In California, populations of this beetle initially increased rapidly, before being brought under control by importation and release of the egg parasitoid Anaphes nitens. The parasitoid has spread with the beetle as it expanded its range, and no further control efforts have been required for several years. More recently, a Eucalyptus tortoise beetle, Trachymela sloanci, was first found in California in 1997. This beetle has caused extensive defoliation of some Eucalyptus species in southern California, and damage has been exacerbated by the introduction of another pest, the red gum lerp psyllid, Glycaspis brimblecombei. Efforts to introduce and establish an egg parasitoid, Enoggera reticulata, for control of T. sloanei are ongoing. This paper will present an overview of the biological control efforts for each of these beetle species Index terms: Phoracantha semipunctata, Phoracantha recurva, Avetianella longoi, Gonipterus scutellatus, Trachymela sloanei

beetles

[1891] DIFFERENTIAL PARASITISM BY AN EGG PARASITOID, AVETIANELLA LONGOI, OF TWO PHORACANTHA SPP. ATTACKING EUCALYPTUS

T. D. Paine¹, K. Luhring¹, J. G. Millar¹ & L. M. Hanks², ¹Dept. of Entomology, Univ. of California, Riverside CA 92521, USA; ²Dept. of Entomology, Univ. of Illinois, Urbana IL 61801, USA

The cerambycid beetle Phoracantha recurva appears to be replacing a well-established congener, P. semipunctata, from their shared ecological niche (stressed Eucalyptus trees and fallen branches) in southwestern California. The proportion of P. recurva in the mixed population increased rapidly from 0.1% in 1995, the first year this species was detected, to 4.7% the following year, and 74% in 1997. Eggs of the P. semipunctata are the typical host of the encyrtid egg parasitoid Avetianella longoi. A field study indicated that egg masses of the two beetle species were located at equal rates by the parasitoid, but that A. longoi oviposited preferentially in P. semipunctata eggs. In no-choice laboratory bioassays, the parasitoid oviposition rate was similar between the two host species when the host eggs were 0.5 d old, but higher in *P. semipunctata* eggs when host eggs were \geq 1.5 d old. Survival of the parasitoids was significantly lower in P. recurva eggs of all age classes than in P. semipunctata eggs. In choice experiments, female parasitoid oviposition rate was significantly higher in P. semipunctata eggs regardless of host egg age. In both experiments, some P. recurva embryos survived the parasitoid attack and emerged as neonate larvae, whereas P. semipunctata embryos never successfully developed in parasitized eggs. These results were corroborated by the results of additional laboratory studies which tested strains of A. longoi reared on eggs of either P. semipunctata (S--strain wasps) or P. recurva (R-strain wasps) for multiple generations. Female parasitoids of both strains preferred to oviposit in P. semipunctata eggs, and survival rates were much higher in P. semipunctata eggs than in P. recurva eggs, for both 0.5 and 2.5 day old host eggs. Preference for and survival of progeny of R--strain or S--strain females on P. semipunctata eggs was not significantly different. A substantial fraction of P. recurva eggs survived parasitism and produced neonate larvae, whereas no P. semipunctata eggs survived parasitism. A larger percentage of *P. recurva* eggs produced neither a parasitioid nor a neonate larva than parasitized *P. semipunctata* eggs. Although *P. recurva* eggs were smaller in diameter and weight than *P. semipunctata* eggs, eggs of both species were large enough to support the development of several parasitoids, so it is unlikely that inadequate nutrition was a contributing factor to survival in eggs of either host species. Cumulatively, these results suggest that eggs of both species contain adequate nutrition for developing parasitoids, but that ovipositing A. longoi females and their developing progeny frequently are not able to manipulate P. recurva egg development.

Index terms: Phoracantha semipunctata, Phoracantha recurva, Avetianella longoi

[1992] BIOLOGICAL CONTROL OF INSECT PESTS OF EUCALYPTUS IN FRANCE.

J.C. Malausa., I.N.R.A. Centre de Recherches d'Antibes, Entomologie et Lutte biologique, 1382 route de Biot, 06560 Valbonne, France, E-mail: malausa@antibes.inra.fr.

Three specific insect pests of eucalyptus have been accidentally introduced from Australia into the mediterranean region. These species have reached France in the last decades : the curculionid *Gonipterus scutellatus* Gyllenhall in 1978, the psyllid *Ctenarytaina eucalypti* (Maskell) in 1979 and the cerambycid *Phoracantha semipunctata* (Fabricius) in 1984.

After a brief history of their geographical dispersal and bionomics, their present status and economic importance in France is reported. P. semipunctata is not reported as a severe pest and seems to be naturally limited by cool winter conditions. The two other species appeared to present a serious risk, particularly for ornamental trees and a classical biological control strategy have been developed successfully to control them. G. scutellatus is now very well controlled by the South-African oophagous parasitoid Anaphes nitens (Girault), first introduced on western Liguria coast in Italy. C. eucalypti reappeared in 1994 on ornamental eucalyptus of the mediterranean French Riviera and also in Brittany in western France. This pest developed heavy populations, causing important economic damage in thes two very different climates. After attempting to establish without success two species of coccinellid, Australian Encyrtidae Psyllaephagus pilosus Noyes was released in the two regions in 1997. Results were spectacular and control of the pest was effective in the first year of the releases. The parasitoids spread repidly over a very long distance and is now present all along the Mediterranean and Atlantic coasts of France. Control of psyllid populations is very effective since this time certainly due to the high mobility and host detection ability of P. pilosus. It is always a concern that introductions of other pests of eucalyptus from Australia may occur in France like in other countries.

Index terms: Ctenarytaina eucalypti, Psyllaephagus pilosus, Phoracantha semipunctata, Gonipterus scutellatus [1893] TRENDS IN INSECT PEST PROBLEMS OF LOCALLY EXOTIC EUCALYPT PLANTATIONS: THE EXAMPLE OF TASMANIAN BLUE GUM IN WESTERN AUSTRALIA

A. D. Loch, CSIRO Entomology and Cooperative Research Centre for Sustainable Production Forestry, c/- Department of Conservation and Land Management, Brain St, Manjimup, WA 6258, Australia, E-mail: a.loch@ccmar.csiro.au.

Tasmanian blue gum, Eucalyptus globulus globulus, is one of the world's most popular eucalypt planiation species because it has excellent pulpwood properties, grows rapidly leading to short rotations, and can grow in a variety of soil types. The species is native to south-eastern Australia (Tasmania and Victoria), but is now grown widely throughout the world in climates with cool winters. Most of the world's two million ha of E. g. globulus plantations have been established where the species is exotic. Even in Australia, most plantations occur outside the species' native range, where it could be termed a locally exotic species. This is the case in south-western Australia where 160,000 ha of E. g. globulus plantations are grown widely under a Mediterranean type climate, with current planting rates reaching 40,000 ha per year. The rapid rise of the *E. g. globulus* plantation industry in south-western Australia has seen a corresponding increase in insect pest problems, with the industry facing a suite of establishment pests that attack trees as small seedlings through to serious defoliators of established trees. The development of these problems is not unexpected given that native eucalypt forests, from which many of these pests have originated, dominate the regional landscape. Also, most pests are exotic species from eastern Australia that prefer E. g. globulus as a host. Given that this plantation system is not unique, with eucalypt species being increasingly grown worldwide, the potential entomological implications for growing eucalypt species in both locally exotic and exotic situations need to be appreciated. This presentation will provide a current perspective on the insect pest problems of this dynamic plantation system and highlight historical and potential future trends in such problems. Possible reasons for insect species becoming pests of this plantation system will be evaluated, with particular reference made to the differences between native and exotic insect pests.

[1894] ASSOCIATIONS OF INSECTS AND PATHOGENS RESULTING IN DISEASE AND DAMAGE TO PLANTATION GROWN *EUCALYPTUS* IN THE TROPICS AND SOUTHERN HEMISPHERE

M. Wingfield¹, J. Roux¹, P. Govender^{1,2} & B. D. Wingfield^{1,3}, Tree Pathology Cooperative Programme (TPCP), Forestry and Agricultural Biotechnology Inst. (FABI), Univ. of Pretoria, Pretoria, 0002, Republic of S. Africa; Dept. of Zoology & Entomology, Univ. of Pretoria, Pretoria, 0002, Republic of S. Africa; Dept. of Genetics, Univ. of Pretoria, Pretoria, 0002, Republic of S. Africa

The tremendous growth and success of plantation-grown *Eucalyptus* in the trepics and southern hemisphere, can partially be attributed to the fact that these trees have been separated from the pests and diseases that affect them where they are native. Diseases and insect pests are, however, gradually causing increasing damage to these trees. Interesting interactions between pests and pathogens have also emerged as threats to *Eucalyptus* in plantations. Various opportunistic pathogens such as species of *Botryosphaeria* and *Cryptosporiopsis eucalypti* cause serious disease on trees damaged by *Helopeltis* spp (Hemiptera: Miridae). *Ceratocystis fimbriata* that causes the recently discovered Ceratocystis wilt disease of *Eucalyptus* in Africa and South America is also likely to have insect vectors. The relationship between insects and fungal pathogens of *Eucalyptus* has largely been ignored in the past. Our belief is that an enhanced knowledge of these insects and the fungi with which they interact will form an integral component of efforts to reduce the damage associated with them.

Key words: Eucalyptus, Botryosphaeria, Helopeltis, Ceratocystis fimbriata

[1895] MONITORING OF LEAF CUTTING ANTS IN REFORESTED AREAS IN BRAZIL

J. C. Zanuncio¹, R. Zanetti², A. C. Oliveira³ & G. D. Freitas³, ¹Dept^a. de Biologia Animal, Univ. Fed. Viçosa, 36571-000, Viçosa, MG, Brasil, E-mail zanuncio@mail.ufv.br; ²Dept^a. de Entomologia, Univ. Fed. Lavras, C. Postal 37, 37200-000, Lavras, MG, Brasil, E-mail zanetti@ufla.br. ³Mannesmann Florestal, Rua Voluntários da Pátria, 81, C. Postal 152, 35790-000, Curvelo, MG, Brasil.

Since1990, Brazilian forest companies have started monitoring programs for leaf cutting ant populations of the genera Atta and Acromyrmex in reforested areas aiming to increase the efficiency and to reduce control costs of these pests besides the amount of insecticide used. Populations of these insects can be sampled with several methodologies including random parcels of a fixed size, based on areas of high level of infestation or with transects. The first consists of parcels of 720 to 1800 square meters where all ant colonies are counted, measure and divided by class of size. In the second method most severe areas of defoliation are identified, where the number and size of ant colonies and of damaged trees are counted and the level of defoliation is estimated. In the transect method imaginary lines of similar length as the plantation block with a width of one to three lines of plants are marked where all ant colonies are counted. Data obtained are processed and the number and size of ant colonies are determined to estimate the necessity of new evaluations, immediate control and of the best control method to be used. Sampling intensity usually varies from 1 to 3% of the area. Because no comparative studies about the accuracy of each methodology exist it is difficult to affirm which is the best one for Brazilian conditions but all of them are producing important information for integrated management of leaf cutting ants. Such methods are allowing reduction of about 30 to 40% of the area receiving leaf cutting ant control compared to companies that are not monitoring and control these pests every six months. A well known monitoring system was developed by Mannesmann Florestal which allowed a reduction of about 88.6% in the number of persons working with leaf cutting ant control and an increase in 64,1% in operational results of such control with an economy of about US\$ 1.200.000,00 in 1992 and of more than US\$ 900.000/ano since 1998. Leaf cutting ants monitoring also allows to analyse interactions between ant populations and the forest and to plan actions for integrated management of this pest. Data of the monitoring system of Mannesmann has also developed growth models for several forest species as function of density of anthills. This made possible to estimate levels of economic damage for this pest besides important information for leaf cutting ant management in forest plantations including the effect of the age of the plant and of the surrounding native vegetation on ant populations, among others.

Index terms: Sampling, Atta, Acromyrmex, forestation

[1896] THE SPATIAL AND TEMPORAL IMPACT OF ENDEMIC NATURAL ENEMIES ON THE MORTALITY OF CHRYSOMELID BEETLES IN EUCALYPT PLANTATIONS

<u>G. R. Allen</u>^{1, 2} & V. S. Patel², ¹ School of Agricultural Science, Univ. of Tasmania, GPO Box 252-54, Hobart, Tasmania, 7001 Australia, E-mail Geoff.Allen@utas.edu.au; ² CRC for Sustainable Production Forestry, GPO Box 252-12, Hobart, Tasmania, 7001 Australia.

The eucalyptus leaf beetle Chrysophtharta agricola has been identified as a major threat to plantations of Eucalyptus nitens in Tasmania. We set up a replicated natural enemy exclusion experiment, across 3 yr old plantations separated by at least 20 km, to examine the impact of natural enemies on the survival of C. agricola in the field. Beetle mortality was assessed at egg, larval and pupal stages using uncaged and 'entire' tree caged treatments. After assessment of egg mortality, six selected branches on all experimental trees were loaded with clutches of first instar beetle larvae (ca. 30 larvae per clutch). Overall mortality and spatial variability in mortality both within and between trees was regularly monitored until emergence of adult beetles. Pupal mortality was assessed using litter cages, dug prior to commencement of the experiment, under each tree. To identify the parasitoid complex and the host stages attacked clutches of 'sentinel' or trap larvae exposed for the duration of each instar were seeded on further treees within the plantation. At least three primary parasitoids (two tachinids and one braconid) and one hyperparasitoid were present in the parasitoid guild which showed temporal separation in their timing of attack. Overall mortality in uncaged treatments exceeded 99 % across all plantations and was spatially variable both within and between trees. Variability in uncaged treatment survival was greater within trees than between trees with spider predation having a large impact on intra-tree larval survival. Within a plantation average mortality of uncaged larvae was up to 10 fold greater than for controls with the majority of loss in control cages occurring within the first few days of larval establishment. Natural enemies were concluded to have a significant impact on populations of C. agricola. Since the majority of larval damage is done in the fourth or final larval instar, yet control decisions are made in earlier instars, beetle monitoring protocols that account for spatial variability and the temporal patterns of both natural enemy attack and parasitoid induced mortality may need to be devised. Landscape approaches to the management of leaf beetles and their natural enemies should also be considered.

Index terms: Chrysophtharta agricola, parasitoids, tachinids, Chrysomelidae, forest insects

[1897] PEST INSECT IN EUCALYPTUS FOREST PLANTATION ON TABASCO STATE, MEXICO

I.Izquierdo, F.C. Gilli & J.L.Soberano, Desarrollo Forestal S.A. de C.V. Calle Sindicato de Agricultura, 701. Colonia López Mateos. 86040 Villahermosa, Tabasco, México. Phone (+5293)14-3672, 14-2654. E-mail: Erro! Indicador não definido. and forgivez@usumacinta.com.mx.

Through the last years the increasing demand for forest products has motivated the establishment of commercial forestry plantations over the world. This activity is in its early stage in Mexico, mainly in the tropical humid zone, where the state of Tabasco is located, using tropical fast growing species of Eucalyptus genus. The variety of crops found in the region and the different management practices allow the presence of problems like pest insects and diseases that could have an important negative economic impact. This paper shows a list of insects considered as a pest, which are affecting the growth rate of eucalyptus plantations. The data was obtained on a monitoring program from our initial plantation, which covers an area of 1,000 ha spread in different regions of the state, from 1994 through 1999. The field observation and collection of entomological material were carried out monthly through visual inspections and collecting methods. The pest insects were classified according to the development stage of the plantation and the economic importance of damage. From this field research we found that the most important pest insect species is the leaf beetle Metachroma inconstans, which causes severe perforations in the leaves, damaging the top of the plant, causing a growth delay, forking and the death of the plant. The leaf cutter ant Atta cephalotes and Acromymex sp cause strong defoliation on small plants, retarding the development or in severe repeated attacks, the death of plants. These species are considered the second pest in economic impact. The buprestid Psiloptera sp and the weevil Pantomorus albicans are secondary insect pests, causing scrapes in the stem promoting the drying of plants. At one-year-old plantations, the butterfly larvae attacks occur with slight or severe level of defoliation, causing the plant growth to delay. The most important species in this category is Sarsina violascens and others with lesser importance such as Notodonta sp, Eupseudosoma sp, Estigmene acraea and Automeris sp. The underground termite Coptotermes crassus is considered one of the most important pest insect attacking mature plantations with damage to the wood and root system. Other species of minor importance is the ambrosia beetle Xyleborus sp, several species of cerambycids and buprestid cause stem galleries, propitiating the entrance of pathogenic agents.

Index terms: Metachroma inconstans, Coptotermes crassus, Eucalyptus, Atta cephalotes, damage

[1898] BODY SIZE DISTRIBUTION OF CARABIDAE IN RELATION TO PRIMARY PRODUCTIVITY IN THE BOREAL FOREST OF NORTHERN SWEDEN

B. E. Aava, Dept. of Animal Ecology, Swedish Univ. Agri. Sci., S – 901 83, Umeå Sweden. e-mail: birgitta.aava@szooek.slu.se

Body size distributions at large scale have been shown to be positively skewed for most assemblages of animal taxa. A number of explanations have been put forward to explain this phenomenon. Among them are energetically related models. However, these models are primarily aimed at explaining the skew for mammalian assemblages, which are certainly dependent on energy for their growth. But, how general are these energetic models? Do they apply to other taxa (like arthropods? If energy is of any functional importance for size distributions of arthropods then we should expect to see differences in frequencies of sizes between sites varying in primary productivity. If energy availability has an effect on the size distribution it may be by setting a limit to how similar in size species within the same guild can be in a local community. This would lead to species being more similar in size where energy availability is good than where energy is limited. Also, species may on average be larger in more productive sites. I examined the effects of primary productivity on the distribution of body lengths of carabid beetles in seven 10 year old clear-cuts of boreal forest stands in the county of Västerbotten, Sweden. The hypothesis was that there would be fewer size classes of carabids in more productive sites and that these sites would contain more of larger sized species than less productive sites. Preliminary data suggest that there is no such relationship.

Key-words: Body size; Primary productivity; Arthropod; local scale

[1899] RESPONSES OF THE PINE PROCESSIONARY MOTH THAUMETOPOEA WILKINSONI TO EXTRACTS OF THE CHINABERRY TREE, MELIA AZEDARACH

E. M. Abou-Fakhr Hammad¹, J. A. Nasr¹ & N. M. Nemer¹, ¹Faculty of Agricultural & Food Sciences, American Univ. of Beirut, 850 3rd Ave. 18th Fl. New York, NY 10022-6297. E-mail: efat@aub.edu.lb.

Outbreaks of T. wilkinsoni were reported lately on Pinus halepensis Mill. and P. brutia Tenore in Lebanon. A comparative study was performed among aqueous extracts of M. azedarach and certain biorational insecticides: Azadirachtin (3%) and Bacillus thuringiensis var kurstaki formulations. Leaves or fruits of Melia were extracted in water at a ratio of 1:5 (w/v) for overnight. The leaf and fruit extracts were tested at 0, 12.5, 25, 50 and 100% concentrations with 3 methods of application: topical application on larvae, introducing larvae after treating pine needles, and topical application on larvae and needles simultaneously. Data on number of dead larvae after treatment were recorded daily. Results have shown that there were significant differences in % mortality among treatments against 1st larval instars. Extracts of *Melia* fruits (100%) and leaves (100%) have caused mortality of 50-96% compared to that of the control, 5.5%. Dipel[®] was comparable in its effect to these extracts at 48 h and above, whereas MVPII[®] was comparable in its effect at 96 h. For 2nd larval instars, there were significant interactions among treatment and method of application at 24, 48 and 96 h. The fruit extract (100%) topically applied have caused the highest mortality followed by MVPII® and fruit extract (100%) topically applied on needles and larvae. At 96 h, the fruit extract (50%) caused mortality of 94% and 78% when applied on needles and over larvae and needles. respectively. At 72 and 120 h, there were significant differences among treatments. The fruit extract (100%) and MVPII® have caused mortality of 94% and 89% respectively at 72 h, but 100% mortality was detected at 120 h. For 3rd larval instars, there were significant interactions among treatment and method of application at 24, 48, 72 and 96 h. The fruit extract (100%) topically applied over larvae was comparable in its effect to MVPII® applied over larvae and needles. At 120 and 144 h, the fruit extract (100%) caused a significant larval mortality of 85% and was comparable in its effect to Azatin®, MVPII[®], and Dipel[®]. Fruit extracts (50%) were comparable in their effect to fruit extracts (100%) only at 144 h. Data analyses have shown EC_{50} values for second instars of 44 mgeq/ml of fruit extract applied on needles and 32 mg-eq/ml of fruit extract applied on larvae and needles at 5 days after treatment. BC_{so} values of 52 and 132 mg-eq/ml of fruit and leaf extracts, respectively, applied on needles against 3rd instars at 6 days after treatment were determined. Thus, Melia extracts were found to be effective against larvae of the pest indicating a potential insecticidal activity.

Index terms: Botanicals, Biorational Insecticides, Pinus sp

[1900] MANAGEMENT OF REFORESTATION INSECTS: FIRST STEP OF SUSTAINABLE FORESTRY

R.I. Alfaro, Research Scientist, Pacific Forestry, Centre, 506-W Burnside Rd., Victoria, BC. Canada.

The white pine weevil, Pissodes strobi Peck, is an indigenous insect of North America, and can be found in most regions of Canada and the United States. In British Columbia (BC) this insect has become a serious pest of reforestation, causing severe damage to young stands of Sitka spruce, Picea sitchensis (Bong) Carr., Engelmann spruce, Picea engelmannii Parry, white spruce, Picea glauca (Moench) Voss, and their hybrids. Attacked trees take to several years to recover. In this process, branches from the uppermost whorl below the damaged terminal compete for dominance, and the tree remains for one or more years with multiple leaders. Depending on the number of internodes destroyed and the growth characteristics of the tree, a permanent stem defect could form at the point of injury. Losses in severely infested stands, due to reduced growth and defect, can be as high as 40% of the stand volume. This paper describes the conditions that make stands of spruce (Picea spp.) susceptible to attack by the white pine weevil in British Columbia and discusses a pest management system which combines silviculture tactics with host genetic resistance. The system relies on restoring ecosystem balance by reducing the conditions that lead to outbreak development. The system recommends tactics that diminish heat accumulation in the stand by encouraging growth of suitable non-host conifers as well as an overstory of deciduous species such as aspen or alder. These conditions render the stand cooler and shadier, reduce oviposition sites and food supply because trees produce short, thin leaders, and may create conditions which enhance natural enemy populations. Reduction of stem defects by sanitation thinning and by planting at close spacing is also recommended. Central to IPM is the continuous monitoring of weevil populations and forecasting of weevil impacts on forest productivity. This can be accomplished through a computerized decision support system, which helps to evaluate the need for, and the possible benefits of a given tactic.

[1901] ARTROPODS DIVERSITY IN SEABIRDS COLONIES: APPLIED TO PHALACROCORAX ARISTOTELIS OF ISLANDS CIES AND ONS (NW PENÍNSULA IBÉRICA)

A. J. Alonso¹ & J. Garrido¹, ¹Dept. de Ecologia y Biologia Animal, Univ. de Vigo, Lagoas-Marcosende 36200, Vigo, Spain, E-mail aiap@uvigo.es and jgarrido@uvigo.es.

In this paper we studied the composition, diversity and trophic relation to arthropods fauna in 19 nests of cormorant (*Phalacrocorax aristotelis*), collected in two sites in NW Spain (Cies and Ons Islands) during 1997. At first, we made a faunistic study where the presence of high number of mites, spiders, ticks, flies, beetles and fleas are constated. Several colonies have been studied in three different breeding phases, except the ectoparasite fauna, most of arthropod fauna prefer to nest in the feeding phase where the organic materia contribution and relativity humidity is higher, in all phases the saprofagous mites are the most abundant group. With the fauna data, we studied the trophic relationship between the different groups, a modelic diagram of energy has been elaborated. Of the 84 present families in the cormorant nests, a large proportion of arthropod families found occurs there occasionally, and penetrated of the circundant habitats, only some families of mites, saprofagous fly larvae and depredators beetles find suitable conditions to survive and develop their life cycle in the nests.

Index terms: bird nest, nest fauna, arthropods.

[1902] RELATIONSHIP BETWEEN TICKS AND SMALL WILD MAMMALS IN A DISTURBED ATLANTIC FOREST FRAGMENT IN ITAPEVI COUNTY, STATE OF SÃO PAULO, BRAZIL

D. M. Barros-Battesti¹, V. C. Onofrio¹, S. M. Simons¹, R. S. Paço¹, M. Miretzki², V. L. N. Bonoldi³ & N. H. Yoshinari³, ¹Lab. Parasitologia, Inst. Butantan, Ave. Vital Brazil, 1500, 05503-900, São Paulo, SP, BR, E-mail-dbattest@usp.br; ²Museu de Hist. Nat. Capão da Imbuia, Dept. Zoo., PMCPR, R. Benedito Conceição, 407, 82810-080, Curitiba, PR, BR, ³Dept. Clínica Médica, Fac. Med., Univ. São Paulo, Ave. Dr. Arnaldo, 455, 01246-903, São Paulo, SP, BR, *Supported by FAPESP.

From January to December 1999, ticks were studied in a fragment of Atlantic Forest in a residential condominium, in the city of Itapevi, State of São Paulo. We investigated the relationship between ticks and hosts, observing the ticks' monthly and seasonal relative density indices (TRDI) and infestation indices per host group. Mammals were captured in monthly trappings carried out for five consecutive days. A total of 163 small mammals were trapped. Of these, 39,3% were infested with 186 ticks. Rodents were infested only by immature ticks, identified as Ixodes didelphidis (N=12), I. loricatus (N=8) and Amblyomma aureolatum (N=13). In these hosts, the higher monthly TRDI was recorded in August, and the higher infestation index occurred in June (during the dry season). Immature Ixodes ticks were collected only on Oligoryzomys nigripes and Bolomys lasiurus, and immature ticks of A. aureolatum were collected on Euryzygomatomys spinosus and on B. lasiurus. The marsupials were infested by adult and immature ticks. The adult ticks were identified as I. didelphidis (N=48), I. loricatus (N=61) and A. aureolatum (N=1). I. didelphidis was collected during the whole year but I. loricatus was more collected during the rainy season than during the dry season. The immature ticks found on marsupials were identified as A. cajennense (N=41), I. loricatus (N=1), and Haemaphysalis juxtakochi (N=1). The higher monthly TRDI and infestation index on marsupials were recorded in October (rainy season), when the highest number of specimens of immature A. cajennense ticks were collected. The difference between the proportion of tick stages per host group, during both seasons, was significant according to Fisher test (P<0.05). An increase of the parasitism of Amblyomma on small wild mammals, when compared to previous studies in this area (where human cases of Lyme-like illness were recorded), was observed. These species of Ixodes and Amblyomma, as well as some small wild mammals, have been found naturally infected with unidentified spirochetes. As such, the increase of Amblyomma on these hosts can contribute to the increase of human infection risk, since both species bite people as well as domestic animals. Index terms: Ixodes - Amblyomma - tick/host infestation indices

[1903] FOREST SOIL CLASSIFICATION BASED ON COLLEMBOLA FAUNA

L. De Bruyu^{1,2}, W. Jacobs², F. Janssens², S. Thys², F. Hendrickx³, D. De Bakker⁴, K. Desender⁴, J.P. Maelfait^{1,3} & B. De Vos⁵, ¹ Inst. Nature Conservation, Kliniekstr. 25, 1070 Brussel, Belgium; ² Dept. Biology, Univ. Antwerpen, Groenenborgerlaan 171, 2020 Antwerpen, Belgium; ³ Lab. Ecclogy, Univ. Gent, K.L. Ledeganckstr. 35, 9000 Gent, Belgium; ⁴ Dept. Entomology, RBINSc, Vautierstr. 29, 1000 Brussel, Belgium; ⁵ Inst. Forestry and Game Management, AMINAL, Gaverstr. 4, 9500 Geraardsbergen, Belgium; E-mail: luc.de.bruyn@instnat.be.

It has been stated by several authors that the abundance, species diversity and life history characteristics of Collembola can serve as excellent ecological indicators of the state of the environment. Specific community characteristics may reveal properties of the habitat that would otherwise be difficult or even impossible to quantify by measuring physical factors or based on vegetation revelés. In the scope of a research project on the occurrence, diversity and bio-indicative value of terrestrial invertebrates, a multitude of arthropod taxa were sampled in 56 forest plot (40 woods) in Flanders (Belgium). The main aim was to classify the forest soils based on the sample animals or animal groups. Collembola were collected with a core sampler (\Box =5cm; depth=10cm) and extracted with a modified McFayden apparatus. In all, about 14 000 specime belonging to 41 species were collected. Collembola community composition, structure and functionality were related to forest soil characteristics (texture and chemistry), vegetation structure and composition, and geographical and landscape ecological setting (forest area, isolation, ...). In general, the Collembola communities fall apart along a soil texture gradient while there is a tendency that the species are grouped according to the main tree species. Index terms: ecological indicators, habitat afinities

[1904] THE EFFECT OF THE INTRODUCTION OF A PINUS CARIBAEA PLANTATION ON THE ANT'S POPULATIONS OF VENEZUELAN SAVANNAS

<u>I. Bulla¹</u>, W. Goytía² y R. Candia¹, ¹Instituto de Zoología Tropical, Fac. Ciencias, UCV, Apdo 47058, Caracas 1041-A, Venezuela, FAX= 605-2204, Email: Ibulla@strix.ciens.ucv.ve.; ⁽²⁾ IDECYT, Univ. Simón Rodríguez, Apdo 47925, Caracas 1041-A. This work was financed by the ISC Program of the European Commission, Project CT 94-0099 VE.

During the last 30 years large plantations of Pinus caribaea were introduced in Monagas State (Venezuela), replacing most of the original savanna vegetation by pine forests and abandoned fields. This change greatly affected the arthropod's fauna of this system. In this article we will analyze their effect on the ant's populations. Ants were sampled using pitfall traps in 7 sites; 1) S1, a Trachypogon plumosus natural savanna that will be used as a baseline; 2) S2, an "island" savanna of 5 ha, completely surrounded by tall (over 10 m) pines; 3) S3, an Axonopus canescens natural savanna (a second baseline); 4) P1, a stand of pines four years old, with remnants of savanna vegetation among the trees; 5) P2, a stand of pure pines 12 mts high, ready for harvest; 6) P3, an area recently harvested, almost bare, with logs and twigs over the ground; 7) P4, similar to P3 but 4 years old. Ten pitfall traps were located in each site and collected monthly. Here we report the results of August (peak rainfall) and November (beginning of drought). A total of 74 species of ants were collected. The most important genera were Pheidole (16 spp), Camponotus (8 spp) and Solenopsis (5 spp). There is little change in the composition of the community between the rainy season (60 spp) and the drought (64 spp), but there are important differences among the 7 sites. Maximum diversity was achieved in P4, the abandoned field 4 years old (35 spp). The natural savannas were poorer with 21-23 spp. The island savanna S2 showed slightly higher diversity. The recently harvested area P3 had a surprisingly high diversity, considering its lack of resources (very scarce vegetation and little cover), of 17 spp in August and 22 spp in November. This is a very rapidly changing system. There is a definite change in the composition of the community as we move from the natural savanna to the mature pine forest and the abandoned fields, with species that characterize each step of the process. P4, the 4 years old field shows signs of recovery of the original fauna, but it seems that many years will be required to complete the process. Index terms: diversity, ants, savannas, pine forest

[1905] WATER STRESS EFFECT ON WORKER CUTTING-ANTS OF ACROMYRMEX HISPIDUS ON THREE ORIGINS OF EUCALYPTUS GLOBULUS GLOBULUS

P. Caffarini¹; <u>A. Peliçano¹</u>; P. Carrizo² &J. Lemcoff¹, I Facultad de Agronomía, Univ. de Bs.As., Av. San Martín 4453 (1417), Cap.Fed., Argentina apelicano@mail.agro.uba.ar, 2 Facultad de Ciencias Agrarias y Forestales, Univ. La Plata, Calle 690 y 119 (1900), La Plata, Argentina

The present study evaluates behaviour changes on worker cutting-ants of Acromyrmex hispidus, because of water stress on its host, Eucalyptus globulus. The influence of three different origins of eucaliptus named Jeeralang, Moogara and Otways National Park on these changes was also tested. The experimental arena was an artificial ant nest kept at 24 +/- 2 C, 80 % of relative humidity, and 12:12 hours of light:darkness. Ants were offered one stem 15 cm long with leaves for each treatment and origin, that were randomly distributed along that arena. This was done six times in a consecutive way. Between those assays, ants were offered other hosts, to prevent them from being acostumed. To create stress conditions, gardening was raisingly restricted for four weeks in the nursery, before samples were taken. Total and eaten Iraf surface was measurdby means of a foliar area gauge. Results, as a percentage of eaten surface by origin and treatment was tested by means of Tukey non-aditivity teste. The test was not meaningful (P=0,455), and transformations were not necessary before performing stadistic analysis. Averages were compared by means of two-way ANOVA (treatment and origin)and Tukey. Eaten average surfaces were significaty differents 31,295 % for the stress treatment and 3,125% for the control (P+0,0004). On the hand eaten average surface by origin was not significantly different (P=0,12). It is known that plant host susceptibility is enhanced as a result of stress. This is a consequence of a different chemical compounds, as a decrease in monoterpens production , tanines and others sustances. However, those tests are performed by direct damage, this means for those insects who really eat the plant. Worker-cutting ants do not use it this way, but it is a substrate for the fungi they feed from, so another response can be expected.

Index terms: preference, eucaliptus, cutting ants

[1906] OCCURRENCE AND DAMAGES CAUSED FOR ONCIDERES SAGA (COLEOPTERA: CERAMBYCIDAE) IN ARBORIZATION

A. G. Carvalho¹, J. G. N. Wendt¹, J. M. Pinto², A. M. Lunz¹ & S. R. S. Ventura¹, ¹Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil; ²Depto. Fitotecnia, Univ. Fed. Rural do Rio de Janeiro. E-mail: acacio@ufrrj.br.

The species of the Leguminosae as the Acacia mangium, Albizzia lebbeck, Clitoria fairchildiana, Delonix regia, Cassia fistula, Cassia javanica, Samanea saman, Piptadenia rigida, Bauhinia forficata and Inga edulis. They are among the more used in the urban arborization of the state of Rio de Janeiro, even so to the these, several insects are associated, among these meet the coleopterans that occupy a prominence position in these forest essences in a general way. Inside of this context it is found the species Oncideres saga (Coleoptera, Cerambycidae), whose popular name is "sawyer", which has been causing damages in the crowns of the species used in the urban arborization in the state of Rio de Janeiro, once the O. saga is known as one of the species more poliphagous, and this coleopteran damages branches and trunks with a great diameter width. This work was accomplished in NUCLEP in the municipal district of Itaguaf, RJ, where were collected and measured all the cut branches, being measured the length of the base of the branch wholesale to the apex of the same, considering the bifurcation of larger extension and the diameter in the base of the branch, where was took place two readings in positions opposed for the obtaining of the medium diameter of the fallen damaged branches on the soil or arrested to the crowns of the trees. The arborization is composed by the following essences: C. fairchildiana, B. forficata, A. lebbeck and D. regia and the number of branches cut by the O. saga was of 2, 3, 111 and 8, respectively, being evaluated therefore a total of 124 branches. The length measures, in meters, for to C. fairchildiana, B. forficata, A. lebbeck and D. regia were of 3.81 ± 2.07 ; 2.76 ± 0.95 ; 2.86 ± 0.66 and 3.36 ± 0.66 0.78 respectively. The found medium diameters, in cm, were of $3,89 \pm 1,26$; $3,25 \pm 0.92$; $3,57 \pm 0.79$ and $3,82 \pm 0.77$ for C. fairchildiana, B. forficata, A. lebbeck and D. regia, respectively. It is ended that the damages provoked by O. saga cause serious damages to the crown and the shaft of the essences that compose the arborization of NUCLEP. A. lebbeck is the dominant essence in the arborization and the most susceptible to the sawyer. Index terms: Urban arborization, "Sawyer".

[1907] ANALYSIS OF THE DAMAGES CAUSED FOR ONCIDERES SAGA (COLEOPTERA: CERAMBYCIDAE) IN A FORESTRY REMNANT IN THE CAMPUS OF UFRRJ, BRASIL

<u>A. G. Carvalho¹</u>, A. M. Lunz¹, M. C. Machado¹ & S. R. S. Ventura¹, ¹Depto. Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: acacio@ufrij.br.

The family Leguminosae counts inside with several species of the Campus of the Universidade Federal Rural do Rio de Janeiro, so much in planted areas as in regeneration, as Mimosa caesalpinaefolia, Inga edulis, Cassia grandis and Samanea saman. The main group of insects associated to these species is the order Coleoptera, where stands out the family Cerambycidae, whose habit of to yearn and to cut branches and even shafts for accomplishment of postures cause great damages to the crowns of the trees. The species Oncideres saga, well known as "sawyer", it is one of the ones that attack a great number of forest species. This work was accomplished in a forestry remnant in the Campus of UFRRJ, close to the Institute of Forests. The diameter of the cut branches was obtained through two readings in positions opposed in the area cut for obtaining of the medium diameter, and the length was measured of the base to the apex of the cut branch. The number of branches cut by O. saga was of 351, being three of M. caesalpinaefolia, five of I. edulis, eight of C. grandis and 335 of S. saman. The found medium diameters, in cm, were of $3,50 \pm 0,33$; $2,64 \pm 0,36$; $2,95 \pm 0,67$ and $3,43 \pm 0,82$ for M. caesalpinaefolia, I. edulis, C. grandis and S. saman, respectively. Already the medium lengths, in meters, for this sequence of species were of $3,87 \pm 2,03$; $1,62 \pm 0,74$; $1,68 \pm 0.98$ and $2,58 \pm 1,23$. It is ended that O. saga causes considerable damages in area with regeneration of native and exotic species, and that the species S. saman is the most susceptible to the attack of this insect.

Index terms: "Sawyer", Mimosa caesalpinaefolia, Inga edulis, Cassia grandis, Samanea saman.

[1908] SUPPRESSION OF SOUTHERN PINE BEETLE INFESTATIONS USING VERBENONE, AN ANTI-AGGREGATION PHEROMONE

S. R. Clarke¹, R. F. Billings², S. M. Salom³ & C. W. Berisford⁴, ¹Forest Health Protection, USDA Forest Service, 701 N. 1st St., Lufkin, TX 75901, USA, E-mail sclarke/r⁸_tx@fs.fed.us; ²Forest Pest Management, Texas Forest Service, P.O. Box 301, Lufkin, TX 75902-0310, USA; ³Dept. of Entomology, Virginia Tech, Blacksburg, VA 24061-0319, USA; ⁴Dept. of Entomology, Univ. of Georgia, Athens, GA 30602, USA.

The southern pine beetle (SPB), Dendroctonus frontalis, is a destructive forest insect pest of pines throughout the southeastern United States, Mexico, and Central America. Cut-and-remove or cut-and-leave treatments are effective in suppressing expanding infestations and reducing impacts, but new tactics are desired which limit the numbers of trees felled, particularly the uninfested trees. Operational methods for two such tactics using verbenone, an anti-aggregation pheromone produced by SPB, have been developed and successfully tested in the southeastern United States. The verbenone-only and verbenone-plus-felling treatments reduce or eliminate the need for tree-felling and thus are compatible with management objectives for sensitive or protected areas such as parks or wilderness. Verbenone pouches, the elution device, are tacked at ca. 4 m to trees either under attack or in a buffer strip around the expanding "spot head". Tables give the number of pouches required per tree and infestation, based on tree diameter and the number of currently-infested trees. A web-site providing training in the use of the two tactics is available for potential end-users. The U.S. Environmental Protection Agency recently registered verbenone, but treatments have not become operational to date. Refinement of the treatment methods continues, and current studies test new elution devices and lower pouch placement height. Trapping studies are also underway to identify other semiochemicals that may improve treatment efficacy when used in combination with verbenone. Trapping studies conducted in 1999 in Honduras suggest that verbenone tactics may also be effective in SPB spot suppression in that country. We plan to test the efficacy of verbenone treatments on SPB infestations throughout the range of the beetle. Index terms: Dendroctonus frontalis, semiochemicals, bark beetles.

[1909] MORPHOLOGICAL CHARACTERISTICS OF NESTS AND CONTROL OF ATTA SEXDENS RUBROPILOSA WITH GRANULATED BAITS IN A PLANTATION OF PINUS TAEDA, SAFAC, WANDA, MISIONES

<u>Q. R. de Coll</u>¹, W. Lange¹, R. A. Friedl¹ & T. M. C. Della Lucia², ¹ Email:odecoll@inta.gov.ar; ²tdlucia@mail.ufv.br

Leaf cutting ants limit agricultural and forest production. Leaf-cutter ants of genus Atta are distributed in the whole province of Misiones, and are pests is of great economic importance because of the damage they cause. They are measured to estimate the surface area and to apply the granulated baits for controlling the ants. The external morphological characteristics of the nests are thus important to determine the correct dose to apply. The main current problem is the correct mensuration of the earth mound. The aims of the present work are to determine the morphlogical characteristics of the nests and the most efficient dose of the granulated bait with sulfuramide in the control of Atta sexdens rubropilosa. Nests were marked in a 19,5 hectare plantation of Pinus taeda of deep red soil belonging to the SAFAC, S. A. company, in the town of Wanda, Misiones, Argentina The assay with granulated bait was carried out in December of 1997. In the plantation, 33 m wide strips were defined and the geographical coordinates of the nests were measured. Values of estimated surface area and volume of each nest were obtained from mathematical formulae, once their leght, width and height were determined. The calculated surfaces were those for the rectangle and the ellipse; the volume was that of a fustrum of right circular cone. The treatments with the sulfluramide bait (0,3 %) HBT 347 consisted of application of 6, 8, 10 y 12 g/m² calculated as a rectangle, a positive control with 10 g/m² of dodecachlor (0,45%) was also used, as well as a negative control, without bait application. The statistical design used was a completely randomized experiment with 6 treatments and 8 replications per treatment. The attractiveness of the granulated bait was evaluated by observations 24, 48 and 72 h after application. Inactive nests were checked after 15, 30, 60, 90 y 303 days. Six nests were selected for excavation after 153 days. Spatial distribution of the nests of A. s. rubropilosa in the pine forest were of contagious type, with 120 m² of nests per ha, with a maximum of 128 m² and a minimum of 9,7 m². The average density was 2,51 nests per ha. The nests of larger area and volume were found The average density was plantation. The nest of maximum area had $33,12 \text{ m}^2$ and that of minimum, $30,18 \text{ m}^2$, with a standard variation of 2,079 m². The volume average was 14,36 m^{3} (maximum 58.32 m³ and minimum, 4,43 m³). The analysis of the results showed that 6 and 8 g/m² were the most effective doses of sulfluramide bait. The number of inactive nests increased with time; 100% of them were inactive at the end of 303 days. On the other hand, 25 % of the nests treated with either 10 or 12 g/m² were still active at that time. Index terms: leaf-cutter ants, nets, control, sulfluramide, Pinus taeda.

[1910] FAUNA OF LEPIDOPTERA IN A TRANSECT OF NATIVE VEGETATION- *EUCALYPTUS* PLANTATION IN IPABA, MINAS GERAIS, BRAZIL

O.T. Dall'Oglio¹, <u>I.C. Zanuncio¹</u>, ¹ Dept. Biologia Animal, Univ. Federal de Viçosa, Viçosa, Minas Gerais, Brasil, 36.571-000, E-mail onice@insecta.ufv.br; zanuncio@mail.ufv.br.

Lepidoptera defoliators are important pests of Eucalyptus in Brazil because forest monocultures represent simplified ecosystems where herbivore insects can be more abundant and cause damage. The maintenance of understorey vegetation and the preservation of strips and remnants of native vegetation have been recommended as a strategy to increase environmental heterogeneity and consequently the diversity of species of insects in reforested areas. The objective of this research was to study the fauna of Lepidoptera in three situations: Eucalyptus, area of transition native vegetation/Eucalyptus and within a fragment of native vegetation in Ipaba, Minas Gerais, Brazil, from April 1997 to March 1998 with five light traps. The first and the second traps were installed in the Eucalyptus plantation at 400 and 200 meters of the transition native vegetation/Eucalyptus; the third in this transition; and the fourth and the fifth light traps inside the native vegetation, at 200 and 400 meters from the transition. Lepidoptera collected were divided in the following groups: i) group 1, primary pest (those species previously recorded in outbreak conditions in Eucalyptus plantations); ii) group 2, secondary pests (species that feed on Eucalyptus but not in outbreak conditions); iii) group 3, species without defined importance to Eucalyptus; and, iv) group 4, non identified species. A total of 20,606 individuals were collected, being 1,808 of group 1; 231 of group 2; 8,874 of group 3 and 9,693 of group 4. Out of 2,039 individuals of primary and secondary pests, 2.94% were only collected in the fragment of native vegetation; 18.69% in the transition native vegetation and Eucalyptus and 78.37% in the Eucalyptus plantation. The species without defined importance to Eucalyptus were collected in higher numbers within the Eucalyptus at 200m from the transition and in the transition with 38.40 and 31.61% of the individuals, respectively, while the group of non identified species presented higher number of individuals in the transition of Eucalyptus with the native vegetation with 37.88%. Pest species presented higher number of individuals per species in the Eucalyptus plantation than in the transition and in the native forest, while non-pest species presented similar number of individuals per species in all points. This shows that areas of native vegetation intermingled with *Eucalyptus* plantations can contribute to a larger diversity of species and to the reduction of the number of individuals of the Lepidoptera pests in these plantations.

Index terms: Insecta, Eucalyptus, pests, forest remnants

[1911] ARTHROPODS IN RELATION WITH ARAUCARIA ARAUCANA: AN APPROACH TO ITS BIODIVERSITY IN ARGENTINA

<u>G. Dapoto</u>, H. Giganti, M. Bondoni & M. Gentili, Depto. Biología Aplicada, Un. Nac. del Comahue, C.C. 85, 8303, Cinco Saltos (R.N.), Argentina. E-mail: gdapoto@uncoma.edu.ar

Araucaria araucana (Araucariaceae) is a native conifer from Argentina and Chile spread mainly over the Andes Mountains between 37°30' to 40° S and 900 to 1700 m o.s.l. approximately. This very old specie has a big economic, biological, social and also anthropological interest, since it was exploited with intensity until some years ago mainly for timber extraction and is in strong cultural relation with people of its spread area, specially the native. It makes different vegetative communities in Argentina. In association with Nothofagus spp:: forests with: N. obliqua, N. dombeyi and N. pumilio, placed with rainfall about 3500 mm/year and with N. antarctica and Lomatia hirsuita (Proteaceae) with less density in places with less rainfall and lower altitude. Going to the East humidity decreases, then it makes a transition with the patagonian steppe up to 250 mm/year approximately. It was studying arthropods in relation to the different associations formed by A. araucana as contribution for to know the biodiversity of this communities and then look for a sustainable development of this natural researches. The specie determined at moment: 6 Acarina in 3 families, 85 Coleoptera in 20 families, 64 Hemiptera in 2 families, 15 Homoptera in 5 families, 25 Hymenoptera in 8 families, 96 Lepidoptera in 16 families, 4 Orthoptera, 4 Diptera and specific reduced fauna of A. araucana (21 specie determined at moment that mean about 9 % of total collected) are reported in this paper.

Index terms: insects and mites, patagonian native forests, biotaxonomy.

[1913] CARABID BEETLES AS MODEL ORGANISMS IN POPULATION GENETIC STUDIES ON HIGHLY FRAGMENTED TEMPERATE FORESTS (FLANDERS, BELGIUM)

K. Desender¹, P. Verdyck¹, V. Versteirt¹ & J.-Y. Rasplus², ¹ Dept. Entomology, RBINSc, Vautierstr. 29, B-1000 Brussels, Belgium. E-mail: kdesender@kbinirsnb.be; ² Centre de Biologie et Gestion des Populations, INRA, Equipe Taxonomie et Ecologie,488, rue Croix de Lavit, F-34090 Montpellier.

Populations of many terrestrial arthropods nowadays only survive in small remnants of natural habitats. Forests in Flanders are well documented historically, but now cover less than 10% of the total surface only. Most of these forest are extremely fragmented, reduced in size and isolated. Within the context of a regional project, effects of habitat fragmentation, including historical ecology, are studied in a wide variety of forest habitat organisms. Ground beetles appear to be extremely useful model organisms in such studies. They are speciose, have a rather well known distribution both in time and space (Red data book available), are highly variable in habitat preference (stenotopic and more eurytopic species) and their dispersal power (-gene flow) is reflected in the development of hind wings and flight muscles (macropterous, brachypterous and wing polymorphic species). Population genetic results based on allozymes, studied by means of cellulose acetate electrophoresis in large samples of several forest ground beetles, invariably show a significant genetic differentiation between populations. Some of the brachypterous species show geographical isolation by distance (Mantel-tests). Highest F5T-values are obtained for rare and brachypterous species (Abax ovalis, A. parallelus and Carabus auronitens). C. auronitens, extremely rare in Flanders and limited to a few ancient forests only, shows a very high FsT value, indicating that a large proportion of its total genetic variation occurs between populations. In the near future, we will therefore also study this ground beetle by means of more powerful or completely neutral markers (microsatellites). Based on allozymes, the smallest value of genetic differentiation is found in Agonum assimile, a common and more mobile species from inundation and valley forests. Abax ater, another common forest carabid, suggests an unexpected negative relationship between genetic diversity and forest area (further study planned with microsatellites). Genetic erosion in small populations is indicated for some very rare and brachypterous carabids, which are known indicators for ancient forests. To conclude, some recommendations are given for regional nature conservation.

Index terms: Carabidae, gene flow, genetic differentiation/diversity, fragmentation.

[1912] BEETLES, SPIDERS AND FLIES AS BIO-INDICATORS IN FORESTS: A LARGE SCALE RESEARCH PROJECT IN FLANDERS (BELGIUM)

K. Desender¹, D. De Bakker¹, P. Grootaert¹, M. Pollet¹, L. De Bruyn², B. De Vos³ & J.-P. Maelfait², ¹ Dept. Entomology, RBINSC, Vautierstr. 29, B-1000 Brussels, Belgium, E-mail: kdesender@kbinirsnb.be; ² Inst. Nature Conservation, Kliniekstr. 25, B-1070 Brussels, Belgium; ³ Inst. Forestry and Game Management, AMINAL, Gaverstraat 4, B-9500 Geraardsbergen.

In 1997, a research project was started on the occurrence, diversity and bio-indicative value of terrestrial invertebrates in 56 forest stands distributed over 40 woods in the entire region of Flanders (Belgium). A complete year cycle of samples was therefore taken in these forests (mainly by means of continuous pitfall trapping for soil surface active invertebrates and the use of coloured pan traps for flying insects). The first part of the study (sampling and identification of about one month of samples for a multitude of invertebrate taxa) involved scientists from several universities [Ghent Univ. (RUG), Antwerp Univ. (RUCA) and Louvain Univ. (KUL)] and scientific institutions (region of Flanders: Institute for Forestry & Game Management and Institute of Nature Conservation; Royal Belgian Institute of Natural Sciences). In the current contribution, we report on the identification (complete year cycle) and ecological analyses of a limited number of animal taxa, i.e. ground beetles (Carabidae), spiders (Araneae) and flies (Empididae and Dolichopodidae). These arthropods are target model organisms because they are (1) well known for what concerns their taxonomy and biology, (2) speciose, (3) documented concerning their former and recent distribution in our region (Red data books), and (4) abundantly occurring in the sampled forests. Besides, a multitude of environmental variables have been quantified from each sampling forest plot. These include local forest soil characteristics (texture, detailed soil and forest floor chemistry), vegetation structure and composition, as well as geographical and landscape ecological setting (forest area, isolation, etc...). Identification of the complete year cycle from 56 forest plots (carabids and spiders) or 49 plots (flies), yields some 200.000 specimens belonging to more than 550 species. Multivariate analyses are based on habitat preference data for the most abundant species (41 ground beetles, 80 spiders, and 39 flies). Indirect and direct gradient analyses yield comparable results in each case. The most differentiated assemblages for spiders and flies primarily seem to react to soil texture and related characteristics. In carabids, on the other hand, an assemblage of large ancient forests is first distinguished from humid lowland forest communities, whereas in the second place mainly soil texture and site productivity seem to define observed assemblages. Index terms: Carabidae, Araneae, Empididae, Dolichopodidae, ecological indicators.

[1914] VARIATIONS IN THE SPECIES COMPOSITION OF CURCULIONOIDEA IN NATURAL AND PLANTED FORESTS OF CENTRAL SPAIN

L. Diodato¹, M. P. Gurrea Sanz² & A. Notario³, ¹Fac. Ciencias Forestales, Univ. Santiago del Estero, Avda Belgrano 1912, 4200-Santiago del Estero, Argentina; ² Dept. Biología, Fac. de Ciencias, Univ. Autónoma de Madrid, 28049, Madrid, Spain; ³ Dept. de Ing. Forestal. ETS Ing. Montes, Ciudad Universitaria, 28040, Madrid, Spain.

In the Central Mountains of Spain, afforestations have been carried out in the last fifty years, which has caused vegetation changes. Hence, it is currently possible to find plantations of *Pinus sylvestris* growing in natural areas that were originally covered with Quercus pyrenaica, thus resulting in landscapes where natural hardwood forests and softwood plantations are adjacent to one another. The purpose of this paper is to analyze and compare the fauna of Curculionoidea in the natural oak forests with that found in the pine plantations. Material resulting from periodic sampling procedures conducted in 1996, 1997 and 1998 in representative stands of both oak forests and pine plantations in various localities of the Sierra de Guadarrama, Madrid, Spain, has been studied. The samples were collected by using the "shaking" and "netting" methods on undergrowth plants and by "shaking" the tree canopies. Specimens belonging to 86 different species of Curculionoidea, representing the families Attelabidae, Brentidae, Curculionidae, Erirhinidae and Nemonychidae, were collected during the study. The cluster analysis conducted on the data revealed that the fauna associated with the undergrowth in both oak forests and pine plantations is the group most similar to each other, followed by the fauna from the oak canopies, while the one associated with the pine canopies constitutes a separate group. Where endemic species may be lost, it is important to consider this process, especially when land management and conservation are sought. Index terms: Coleoptera, Pinus sylvestris, Quercus pyrenaica, reforestations.

[1915] EFFECTS OF NON-NATIVE SPRUCE PLANTATION ON CARABID BEETLES

Z. Elek¹, <u>T. Magura¹</u> & B. Tóthmérész², ¹Dept. of Zoology, Kossuth L. Univ, P. O. Box 3, Debrecen, H-4010, Hungary, E-mail elekz@tigris.klte.hu and magura@tigris.klte.hu; ²Ecological Inst., Kossuth L. Univ., P. O. Box 71, Debrecen, H-4010, Hungary.

The impacts of non-native spruce plantation on carabid beetles were studied in the Bükk National Park in Hungary, Central Europe. Pitfall catches from recently established (5 years old), young (15 years after planting), middle-aged (30 years after planting), old spruce plantation (50 years after planting), and from a native submontane beech forest as a control stand were compared. Indicator species analysis (IndVal approach) shows that deciduous forest species decreased significantly in abundance in the plantations, and they appeared in high abundance only in the native beech forest. Furthermore, species characteristic of open habitat increased remarkably in abundance in the recently established plantation. Carabids were significantly more abundant and more species rich in the native forest than in the plantations, while these parameters were not significantly different among the plantations. Multiple regression between the abundance and species richness of carabids and twelve environmental measurements shows that pH of the soil, cover of the herbs and density of the carabids' prey have a significant effect in determining abundance and species richness. Our results proved that plantation of nonnative spruce species has detrimental effect on the composition of carabid communities and no regeneration can be observed during the growth of plantations even 50 years after the establishment. It emphasises the importance of an active nature management practice to facilitate the recolonization of the native species.

Index terms: carabid beetles, spruce plantation, species richness, indicator species, nature management.

[1917] WOOD LOSS IN EUCALYPTUS PLANTATIONS BY *COPTOTERMES* SP. (ISOPTERA:RHINO TERMITIDAE) IN GOIAS-BRAZIL

<u>P. M. Fernandes</u>¹; A.E.Fardin²; A. Forlin² & C. Czepak, ¹Universidade Federal de Goiás, Escola de Agronomia, c.p. 131, Cep. 74001-970, Goiânia -GO. Pmarta@terra.com.br²CODEMIN S/A, Niquelândia-GO.

Eucalyptus is the main forest species grown in Brazil with a planted area around five millions hectares. Trees attacked by termites at harvest are very common to be found however; economic losses due to termites have not been determined. This study was conducted in a eucalyptus plantation belonging to CODEMIN S/A, at Niquelândia, Goiás. The species of termites in association with eucalyptus were collected and identified. Index of plants attacked and the volume of wood per tree also was estimated. The estimates of the volume of wood lost by termite infestation were obtained from 10 trees in six sample dates: 16/04/97, 21/08/97, 28/11/97, 13/03/98, 03/09/98, and 27/11/98. The index of plants attacked by termites was determined in areas harvested in 1997, 1998 and 1999. In each patch, the evaluations of the number of trunks attacked were made about 60 days after cutting in one complete row and in each 20 rows. The main species of termites observed associate to euclyptus trees Coptotermes sp, Nasutitermes sp., Labiotermes sp., Heterotermes sp., Cornitermes sp. The genus Coptotermes was frequent found attacking central part of the trunk being the main responsible for this type of injury. The percentage of volume of wood loss by termite attack was variable among sampling dates. The highest loss was observed for Eucalyptus of species E. cytriodora and the lowest for E. urophylla with mean of 1,36%. The incidence of trunks attacked was low, ranging from 0.65 to 14.40% and a mean of 6,81%. These results allowed to conclude that mean of losses in volume of wood/ha due to attack of termites were very low and were below 0.1% in all patches evaluated.

Index terms: termites, eucalyptus, wood loss

[1916] NATURAL RESISTANCE OF TEN CUBAN FOREST SPECIES AGAINST TERMITE ATTACK

H. C. Escoto¹, N. T. Isasi-¹, J. M. Montalvo², ¹Dept. of Entomology, Forest Research Institute, 174 street no. 1723 e/ 17B and 17C. Siboney. Playa,. C. Havana, Cuba, E-mail iif@ip.etecsa.cu.

Wood samples of sapwood and hardwood of ten Cuban forest species were selected to study its natural resistance against Cryptotermes brevis (Isoptera: Kalotermitidae). Assays of alimentary selectivity and compulsory alimentation in laboratory conditions during 60 days were conducted. Species included in this work are: Cinnamomun parviflorum (White sweet potato); Laurocerasus occidentalis (Male Cuajani); Swietenia mahagoni (Cuban mahagoni); Sapium jamaicennsis. (Piniche); Colubrina arborescens (Guaguasi); Pithecellobium arboretum (Sabicu moruno); Quercus cubana (Oak); Pithecellobium obovale (Encinillo) and Zanthoxylum elephantiasis (Bayúa). The weight loss records were analyzed by the Newman-Keuls Test applied to a significance level of 5%. Results allow classifying the relative resistance of the sampled species that relating them with data from field studies will give a complete information of the resistance of these woods to termite attack.

Index terms: Cryptotermes brevis, durability, Cuban woods.

[1918] SCOLYTIDAE TRAPPINGS IN YOUNG LOBLOLLY PINE (PINUS TAEDA) STANDS

C. A. H. Flechtmann¹, D. C. Oliveira¹ & L. Cordeiro², ¹Dept. of Biology, FEIS/UNESP, Av. Brasil 56, 15385-000 Ilha Solteira/SP, Brazil, E-mail flechtma@bio.feis.unesp.br; ²Klabin do Paraná Papéis, Lagoa Fazenda Monte Alegre, 84279-000 Telêmaco Borba/PR, Brazil, E-mail leordeiro@klabinpr.com.br

Tropical (Pinus oocarpa and Pinus caribaea) and subtropical (Pinus taeda) pines comprise ca. 35% of the total reforested area in Brazil. Native Scolytidae beetles, the great majority of them originally found on hardwoods, are quickly adapting to these exotic pines. These insects are among the most important pests in temperate forests throughout the world, and they are quickly becoming important in Brazil, where they are growing in abundance and diversity. The results presented here originated from an experiment originally designed to monitor Scolytidae populations from implantation until harvest of a stand of pines, and to correlate/predict them through a time series analysis which includes factors as various as thinning, stand age, temperature, rainfall, humidity, delimbing, and stand density among others. The trap used was a vane flight intercept trap type baited with 95% ethanol, released at a rate of ca. 0.52 g/d at $21\Box C$, and deployed in a *Pinus taeda* and *P. taeda* \times *P. elliottii* hybrid stands, owned by Klabin do Paraná Papéis, and located in Telêmaco Borba, Paraná state, Brazil, The site (originally *P. taeda*) was harvested in November 1997 and planted in March 1998; stumps and abundant slash were present. Areas surrounding the experimental site were composed of woods (native vegetation), young loblolly pine and old loblolly pine (ranging from 13 to 22 yr old). Traps were placed in a 5 x 5 grid, spaced 100 m apart, on 11 June 1997, and beetles trapped were collected every 7 d. After 82 wk, in total 331,930 scolytid specimens (47 species) were trapped, the majority of them ambrosia beetles. The most abundant species were Xyleborus ferrugineus (90.8% specimens), Hypothenemus eruditus (8%), Xyleborinus linearicollis (0.7%) and Hypothenemus obscurus (0.3%). Results indicate that X. ferrugineus is developing in stumps and slash of larger diameter, while the remaining 3 species were developing in smaller diameter slash. "Border" traps (traps at the outer margin of the grid of 25 traps) caught significantly more specimens than "inner" traps for X. ferrugineus and H. eruditus, maybe due to a combination of competition among traps (border traps compete less with other traps than inner traps) and immigration of scolytids from nearby stands (there is a greater chance of those incoming beetles to meet a border trap than an inner trap). Traps closer to older stands (woods and old pine) caught significantly more individuals of the 4 species mentioned above than in traps closer to young loblolly pines. Index terms: ambrosia beetles, trap competition, scolytid migration, Xyleborus ferrugineus, Pinus taeda.

[1919] RESPONSE OF BRAZILIAN AMBROSIA BEETLES (COLEOPTERA, SCOLYTIDAE) TO KAIROMONES AND PHEROMONES

C. A. H. Flechtmann¹, V. L. S. Sagi¹ & L. Cordeiro², ¹Dept. of Biology, FEIS/UNESP, Av. Brasil 56, 15385-000 Ilha Solteira/SP, Brazil, E-mail flechtma@bio.feis.unesp.br; ²Klabin do Paraná Papéis, Lagoa Fazenda Monte Alegre, 84279-000 Telêmaco Borba/PR, Brazil, E-mail lcordeiro@klabinpr.com.br

Reforestation in Brazil is relatively new, as establishment for most of the plantations began in the mid 60's. For years pine plantations remained surprisingly free of pests, and to this date few insects constitute any regular, economically important pests. Yet, scolytid beetles, constituted mainly by xylomycetophagous ambrosia beetles, are growing in abundance and diversity in pine stands over the years, demanding constant monitoring. The main lure (if not the only one) used in traps to monitor these beetles in Brasil is the kairomone ethanol. However, it is well known that many species respond little or do not respond at all to this attractant. The objective of this experiment was to evaluate, for a Brazilian reforested stand, the attractiveness of scolytids to some semiochemicals widely used in temperate forests in North America and Europe. Multiple funnel traps (Lindgren7) were baited with the kairomones D-pinene and ethanol and the pheromones sulcatol (racemic) and (+)-sulcatol (retusol), plus a control (blank). Traps were deployed in a mature *P. taeda* stand (owned by Klabin do Paraná Papéis, and located in Telêmaco Borba, Paraná state) in 3 lines (5 traps/line); traps were 5 m apart within each line, and lines were spaced 20 m apart. Beetles trapped were collected every 7 d, at which time traps were randomized within each line to reduce positional effects. The experimental design was a randomized complete block design. In 11 wk of trapping, a total of 9,031 scolytid specimens were trapped, distributed in 35 species. The kairomone □-pinene proved unattractive to all scolytid beetles; however, it was highly attractive to an unidentified predatory Tenebrionidae. H. eruditus, H. obscurus (Cryphalini), X. gracilis, X. linearicollis, X. ferrugineus and X. retusus (Xyleborini) were significantly more trapped in ethanol-baited traps over other treatments. Despite the fact that it is assumed (however never proved) that there is no pheromone production in Xyleborini, X. adelographus and X. affinis were surprisingly clearly attracted to sulcatol- and retusol-baited traps over other semiochemicals; no X. adelographus specimens were trapped in ethanol-baited traps. Results show that monitoring can be improved with the use of lures other than ethanol, and that D-pinene could perhaps be used in pine stands as a way of concentrating scolytid natural enemies to a certain area.

Index terms: response to kairomones and pheromones, Xyleborus adelographus, Xyleborus affinis, Pinus taeda, Brazil.

[1920] DISTRIBUTION AND ABUNDANCE OF *MONOCHAMUS* SPECIES ON PINES IN ITALY

V. Francardi¹, F. Pennacchio¹, P.F. Roversi¹, A. <u>Binazzi</u> ¹& A. Leccese¹, ¹ Exper. Inst. of Agric. Zoology, Forest Entomology Section, via di Lanciola 12A, Cascine del Riccio, 50125 Firenze, I, E-mail isza@fi.flashnet.it, abinazzi@dada.it.

4 species of longhorn borers are present in Italy, Monochamus sutor (Linnaeus), M. sartor (Fabricius), M. saltuarius (Gebler) and M. galloprovincialis (Olivier), the last with two subspecies, M. g. galloprovincialis and M. g. pistor (Germar). M. sartor and M. saltuarius develop on Picea abies, Abies alba, Pinus sylvestris and P. nigra, M. sutor also on P. mugo while M. g. pistor lives on Pinus sylvestris and P. nigra; all these cerambycids are widespread in alpine and prealpine zones with continental climatic conditions. Moreover, M. g. galloprovincialis lives on P. pinaster, P. halepensis, P. pinea and P. sylvestris in Mediterranean regions. Attacks of this longhorn beetle are common also on exotic pine timber plantations (i.e., P. strobus, P. radiata and P. insignis). In the last years, the occurence in our country of hot-dry summers causing many fires especially in the N-W and, in the same time, an outbreak of the maritime pine bast scale Matsucoccus feytaudi Duc., have led to a progressive decline of pine stands in those areas causing an epidemic increasing of native populations of M. g. galloprovincialis. The possible implications for the pine stand health of the recent introduction in Europe (Portugal) of the pine wood nematode (PWN) Bursaphelenchus xylophilus (Steiner & Buhrer) which causes pine wilt diseases as well as the possibility that indigenous Monochamus can be its main vectors, lead the control of M. g. galloprovincialis populations to be attempted. Management practices aimed to the cerambycid population reduction have to be carried out mainly on the coastal zones where the climatic conditions are more favourable to the PWN possible development.

Index terms: longhorn beetles, vectors, phytopathogen nematodes

[1921] COMMUNITIES OF SOILS INSECTS ON FRENCH GUYANA INSELBERGS : A SYNCRONIC STUDY THROUGHT VEGETATION DYNAMICS

R. Garrouste^{1,2}, ¹Muséum National d'Histoire Naturelle (MNHN), Antenne de Guyane c/o IRD BP 165 F-97323 Cayenne cedex, French Guyana, E-mail : garroust@mnhn.fr; ²MNHN Laboratoire d'Ecologie, 4, avenue du Petit-Château F-91800 Brunoy, France.

Inselbergs are very common in French Guyana (FG), as well as rocky outcrops, and host a mosaic of vegetation types with floristic singularities ("savane roche"). On two average altitude granitic inselbergs in center of FG, (Le Mont Chauve and Savane Dashine) studied by a pluridisciplary team (faunistic and floristic surveys) specialy dropped by helicopter, communities of soil arthropods where studied with emphasis on insect community, as prelimary results (during the rainy season). Adaptation of a Berlese-Tullgren extraction method was used in the field, using a glasshouse-like device to insure light and dry. Vegetation dynamics is studied throught soils insects from several plots at different stages, from epiphytic bromeliad mats to forest, using ordination. Formicids are dominant, and sometimes soils termits, who plays certainly a important role in soils dynamics. Index terms : insect community, dynamics, ordination

[1922] RESIN-COLLECTING BEES (HYMENOPTERA, APIDAE) ON CLUSIA PALMICIDA (CLUSIACEAE) IN A RIPARIAN FOREST IN BRAZIL

S. J. Gonçalves-Alvim, T. C. Lana & B. D. Ranieri, Ecologia Evolutiva de Herbívoros Tropicais, DBG/UFMG, CP 486, Belo Horizonte, MG, 30161-970, Brazil, E-mail silmarv@icb.ufmg.br

Primary flower resources to bees, i.e. those that satisfy the basic needs such as feeding and reproduction, include pollen, nectar, oil, resin and gums. Although resin provides an essential resource for the reproduction of a large number of bees in tropical communities. there are few studies about resin-collecting bees on Clusia ssp. This system was studied with monthly collects made during a year (July /92 to June/93) in a riparian forest, in Alcântara (2⁰23'00"S and 44⁰25'00"N), State of Maranhão (Northeastern Brazil). An amount of 178 bees belonging to 5 genera and 9 species of Apidae were collected both in pistilate and staminate plants of Clusia palmicida (Clusiaceae). The most abundant species were Trigona fuscipennis, T. pallens, and T. fulviventris. The other species, Euglossa piliventris, Partamona sp., Eufriesea surinamensis, Eulaema cingulata, Euglossa sp. and Partamona pearsoni had less than seven specimens captured. Bee activity was checked from 0600 to 1800 h, and the highest bee activity occurred from 0600 to 1000 h. The smallest abundance of bees occurred from 1200 to 1500 hours, when the temperature was too high for bee activity. Along the year, bees were more frequent from February to June (rainy season) and the highest number of bees was obtained in the end of the rainy season and the beginning of the dry season (in July). The smallest abundance was in October. We also found a positive correlation between number of individuals and number of bees species along the year (Pearson's correlation index = 0.69, P < 0.05). The highest frequency of large bees, such as Eulaema, Eufriesea and Euglossa, was observed in the staminate flowers of C. palmicida that have a greater load of resin. Visits of larger bees on pistillate flowers were less frequent. In addition, the meliponine bees (smaller bees) were frequently observed on two flower sexes. As larger bees can transport larger loads of resin in their corbiculae and in some cases these bees prefer to visit bigger inflorescence than smaller ones, we argue that this behavior is advantageous energetically. Index terms: Meliponinae, Euglossinae, social bees, foraging behavior, flower resources, resin.

[1923] ARBOREAL ARTHROPOD COMMUNITY STRUCTURE ACROSS FOUR MILLION YEARS OF ECOSYSTEM DEVELOPMENT IN HAWAII

D. S. Gruner¹ & D. A. Polhemus², ¹Dept. of Zoology, Univ. of Hawai'i at Manoa, 2538 the Mall/Edmondson Hall, Honolulu, HI 96822, USA, E-mail: dgruner@hawaii.edu; ²Department of Entomology MRC 105, National Museum of Natural History, Smithsonian Institution, Wash., D.C. 20560, USA.

The Hawaiian archipelago forms a linear time series of replicated communities, with ages of volcanic origin varying over seven orders of magnitude. Important ecosystem attributes, such as parent substrate, climate and elevation, may be held constant at selected sites along the series. Previous studies along a montane mesic chronosequence (300 yrs.--4.1 million yrs.) have shown that rates of many ecosystem processes peak at sites of intermediate volcanic substrate age (20,000 yrs.—1.4 myrs). At these sites, the canopy is dominated by a single tree species, Metrosideros polymorpha (Myrtaceae) and arthropod lineages are largely conserved. These features make the islands an ideal natural laboratory to test the relative importance of ecological versus historical and evolutionary hypotheses of community organization. In 1997, we used pyrethrum canopy fogging to sample freeliving arthropods on 41 M. polymorpha trees at 4 sites on 3 islands. Total arthropod densities and biomass were highest at more productive, intermediate-aged sites. Foliar nitrogen concentrations were highly correlated with total arthropod density on individual trees. However, species richness of phytophagous true bugs (Heteroptera) and predatory carabid beetles (Coleoptera: Carabidae) increased as a function of geological age. Moreover, one of three indigenous tribes of Carabidae (Psydrini) was completely absent from, and presumably has not colonized, the oldest site. Although contemporary ecological processes appear to determine relative species abundances and biomass in local communities, regional species pools determine local richness and historical or phylogenetic accidents place constraints on composition.

Index terms: Hawaii, canopy arthropods, Carabidae, Heteroptera, pyrethrum fogging.

[1925] THE ASSOCIATED FAUNA COMPOSITION AT THE *EUPHALERUS* SP (HEMIPTERA:PSYLLIDAE), IN SEROPÉDICA, RJ, BRAZIL

M. Guaiará¹, A. G. de Carvalho¹, W. Santos² & A. Calcagno², UFRRJ – BR-465, Km 7. Seropédica, RJ, Brasil. CEP: 23.835. ¹ Depto. de Produtos Florestais, E-mail: guajara@ufrrj.br, ² DEnF/ CIMP, E-mail: cimp@ufrrj.br.

The associated fauna at the Euphalerus sp (Hemiptera:Psyllidae), that colonize the leguminous Clitoria fairchildiana ("sombreiro") was checked, althrough material collected in municipal district of Seropédica - RJ. The objective was to obtain incial data about the potential species natural controlers, that has been observed for the first time, as in the municipal district as in association with said vegetal host. To the propositions, were demarked four distinct environments in Seropédica and in each one of them was selected one tree of the C. fairchildiana. In each tree was collected 120 folioles, distributed uniformently to the four squareds and in three heights on the trees, to represent even better the crown. At laboratory, the folioles was put each one in Petri's board and so left by 15 days. The emerged insects were collected and deposited in glass flask, with alcohol at adys. The energed insects were conducted to identification. It was detected, complete, 161 70%, and after it has been conducted to identification. It was detected, complete, 161 specimens, that complied this distribution: Acarina – 66 individuals (40,99%); Hymenoptera - 59 individuals (36,65%); Aranae - 22 individuals (13,66%); Hymenoptera:Formicidae - 3 individuals(1,86%), Chrysopidae - 3 individuals (1,86%); Diptera - 3 individuals (1,86%); Coleoptera - 3 individuals (1,86%) and Thysanoptera - 2 individuals (1,24%). Although we haven't apllied an efficient methodology to quantify this information, it registered the adults number of Olla abdominalis (Coleoptera: Coccinellidae) that chased during the sampling. Some examples of this species already has been created at laboratory, fed with nymphs and adults of Euphalerus sp to potential predatory verification has been obtained two generation, below this condition. It is register the colonization by entomopathogenic fungi *Cladosporium* sp, that is in almost all folioles studied, mainly in attack advanced age of Euphalerus sp, when the folioles are dry on the floor.

Index terms: Clitoria fairchildiana, natural controlers, Olla abdominalis, entomopathogenic, Cladosporium

[1924] DISTRIBUTION OF *EUPHALERUS* SP (HEMIPTERA: PSYLLIDAE) IN STATE OF RIO DE JANEIRO, BRAZIL

<u>M. Guajará</u>¹, A. G. de Carvalho¹, B. Cerqueira² & J. C. da Conceição², UFRRJ – BR-465, Km 7. Seropédica, RJ, Brasil. CEP: 23.835. ¹ Depto. de Produtos Florestais, E-mail: guajara@ufrrj.br, ² DEnF/ CIMP, E-mail: cimp@ufrrj.br.

In order to check the dispersion and the distribution of Euphalerus sp on Rio de Janeiro, where the species was recently registered in association with Clitoria fairchidiana, were accepted two methodology: a) questionary, with pictures showing aspects of the occurrence of Euphalerus sp, directed to the development agent of 17 regions that form the state, for dispatch to the municipal district and b) visity municipal districts on Rio de Janeiro, annotating which one that the insect was occurring, with observation at infestion level found. Through to the first methodology only 7 municipal districts directed reply. The preliminary appointment showed the occurrence of Euphalerus sp on: Northwest Region I- Varre-Sai, Porciúncula, Natividade e Bom Jesus de Itabapoana; Northwest II: Itaperuna; North II: Conceição de Macabu; North III: Italva; Medium Paraíba I: Valença, Pinheiral, Piraí, Barra do Piraí e Rio das Flores; Medium Paraíba II: Volta Redonda, Barra Mansa e Rio Claro; Medium Paraíba III: Porto Real, Itatiaia, Resende e Quatis; Baía de Ilha Grande: Angra dos Reis, Parati e Mangaratiba; Metropolitan: Paracambi, Seropédica, Itaguaí, Japeri, Queimados, Nova Iguaçu, Duque de Caxias, Belford Roxo, São João de Meriti, Nilópolis, Rio de Janeiro, Niterói, São Gonçalo e Maricá; South Center I: Parafba do Sul, Levi Gasparian e Três Rios; South Center II: Vassouras, Paulo de Frontin, Mendes, Paty do Alferes e Miguel Pereira. The insect, that had the first register on March of 1999, haven't been found on the two last municipal districts when the appointment initiate, on December of the same year, but it has been found there on February of 2000. Taked place though than the trees recently attacked, as attacked was flowered, while the others, that was constantly striped haven't none indication of flower.

Index terms: Clitoria fairchildiana, development agents, municipal districts - RJ

[1926] PATTERNS OF SPECIES RICHNESS AND ABUNDANCE OF DEFOLIATOR LEPIDOPTERA ASSOCIATED WITH *EUCALYPTUS GRANDIS* IN BRAZIL AND HOW THEY RELATE TO PLANT AGE

<u>**R.N.C. Guedes¹**</u>, **J.C. Zanuncio¹**, **T.V. Zanuncio¹** & **R. A. Araújo¹**, ¹Dept. of Animal Biology, Federal Univ. of Viçosa, Viçosa, MG 36571-000, Brazil, E-mail: guedes@mail.ufv.br.

The present work documents patterns of species richness and abundance of defoliator Lepidoptera associated with an Eucalyptus grandis plantation, established in an area previously occupied by the Atlantic tropical forest in Brazil, and how they relate to plant age using data of a five-year survey. The higher number of species collected (1,385), the lack of dominant species, and the non-occurrence of any pest outbreaks during the survey may be due to the high plant diversity of the native forest reserves maintained in the area. There was no significant seasonal fluctuation of species richness, but there were seasonal fluctuations on species abundance with outbreak species prevailing in October, at the start of the rainy season. Species richness and abundance of defoliator Lepidoptera were positively correlated. There was an increase on both with plant aging. However, largest numbers of major outbreak species and minor eucalypt defoliators, which accounted for 14% of the insects collected, were observed in plants near mid-age (four to five years-old) of their cutting cycle (seven to ten years). This may be due to a higher amount of better quality plant leaves at mid-age or the decrease in silvicultural management practices at this period of Eucalyptus cutting cycle in Brazil. The abundance of the main outbreak species observed in the survey, Stenalcidia grosica (Geometridae), was adversely affected by plant age. Nonetheless such effect was weak (r = -0.21, p = 0.03) and we were not able to obtain further significant correlations between plant age and abundance of the other most frequent and constant species collected.

Index terms: Insect survey, Stenalcidia grosica, insect abundance, outbreak species, eucalypt defoliators.

[1927] CRYPTORHYNCHUS LAPATHI ATTACKING POPLARS IN TURKEY

N. Guler, Plant Protection Section, Poplar and Fast Growing Forest Tress Research Institute, P.K. 93, 41001, Izmit/ TURKEY, E-mail: kavak@turnet.net.tr

In Turkey, aproximately 5 million cubic meter of poplar wood is producued annually. More than a quarter of this total poplar wood production is obtained from plantations in the Marmara and Western Black Sea regions of Turkey where the damage caused by Cryptorhynchus lapathi L. (Coleoptera - Curculinidae) is observed. C. lapathi causes damage on stems of poplars in nurseries and in plantations. Although the adult of C.lapathi can not move very far away, the size and the number of infested plantation sites have increased because of the use of infested nursery stock. The most serious problem in preventing the extension of this insect is due to the diffuculty that the ordinary poplar growers face in diagnosing the infested poplar saplings to plant. The life cycle of C.lapathi was investigated on two of the poplar clones: P.x euramericana cv. "1-214" and "1-45/51" which are widely used in commercial plantations in Turkey. The insect lays its eggs on the stem barks and the larvae from eggs feed and then hibernate in bark tissues. As soon as the vegetation starts, the larvae also start feeding and boring galleries in bark and in wood. Majority of the galeries (approximacly 60 percent) penetrates obliquely into wood then continues parallel to tree axis being mostly upward. Some other galleries (approximately 35 %) continue obliquely towards to tree axis. Few galleries are bored perpendiculer to tree axis. No correlation was observed between the length of galleries bored by C.lapathi and the diameter of infested trees. Although some authors reported that the adults of C.lapathi may also hibernate, hibernation of an adult C.lapathi has never been observed by us, but only the larvae. The generation period of C.lapathi lasts for one year in the Marmara and Western Black Sea regions of Turkey. Chemical control of C.lapathi is required in poplar nurseries and plantations. In order to secure the effectiveness of chemical control, it should be applied before the larvae penetrate into wood. In the Marmara and the Western Black Sea regions of Turkey, mean temperature is 12 °C in midapril during which the larvae of C.lapathi are in the bark tissues at a proportion of 45 % and under the bark on the surface of wood at a propartion of 55 %. Whereas, in the early may, more than 20 % of larvae are in galleries bored in wood. Therefore, delay in chemical application results with an ineffective control of C.lapath. Poplar plantations growing on sites with high water table during vegetation period and coppiced plantations are observed to be more sensitive for C.lapathi infestation. The rate of infestation decreases by the enlargement of tree diameter. Application of efficient cultivation techniques and good site conditions reduce the rate of insect damage and its infestation. Index terms: Poplar cultivation , Cryptorhynchus lapathi L.

[1928] THE EXOTIC FOREST PEST INFORMATION SYSTEM FOR NORTH AMERICA

R. A. Haack¹ & J. G. O'Brien², ¹ US Dept. Agriculture, Forest Service, North Central Research Station, 1407 S. Harrison Rd., East Lansing, MI 48823, USA; E-mail: rhaack @fs.fed.us; ² US Dept. Agriculture, Forest Service, Forest Health Protection, 1992 Folwell Ave., St. Paul, MN 55108, USA; E-mail: jobrien @fs.fed.us

The Exotic Forest Pest Information System for North America is a project sponsored by the North American Forestry Commission, comprised of members from Canada, Mexico, and the United States. This Internet-accessible database identifies insects, mites and pathogens with potential to become established and cause damage to forest resources in any of the three North American countries. Emphasis is placed on organisms not yet present in North America. Each record in the database consists of a brief pest risk assessment and a pest information section. For each organism, the risk assessment section qualifies risk by probability of establishment, economic impact, and environmental impact. The pest information section provides details on host plants, geographic distribution, methods for detection and identification, means of spread, control measures, general biology, and a bibliography. It is anticipated that this information will prove useful in assessing and managing future pest organisms in both North America and worldwide. The web site and pest records will be available in English, French, and Spanish. The directors of the project are actively seeking authors to write new pest records for the database, as well as qualified people to review current and future records. A new record can be submitted in any of the three official languages: English, French, or Spanish. Once approved and edited in the language in which it was first submitted, each record will then be translated to the other two languages by project members. The original authors and their affiliations are listed for each record. For further information, or to participate in the development of this information system, visit the web site at: http://www.exoticforestpests.org

Index terms: database, exotic pest, quarantine pest, risk assessment

[1929] AZADIRACHTIN FROM THE NEEM TREE: AN EFFECTIVE NATURAL PRODUCT FOR FOREST INSECT PEST MANAGEMENT

B. Helson¹, D. Lyons¹, P. de Groot¹, D. Thompson¹, R. West², & K. Wanner³, ¹Canadian Forest Service, Natural Resources Canada, P. O. Box 490, Sault Ste Marie, ON P6A 5M7, CANADA, E-mail bhelson@nrcan.gc.ca; ²Box 515, Portugal Cove, NF, A0A 3K0, CANADA, ³Dow AgroSciences, 5501 Oberlin Dr., San Diego, California 92121 USA

In the laboratory, azadirachtin in a commercial EC formulation of neem seed extract was very active on 13 species of tree-defoliating, lepidopteran and sawfly (Hymenoptera) larvae. Open-feeding sawfly species were much more susceptible than lepidopteran species. In field trials, ground-based foliar applications of neem at 50 g azadirachtin/ha by motorized backpack mistblower or compressed air sprayer have proven effective against white pine weevil, pine false webworm and introduced pine sawfly on pines. Dosages of 100 g/ha gave acceptable protection from spruce budworm damage on spruce and fir. Ultra-low-volume, aerial applications of EC formulations at 50 g/ha were effective against balsam fir sawfly on balsam fir and pine false webworm on red pine. Neem seed extracts also possess systemic properties against forest defoliators and leafminers when inoculated into the trunks of trees. In field trials against pine false webworm, trunk inoculations of small red pine trees with undiluted EC formulations at 0.05g azadirachtin per tree before egg hatch provided excellent protection of both old and new foliage. Trunk inoculations of large, 25-30 cm dbh, 20-m tall, red pine at 0.02 and 0.05g azadirachtin per cm dbh also provided excellent protection. Dosages of 0.1-0.2 g/cm dbh in large white spruce were effective against spruce budworm larvae. A dosage of 0.1 g/cm dbh greatly reduced cedar leaf miner populations on white cedar. Systemic neem applications are also persistent. Treatment of 20-cm dbh white pine at 0.1 g/cm dbh resulted in high mortality of introduced pine sawfly larvae for at least 77 days. Injections for pine false webworm control can be made before winter at least 7 months before egg hatch the following spring. A novel device, the Systemic Tree Injection Tube has been developed to inject neem formulations into trees under pressure, quickly, easily and cheaply. Azadirachtin has proven to be an effective, versatile bioinsecticide in ground, aerial and systemic applications for the management of several forest pests, particularly sawfly species in high value plantations.

Index terms: Acantholyda erythrocephala, Diprion similis, Neodiprion abietis, Pissodes strobi, Choristoneura fumiferana

[1930] INTERACTIONS BETWEEN BEETLE ATTACK RATE AND PINE TREE DEFENSES PRODUCE POSITIVE DENSITY DEPENDENCE IN DENDROCTONUS FRONTALIS

<u>R.W. Hofstetter</u>¹, M.P. Ayres¹ & P.L Lorio², ¹Dept. of Biological Sciences, Dartmouth College, 202 Gilman Hall, Hanover, NH 03755, USA, E-mail rwh@dartmouth.edu; ²U.S.D.A Southern Research Station, 2500 Shreveport Hwy, Pineville, LA 71360, USA.

The southern pine beetle, Dendroctonus frontalis, is a significant agent of mortality for pines in Mexico and the Southeast United States. The flow of resin from pines is the primary defensive mechanism against *D. frontalis.* However, resin flow is impacted by abiotic conditions and time of year, and differ greatly among individuals. The interaction between the tree resin system and beetle attack behavior influence the population dynamics of D. frontalis. By experimentally altering the attack rates on trees with varying capacity for resin production, we were able to test the hypothesis that the interaction between attacking beetles and pine tree resin systems creates positive density-dependence (Allee effect) in bark beetle populations, which will tend to destabilize beetle population dynamics. As predicted, attack success was highest in trees with the lowest resin flow and the highest landing rate of beetles. There was a threshold of beetle attack rates (around 1.5 beetles/day/dm²) in our study in which resin flow declined and beetles successfully reproduced, and below which resin flow was maintained or even increased and beetles failed to reproduce. Factors that influence attack rates near the attack threshold would have strong effects on population growth rates. The interaction between beetle attack rates and tree resin production appears to produce positive density dependence which tend to destabilize population dynamics.

Index terms: Population dynamics, bark beetles, tree defenses, Allee effect

[1931] CHEMOTAXIS OF SOME SCOLYTIDS AND THEIR PREDATORS TO 4-ALLYLANISOLE AND ETHANOL IN CENTRAL OREGON PINE FORESTS

G. Joseph¹, <u>R. G. Kelsey²</u>, R. W. Peck² & C. G. Niwa², ¹Dept. of Forest Science, Oregon State Univ., Corvallis, OR 97331, USA., current address, Dept. of Crop Science, UAS, GKVK Campus, Bangalore 560065, INDIA; ²U.S. Forest Serv., PNW Research Station, 3200 Jefferson Way, Corvallis, OR 97331, USA, E-mail kelseyr@fsl.orst.edu.

Lindgren multiple funnel traps were set up in central Oregon pine forests to determine the response of scolytid bark beetles to 4-allylanisole (4AA) and ethanol. Traps were baited with three release rates of 4AA (0, 0.6, 4.3 mg/h) and two release rates of ethanol (4.5, 41.4 mg/h) in a 3 x 2 factorial design. All baits had a 1:1 mixture of \Box - and \Box -pinene with a release rate of 11.4 mg/h. Of the 13,396 scolytids caught, *Dendroctonus valens* made up 60%, *Hylurgops* spp. 18.5%, *Ips* spp. 16%, *Hylastes* spp. 1.8%, *Gnathotrichus retusus* 0.9%, and bark beetle predators another 2.8%. Increasing the release rate of ethanol in the absence of 4AA increased the number of most scolytid species caught by 1.5 to 3.7 times confirming its role as an attractant. Ips latidens, Temnochila chlorodia, and Clerid predators were exceptions and did not show a response to higher ethanol release rates. The release of 4AA at the lowest rate inhibited the response of most scolytids, with a significant reduction in G. retusus, Hylastes macer, and Hylurgops porosus when compared to traps without 4AA. The high release rate of 4AA further inhibited the response for most beetles compared to low 4AA. Seven species were significantly deterred by high 4AA including the latter three, and Hylastes longicollis, Hylastes nigrinus, Hylurgops reticulatus, and Ips latidens. Exceptions include Hylurgops subcostulatus which was attracted significantly to both low and high 4AA, and I. pini which was attracted to low and high 4AA, but only in combination with low ethanol. Dendroctonus valens was attracted significantly to the low 4AA, and unaffected by the high 4AA. The predators appeared to be less inhibited by 4AA than most bark beetles. Gnathotrichus retusus and Hylastes longicollis showed the most positive responses to ethanol and they were also strongly inhibited by high 4AA. Although 4AA can deter the response of some secondary bark beetles attracted to ethanol in combination with - and D-pinene, this inhibition could be weakened for certain species by increasing the release rate of ethanol. 4-Allyl- anisole may have some utility for managing the behavior of secondary bark beetles that are most sensitive to this compound.

Index terms: Methyl chavicol, bark beetles, primary attraction, host selection.

[1932] TERMITES (INSECTA: ISOPTERA) IN *EUCALYPTUS* SPP. PLANTATIONS OF THE FOREST EXPERIMENTAL STATION, UNIVERSITY OF SÃO PAULO, IN ANHEMBI, STATE OF SÃO PAULO, BRAZIL

L.K.Junqueira¹ & E. Berti-Filho², ¹ Depto. de Ciências Florestais ESALQ/USP. E-mail: lkjunque@carpa.ciagri.usp.br; ²Depto. de Entomologia, Fitopatologia e Zoologia Agrícola - ESALQ/USP, C.P. 9, 13418-900, Piracicaba, SP. Financial support: CAPES.

Termites are important pests of *Eucalyptus* plantations in Brazil, and considered a limiting factor for the implantation of commercial forests, because they attack from seedlings to adult trees. This research was carried out to determine the percentage of seedlings killed by the termites species and to survey the termite species occurring in two *Eucalyptus* plantations (area 1 - *E. saligna*, area 2 - *E. urophylla* x *E. grandis*) of the Forest Experimental Station of the University of São Paulo, in Anhembi, State of São Paulo, Brazil. A total of 9,198 seedlings were found attacked by the termites and 658 cardboard traps (Termitrap *), distributed in a 9.0 m x 10.0 m spacing, were used for a 3 week period. The results were as follows: Area 1 (*E. saligna*) - 11.08% of dead seedlings and 4,29% of cardboard with termites (*Embiratermes* sp., *Cornitermes* sp. and *Heterotermes tenuis*); Area 2 (*E. urophylla* x *E. grandis*) - 9.15% of dead seedlings and 2.09% of cardboard with termites (*Cornitermes cunulans*, *H. tenuis*, and specimens of the Subfamily Apicotermitinae). It is suggested that the cardboard traps do not show the same efficiency observed in the agricultural areas, because in forested areas there are roots, remainings of bark and wood which are more attractive to the termites. Index terms: eucalipts, termites, sampling, traps

[1933] ATTRACTION OF SCOLYTUS UNISPINOSUS BARK BEETLES TO WATER-STRESSED BRANCHES OF DOUGLAS-FIR CONTAINING ETHANOL

R. G. Kelsev¹ & G. Joseph², ¹U.S. Forest Serv., PNW Research Station, 3200 Jefferson Way, Corvallis, OR 97331, USA, E-mail kelseyr@fsl.orst.edu; ²Dept. of Forest Science, Oregon State Univ., Corvallis, OR 97331, USA., current address, Dept. of Crop Science, UAS, GKVK Campus, Bangalore 560065, INDIA.

Three similar-sized branches on each of seven Douglas-fir (Pseudotsugae menziesii) trees with a southern exposure were selected randomly to receive a water-stress, defoliation, or control treatment. Water-stressed branches were prepared by freezing them at the base with dry ice. Defoliated branches were also frozen with dry ice, but all secondary branches and needles were immediately removed to eliminate transpiration and minimize water loss. All water-stressed branches were attacked by Scolvtus unispinosus at 12 to 24 days after imposing treatments, resulting in a significantly higher density of gallery holes (107 m⁻²) than in the defoliated or control branches, which were not attacked. Needles and woody tissues from stressed branches, sampled after being attacked, contained significantly higher ethanol concentrations (2.91 to $15.26 \square mol g^{-1}$ fresh wt.) than tissue from defoliated or control branches (0.005 to 0.12 [mol g1 fresh wt.), which did not differ from each other. The water content in woody tissues and needles of stressed branches was 40.9 and 28.1% of the amount in control branches, respectively, when sampled for ethanol analysis. Woody tissues in defoliated branches remained moist, with 91.3% of the water in controls. Drying needles from water-stressed branches lost 18.3 to 33.7% of their total monoterpenes compared to needles on the controls. The mechanism for ethanol synthesis in water-stressed branches appears to be distinctly different from that of logs overwintering on the forest floor. Ethanol synthesis in stressed branches probably was initiated by cytoplasmic acidification as a result of damage to cellular membranes from drying and heating. Ethanol that accumulated in needles and woody tissues of stressed branches functioned as a primary host attractant for S. unispinosus at our Willamette Valley, Oregon, site.

Index terms: host selection, primary attraction, kairomones, ethanol, Scolytidae.

[1934] ARTIFICIAL REARING OF AN AMBROSIA BEETLE, *PLATYPUS QUERCIVORUS* (COLEOPTERA: PLATYPODIDAE) ON BOLTS OF A DECIDUOUS OAK, *QUERCUS SERRATA*

H. Kitajima, Dept. of Forest Biology, Forestry and Forest Products Res. Inst., Kukizaki, Inashiki, Ibaraki-Pref., 305-8687, Japan, E-mail kitajima@ffpri.affrc.go.jp

The ambrosia beetle Platypus quercivorus is a pest of oak and other broad-leaved trees and is a supposed vector of a pathogenic fungus causing mass mortality of oak trees in Japan. A method of inducing P. quercivorus adults to initiate reproduction in bolts (50 cm long, 6.7 to 12.0 cm long) of a deciduous oak, Quercus serrata, one of the host species of the beetle, was developed. Used individuals were new adults that had emerged from attacked trees of Q. mongolica. One soaked bolt immersed in water for 10 to 15 days under a condition of 25°C 16L8D and a unsoaked bolt stored at 5°C were put in three plastic boxes (41×70×35cm), and kept at the same condition. Fifteen adult males were released into each plastic box, then the number of holes bored by the males was counted daily for one week. A mean of 26±5(SE) % of the released males initiated holes on the soaked bolt, while no males attacked the unsoaked one. The rate increased to 78±3 % by placing the soaked bolt on wet bog moss spread on the bottom of the plastic cases. A single virgin female was introduced into the entrance of holes with living males to induce copulation. Copulation occurred at 55 and 83% of the tested holes on the 3rd and 4th day after the males initiated them. In cases where copulation did not occur, introduced females paid no attention to the holes or males rejected copulating with females. Therefore, the best time of introduction of the female was the 4th day after the male initiated a hole. After 30 days from introduction of females, one bolt with 11 holes each with a pair of adults was dissected and development of progeny was investigated. The 11 pairs had excavated galleries, and ten of them had a large number of eggs and 1st to 5th instar larvae in the galleries. These results indicate the possibility of rearing P. quercivorus under artificial conditions.

Index terms: soaked bolt, male induction, copulation, development of progeny.

Symposium and Poster Session

[1935] MAIN INSECT FOREST PESTS AFFECTING PINES IN THE PATAGONIA ARGENTINA

P. Klasmer¹, E.N. Botto², J.C. Corley³, J.M. Villacide³ & V.F. Arhex³, ¹ INTA, El Bolsón, (8430), Rio Negro, Argentina.; ²INTA, IMYZA, CNIA, (1712) Castelar, Buenos Aires, Argentina. ³INTA, S. C. de Bariloche, (8400), Rio Negro, Argentina.

Insect forest pests are the main adversities affecting pines production in the Patagonia region of Argentina. Among the different insects causing damage to pine plantations only two exotic pest are really relevant due to its economical impact, the siricid woodwasp Sirex noctilio (Hymenoptera: Siricidae) and the european pine shoot moth Rhyacionia buoliana. (Lepidoptera: Tortricidae). S. noctilio (SN) was accidentally introduced in the Patagonia in 1989 and detected in plantations in 1993. It is at present well established and spreading slowly in the area nearby San Carlos de Bariloche (province of Rio Negro). Bioecological studies started in 1993 revealed that the pest could have a one, a two or a three years generation as well as Ibalia leucospoides (Hymenoptera: Ibaliidae), a natural enemy of SN, introduced into the area simultaneously with the woodwasp. Although population levels of SN are not significantly high its sole presence and its potential to kill live trees became a real threat to the promoted forest production in the region. Therefore biological control strategies based on the use of the above mentioned I. leucospoides, the recently introduced nematode Deladenus siricidicola (Nematoda: Neotylenchidae) and the exotic entomophagous parasitoids Rhyssa sp. and Megarhyssa sp. (Hymenoptera: Ichneumonidae) has been started. The european pine shoot moth (EPSM) became a pest to the pines in the Patagonia in 1981. At present this insect is well established in the provinces of Chubut, Neuquen and Rio Negro. In this region EPSM has only one generation per year (univoltine pest). Despite population levels recorded for EPSM in the Patagonia are not as high as those observed in other countries (i.e., Chile), this pest accounted for the 20% to 30% damage assessed in most pine plantations surveyed. Fortunately EPSM is being naturally attacked by a set of entomophagous parasitoids acting on different life stages of the moth: *Trichogramma* sp. (Hymenoptera: Trichogrammatidae) on eggs, Orgilus obscurator (Hymenoptera: Ichneumonidae) on larvae and Coccigomymus fuscipes (Hymenoptera: Braconidae) on pupae. The role of these biological control agents as well as the performance of the introduced egg parasitoid Trichogramma nerudai, are being evaluated to be used in biocontrol strategies.

[1936] PERFORMANCE OF NEEDLE-FEEDING INSECTS ON SCOTS PINES EXPOSED TO DROUGHT AND NUTRIENT STRESS

M. Kyto, Finnish Forest Research Institute, Vantaa Research Centre, P.O.Box 18, FIN-01301 Vantaa, Finland, E-mail maarit.kyto@metla.fi.

11-year-old Scots pines growing on a forest site with limited nutrient availability were subjected to four different treatment combinations consisting of water deprivation/natural water availability and NP-fertilization/natural nutrient availability. Pine sawfly (*Diprion pini*) larvae and grey pine aphids (*Schizolachnus pinet*) were reared on the trees in two consecutive years to study the effects of host tree stress on their performance. The treatments clearly affected tree growth, the concentrations of nitrogen and annino acids in the needles, and the carbon-nutrient ratio. Effects on starch and sugar concentrations of the needles were less marked, and the resin acid concentration was unaffected by the treatments. Results from the insect rearing experiments (sawfly cocon size, diapause, and egg-production; aphid survival and reproduction rate) are presented and discussed. Index terms: *Diprion pini*, *Schizolachnus pineti*, *Pinus sylvestris*, resistance, defoliator [1937] CHEMICAL PROTECTION OF *EUCALYPTUS* SEEDLINGS FOR LEAF CUTTING ANT DAMAGE

D. Link. Centro de Ciencias Rurais-UFSM. Cidade Universitaria, Predio 42, Santa Maria, RS. 97105-900 Brasil.

The leaf cutting ants are the most important defoliators of the cultivated forest trees in Brazil. A search was made to evaluate the effects of chemical products against leaf cutting ant damage on *Eucalyptus* seedlings after field planting. The defoliation caused by the leaf cutting ant, *Acromyrmex crassispinus* can give rise to the seedling death. Seedlings were sprayed with 0.7, 1.05, 1.4 and 2.1g a.i. of Thiamethoxam; 1.4, 2.1, 2.8 and 3.5g a.i; of Imidacloprid; 0.7 and 3.3g a.i. of Acetamiprid; 0.7, 1.05 and 1.75g a.i. of Thiodicarb; 1.6 and 2.4g a.j. of Fipronil and water (check). Each treatment was sprayed on 1,000 seedlings before field planting. Two check treatments were used, one with *E. saligna* seedlings and another with *E. camaldulensis*. 1 20g1033 Each two or three days the experimental area was examinated and annotated the data of damaged seedlings and ant nests. Thiamethoxam, Imidacloprid and Acetamiprid shielded the seedling a month. The defoliation at check treatments changed of 4.7% in *E. saligna* at 13.5% in *E. camaldulensis*. Index trems: *Acromyrmex crassispinus*, cultivated forest, pesticides, losses

[1938] SPATIAL DISTRIBUTION OF NESTS OF THE LEAF CUTTING ANT ATTA SEXDENS RUBROPILOSA (HYMENOPTERA: FORMICIDAE) IN PLANTATIONS OF EUCALYPTUS UROPHYLLA IN BRAZIL

E. T. Lopes¹, <u>J. C. Zanuncio²</u>, L. Couto¹ & D. Pratissoli³, ¹ Dep. de Engenharia Florestal, Univ. Federal de Viçosa, 36.571-000 Viçosa, MG, BRAZIL. ² Dep. de Biologia Animal, Univ. Federal de Viçosa, 36.571-000 Viçosa, MG, BRAZIL. E-mail: zanuncio@mail.ufv.br. ³ Dep. de Fitossanidade, Univ. Federal do Espirito Santo, 29.500-000, Alegre, ES, BRAZIL.

Atta and Acromyrmex (Hymenoptera: Formicidae) leaf cutting ants are important pests in Brazil because they are adapted to the majority of ecosystems in this country specially to those disturbed by activities of human being. This research was developed in June and July 1998 in Montes Claros, State of Minas Gerais, Brazil in ten blocks of a 72 months old *Eucalyptus urophylla* plantation with 365.4 hectares. This region presents average altitude of 630 meters, Latitude of 16° 43' 32" South, Longitude of 43° 51' 52" West and tropical hot dry climate with temperatures between 25° and 40° in the summer. Mean rainfall is 1,000 mm concentrated mainly in November and December with an average relative humidity of 65.0%. All ant colonies of the leaf cutting ant Atta sexdens rubropilosa (Hymenoptera: Formicidae) were identified, mapped and their areas were measured considering the largest length and width of each ant colony besides their respective distance from the nearest border of each block of Eucalyptus. After this a fog equipment was used to find the number of ant holes per ant colony. All ant colonies of this leaf cutting ant were distributed in classes according to their location from the border of each block of *Eucalyptus*. A total of 222 ant colonies of *A. sexdens rubropilosa* was found with largest percentages of ant colonies, total area of ant colony and number of ant holes in the classes from 0.0 to 10.0 meters with respectively, 29.3%; 22.7% and 10.3% for each of these parameters. If a total of 20.0%; 40.0%; 60.0%; 80.0% and 100.0% of ant colonies of this leaf cutting is controlled in this area of Eucalyptus the total area controlled would be 64.00; 113.70; 179.70; 240.30 and 319.10 hectares, respectively, out of 365.40 hectares. The knowledge of the spatial distribution of ant colonies of A. sexdens rubropilosa in plantations of Eucalyptus could allow the control of this pest in strips inside their border thus reducing labour costs and amount of insecticides in the environment. Index terms: Atta sexdens rubropilosa, spatial distribution, monitoring, reforestation

[1939] APPLICATION OF A GEOGRAPHICAL INFORMATION SYSTEM TO THE STUDY OF SIREX NOCTILIO (IIYMENOPTERA-SIRICIDAE) IN CALAMUCHITA VALLEY, CÓRDOBA, ARGENTINA

A. Lopez¹; M. Demaestri; E. Zupan; G. Moretti; O. Barotto; J. Gonzáles & G. Balbi, Univ. Nac de Río Cuarto-R. N. 36 km 601-5800 Río Cuarto- Argentina. E-mail: alopez@ayv.unrc.edu.ar

Since 1996 work was carned out at the University of Rio Cuarto, Argentina, using a System of Geographical Information (SIG) to gather knowledge about presence, distribution and severity of damage made by the "Pine Borer Wasp" (Sirex noctilio F.)in Calamuchita Valley. This methodology has not been applied previously in this country. Its importance rest on the benefit of making possible the ordinately assembling of a great number of data for processing, modyfying, amplifying, and combining them at will. Feeding a data base with damage percentages obtained in several locations, insect outbreaks development and stabilization, and age of forested areas, would allow to analyze the yearly evolution of S. noctilio in the region with the aim to establish a strategy of management of the pest. The area of study consist of 36.200 forested hectareas with 31.125 of Pinus elliottii being the rest been planted with P. taeda and P. radiata. Seven operational areas were established according to the geographical location, planimetric surface (has.), age of trees over 10 years old, and management of the forest. To quantify the grade of outbreaks permanent transects were utilized. In each operational area three sample seasons were fixed up with at least two transects, of 200 trees long. These trees were distributed into two contiguous lines running through different landscapes (lowland, hillside, and hill). Monitoring data were used to feed the SIG made up of two different data base frames: spatial and thematic information. The graphical outcomes are analog maps made up by means visual analysis of fhotogramas, scale 1:50.000, digital processing of satellite image analysis LandSat TM 5 and generation of thematic maps. To digitalize the analog information the vectorial system ARC/INFO was applied. Database were created using the entity-relation model with Visual dBASE, 1995 software. The information is cartographically modelled with the ARCVIEW software, using the digital obervation provided by the "Atlas del Suelo INTA, 1995".

[1940]ANALYSIS OF THE DEGRADATION OF THE WOOD OF SIX FOREST SPECIES FOR SCOLYTIDAE (COLEOPTERA)

A. M. Lunz¹ & A. G. Carvalho¹, ¹Depto. Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: amehl@zipmail.com.br

The field rehearsals are valid in the evaluation certain arboreal species when exposed to the action of degradation agents. Bodies of test of standardized dimensions were put outdoors so that, through periodic inspections, it was possible to observe the degradation of the wood. Among the degradation agents are the coleopterans of the family Scolytidae. that attack wounded and recently abated trees. The study was driven in the period of September 11, 1998 to April 2, 1999, in the campus of the Universidade Federal Rural do Rio de Janeiro, in a total of twelve collections. This work had as objective to verify the attraction degree of wood of six forest species when exposed to the atmosphere, using a methodology similar to the rehearsal of traditional field. The following species were chosen: Clitoria fairchildiana (sombreiro), Samanea saman, Gmelina arborea, Lophantera lactescens (lanterneira), Mimosa caesalpinaefolia (sabiá) and Eucalyptus citriodora. Ten bodies of test of each species were cut, measuring 1,20 m of length and with medium diameter of 17 cm. After the beginning of the exhibition, evaluations were weekly accomplished to register of the beginning of the attack of the insects. Samples of 10 cm of length were removed of each test body, biweekly, after having been verified that the attack had begun. One of the variables analyzed in the retired samples in the field was

(1941) DIVERSITY AND ABUNDANCE OF BEES IN AN ARAUCARIA FOREST OF RIO GRANDE DO SUL, BRAZIL

Birgit Harter Marques 1.2, 1 LPB, PUCRS, 90619-900 Porto Alegre, RS, Brazil, e-mail biggi@pucrs.br; ²Zool. Inst., Univ. of Tübingen, 72076 Tübingen, Germany.

The south Brazilian Araucaria forest is part of the Atlantic rain forest biom. This special type of forest is mainly found at higher altitudes. Originally it covered most of the upper mountain ranges from Minas Gerais and Rio de Janeiro to Rio Grande do Sul. Massive clearings during the past decades have left only small remnants of this ecosystem. In an Araucaria forest reserve of 4,500 ha located on the Serra Geral at 30° S comprising primary and secondary forest as well shrub and grassland areas, the effect of habitat fragmentation on the apifauna and the melittophilous flora was studied over a period of four years. Bees of nearly 200 species were recorded visiting flowers of also about 200 species of plants belonging to 53 families. Within the bee sample, the halictides represented the greatest α -diversity, followed by anthophorides, megachilides, and renides and colletides. Only 15 species of Apidae were recorded. Bee of about 1/3 of the species were observed on flowering plants in all the different habitats. Others occurred only in the forest or in the secondary vegetation. Foraging stingless bees were the most abundant flower visitors, especially in arboreus habitats. In the open grassland halictids were the dominating foragers. There was some correlation in species richness between the taxa of abundant bees and the families of mainly exploited plants. Within these melittophilous plants, asteracean shrubs were the most important nectar and pollen sources. There impact as pioneer elements in the succession of natural Araucaria forest regeneration and the role of a highly divers bee community in angiosperm pollination in this ecosystem is discussed. Index terms: Araucaria forest, bee diversity, melittophilous plants, ecosystem analysis.

[1942] USDA FOREST SERVICE FOREST HEALTH PROTECTION INTERNATIONAL PARTNERSHIPS AND ACTIVITIES

J. D. McMillin¹ & D. B. Twardus², ¹USDA Forest Service, Forest Health Management, Rapid City, SD 57702, USA, E-mail jmcmilli/r2_blackhills@fs.fed.us; ²USDA Forest Service, Forest Health Protection, Morgantown, WV 26505, USA.

The USDA Forest Service Forest Health Protection (FHP) provides assistance in the identification, monitoring, and management of insects and diseases on federal, state and private lands in the United States. Because of trade agreements, the ease of travel between countries, increased demands worldwide on forest resources, and the threat of exotic insects and diseases to native forests, FHP is also actively involved in the international arena. An International Activity Plan guides FHP international activities. Goals of the Plan and examples of FHP projects toward meeting these goals include: Goal 1. U.S. Forests are protected from exotic pests. Includes reviewing and supporting regulatory laws, policies, and programs. And, identifying and developing technologies to assist in protecting U.S. forests. This latter effort has included: cooperative port monitoring in the Russian Far East for Asian gypsy moth, investigating potential natural enemies of the common pine shoot beetle, and identifying semiochemicals for use in detection of Asian long-horned beetle. Goal 2. North American countries have strong forest pest management programs. This includes developing cooperative projects, sharing technical expertise, and enhancing working relationships. For example, aerial survey detection training has been provided to strengthen the Mexican pest management program. Goal 3. Biological control options are in place to protect forests from exotic pests. Objectives include increasing our knowledge of biological control techniques and where feasible developing and implementing biological control programs. A biological control program for hemlock wooly adelgid is currently underway in the eastern U.S. In addition, efforts to coordinate a biological control program for mealybug in the Peoples Republic of China is in progress. Goal 4. Forest health technology and expertise are shared worldwide. Technical assistance has been made available including the evaluation of remote sensing needs and capabilities of detecting Sirex in Brazil, providing assistance in aerial application for gypsy moth suppression in Bulgaria, and hosting visiting scientists for the purpose of sharing information and technology. These examples are only a few of the more than 65 projects in 20 countries that FHP has participated in over the last two years. FHP international activity partners include the participating countries, the UNFAO, USAID, USDA Forest Service International Programs and APHIS. USDA FS Forest Health Protection continues to explore opportunities for additional partnerships and activities worldwide.

Index terms: Forest health management, international forestry

the number of perforations done by the insects. A total of 1497 perforations were counted, being almost whole done by Scolytidae. The action of another families of wood-boring beetles was verified in the presence of perforations and typical galleries of Bostrichidae and Platypodidae, besides some postures, galleries and holes of emergency of Cerambycidae. The species C. fairchildiana were more attacked, with 731 perforations (48,83%), proceeded by S. saman, with 458 (30,59%); E. citriodora, with 179 (11,96%); M. caesalpinaefolia, with 84 (5,61%); L. lactescens, with 26 (1,74%), and Gmelina arborea, with just 19 perforations (1,27%). The percentage of perforation of the first two species was superior significantly to the others at level of 5% of probabilities. This presupposes physical and chemical properties especially adapted to the development of those agents degradadores in these two species, or still, they can liberate attractive chemical components to the insects in larger amount than the other wood, demanding larger attention to avoid an accentuated degradation when exposed in the field. Index terms: Test bodies, Perfurations, Cerambycidae, Bostrichidae, Platypodidae
[1943] IMPACTS OF DOUGLAS-FIR BEETLE ON FOREST OVERSTORY AND UNDERSTORY CONDITIONS OF THE GREATER YELLOWSTONE AREA

J. D. McMillin¹ & K. K. Allen¹, ¹USDA Forest Service, Forest Health Management, Rapid City, SD 57702, USA, E-mail jmcmilli/r2_blackhills@fs.fed.us.

Douglas-fir beetle (Dendroctonus pseudotsugae) infestations frequently result from disturbance events that create large volumes of weakened Douglas-fir (Pseudotsuga menziesii) trees. Although research has focused on determining the susceptibility of forest stands to Douglas-fir beetle and predicting the amount of tree mortality caused by Douglas-fir beetle infestations following disturbance events, there has been an inadequate amount of work on consequent changes in both the overstory and understory. In the early 1990's, populations of Douglas-fir beetle increased in fire-scorched trees and then infested undamaged neighboring stands on the Shoshone National Forest, Wyoming, U.S.A. In 1999, transect sampling (32 km) and 25 pairs of previously infested and uninfested plots were used to quantify changes in forest stand conditions and subsequent responses in the understory caused by Douglas-fir beetle infestations. Significant effects of the Douglas-fir beetle infestation included: 1) Basal area was reduced by 40 - 70 percent, average tree diameter decreased by 8 - 40 percent, and the Douglas-fir component of the overstory decreased by more than 15 percent. 2) Conifer seedling regeneration increased nearly four-fold in the infested plots and 90 percent of the regeneration was Douglas-fir. 3) The understory vegetation (forbs, grass, and shrubs) had a three-fold increase in the infested plots compared with uninfested plots. In addition, basal area of Douglas-fir killed by the Douglas-fir beetle was significantly correlated with initial Douglas-fir basal area and percent of Douglas-fir, but not tree diameter or trees per hectare. Significant inverse relationships were also found between post-infestation basal area and the abundance of forbs, grass, shrubs, and understory height. Douglas-fir beetle infestations are causing significant short-term impacts in both the overstory and understory and contributing to the mosaic in forest structure observed in the Shoshone National Forest.

Index terms: Bark beetles, Dendroctonus pseudotsugae, forest succession, insect impact

[1945] IMPACT OF DEFOLIATION BY COSTALIMAITA FERRUGINEA (COLEOPTERA: CHRYSOMELIDAE) IN EUCALYPTUS GRANDIS

J. E. P. Mendes¹, N. Anjos¹ & F. R. A. de Camargo², ¹Dept. of Animal Biology (Entomology), Universidade Federal de Viçosa, P. H. Rolfs Avenue, n/w. Zip code 36571-000, Viçosa - MG, Brazil. E-Mail: jmendes@alunos.ufv.br. ²Votorantim Celulose e Papel, Dept. Research Unity Jacaref, H. Gal. Euryale de Jesus Zerbine, Km 84, Zip Code 12300-000, Jacaref - SP, Brazil.

The objectives of this work was evaluate the population dynamics and the injuries caused by Costalimaita ferruginea, as well as the consequences of its attack on a young plantation of Eucalyptus grandis, in Pindamonhangaba, São Paulo State, Brazil. The worst focus technique was used throughout the period of study as the monitoring system of the C. ferruginea population dynamics at Votorantim Celulose e Papel. An experiment was carried out soon after the end of the outbreak, to evaluate the consequences of the attack, where three pest attack intensities were evaluated as well as a control. The experimental design used was in random blocks, with five repetitions. It was measured the diameters of the trunk at 20 cm and 1,30 m of the soil, the height and the survival of the trees at four time intervals after the attack. The wood volume was calculated and the relationships among the growths in diameter and height, were studied besides the distributions of frequencies of diameters and height. The obtained data were submitted the regression analysis and the models compared by the test of F (p≤0,05). The quality of the trees 12 months after the attack were also evaluated. Tukey's multiple range test (p≤0,05) was used to compare the quality of the trees and frequency distribution. The injuries happened from the apex to the base of the canopy and they increased with time. The impacts on the growth and production of the trees increased, proportionally, with the different intensities of attack of the pest and with time. Which ranged from 2,38 and 13,93%, for DA20; 2,63 and 13,47% for DAP; 1,35 and 10,34% for height and, 4,28 and 28,45% for the wood volume 24 months after the attack. The rate of trunk diameter growth (DA20/DAP), as well as the rates between height and diameters (H/DA20 and H/DAP) were only altered by the largest attack intensity. The frequency distributions were altered with the attack intensity, altering the dynamics of the plantation growth. The trees more intensely attacked were more tortuous and suffered alterations in the process of natural disbudding, and they also had an increase in mortality and decrease in the volumetric production. Therefore, Costalimaita ferruginea is a pest of great importance for young plantations of eucalypts. Index terms: forestry insects, leaf beetle, Integrated management, eucalypts, defoliation

[1944] NEW RECORDS OF COLEOPTERA AND HYMENOPTERA FROM ARAUCARIA ANGUSTIFOLIA TREES IN THE SOUTH OF BRAZIL

<u>R. Mecke^{1,2}</u>, W. Engels² & M. H. M. Galileo³, ¹Lab. Pesq. Biol., Pontificia Univ. Católica, P. O. Box 1429, Porto Alegre, RS, 90619-900, Brazil; ²Zoolog. Inst., Univ. Tübingen, Auf der Morgenstelle 28, 72076 Tübingen, Germany, E-mail roland.mecke@tonline.de; ³Mus. Ciênc. Nat., Fundação Zoobot., P. O. Box 1188, Porto Alegre, RS, 90001-970, Brazil.

During a reforestation research project looking for more efficient methods to restore the South-Brazilian araucarian forests, the insect fauna associated with the parana pine (Araucaria angustifolia) has been investigated. The study has been realized in the area of 'Centro de Pesquisas e Conservação da Natureza Pró-Mata" of the Pontifícia Universidade Católica do Rio Grande do Sul (Porto Alegre, RS, Brazil), located on the Serra Geral at S 29° 28', W 50° 10'. A special interest was given to the Coleoptera and Hymenoptera developing under the bark, in the wood or in the reproductive organs of A. angustifolia and also to the predators of these insects. To extract the insects from the plant material (wood, male and female cones) photoeclectors have been used. Additionally larvae, pupae and adults have been collected by hand. The collected phytophagous, entomophagous and parasitic insects belong to the families Alleculidae, Brentidae, Buprestidae, Cerambycidae, Cleridae, Curculionidae, Melandryidae, Nemonychidae, Oedemeridae, Ostomatidae, Platypodidae, Scolytidae, Silvanidae (Coleoptera), Braconidae, Ichneumonidae, Orussidae, Xiphydriidae (Hymenoptera). Altogether there have been found more than 20 new records of Coleoptera and Hymenoptera species for the parana pine, at least 3 of them being new species. For the first time a wood-boring sawfly species (Hymenoptera: Xiphydriidae) has been recorded developing in branches of araucaria trees. There could be reared a large series of this species which now gives the possibility to describe the intraspecific variation of a neotropical xiphydriid wasp. Furthermore the relationships between some wood-boring Coleoptera (Cerambycidae, Curculionidae, Scolytidae) and their natural antagonists (Brentidae, Cleridae, Ostomatidae, Braconidae, Ichneumonidae) have been analysed.

Index terms: forest entomology, reforestation, parana pine, biological control.

[1946] EFFICIENCY OF GRANULATED SYSTEMIC INSECTICIDES TO ELIMINATE THE *COPTOTERMES HAVILANDI* COLONIES ATTACKING ROOTS OF TREES

E. B. Menczes¹, L. O. Andrade¹, A. C. Bicalho¹, G. T. Araújo¹ & E. L. Aguiar-Menczes², ¹CIMP "CRG"/ UFRRJ, BR 465, km 7, Seropédica, RI 23890-000, Brazil, Email ebmen@zaz.com.br; ²Embrapa Agrobiologia, Caixa Postal 74505, Seropédica, RJ 23840-000, Brazil, E-mail menczes@cnpab.embrapa.br.

The subterranean termite Coptotermes havilandi is an exotic species and considerate the worse pest in urban, suburban and rural areas of Brazil. However, the real concentration is in the metropolis like São Paulo, Rio de Janeiro and Niterói. This pest are adapted to the residential buildings, commercial buildings, fabrics, etc. The occurrence of this pest has been found attacking root system of trees that are used as shade and/or ornamental plants in the streets, avenues, parking lots, and as fruit trees in the backyards of houses. This present research had as objective to verify the efficiency of four systemic insecticides used in the granulated formulation applied in the soil to control C. havilandi. The insecticides used were never indicated and registered to control the infestation of C. havilandi in any circumstances. Preliminary observations showed that the infestation of the roots of the majority of the trees, when isolated or not, is very frequent. In such case, four insecticides of the toxicological class I were chosen to analysis their efficacy as contact, stomach or fumigant products against this species. Aldicarb 150G, carbofuran 50G, termophos 50G and carbosulfan 50G were used in the dosages recommended to control the coffee pests by the manufacturers. Five different species of native trees and five exotic trees were chosen for treatment. The native trees were: cashew (Anacardium ocidentali); jobo plum (Spondia venulosa); pinecone (Rollinia mucosa); guava (Psidium guajava); and Clitoria faschildiana (shade tree). The exotic ones were: flamboyant (Delonix spp.); eucalyptus (Eucaliptus spp.); Casuarina spp.; mango (Mangifera indica); and avocado (Persia americana). Before the treatments, we used monitoring stakes for detecting the presence of the termites. Although we had suspected of the presence of the nests in the root system, the method used for inspection was not enough to detect them. The four insecticides used showed 100% of efficiency, destroying the colonies completely in a short time. However, aldicarb 150G showed to be more efficient than the others in relation to the its time of action. It killed C. havilandi in 24 hours after the application, while the others had their action delayed (48 hours). However, there was no significant difference among the treatments.

Index terms: subterranean termite, chemical control

[1947] PRELIMINARY INVENTORY OF ARBOREAL INSECTS IN SANTA MARIA, RS, BRAZIL

A. B. B. Morais, Depto. de Biologia, CCNE, Universidade Federal de Santa Maria, 97105-900, Santa Maria, RS, Brasil e-mail: amorais@ccne.ufsm.br

Santa Maria city is localized in the transition zone between Brazilian Meridional Plain and Central Depression, in the state of Rio Grande do Sul. The subtropical forest, originally covering the highest localities, is now fragmented and differentialy modified by human settlement. The present study aims to obtain a preliminary inventory of arboreal insects and evaluate them as bioindicators of ambiental disturbance. Three field places were visited from March 1998 to February 1999: Cidade dos Meninos, Perau Velho and São Marcos. Insects were collected by use of a beating umbrella and conserved in 70° alcohol. From 5805 insects collected, 2074 in 15 Orders (35.73%) were from CM, 1940 in 12 Orders (33.42%) were from PV, and 1791 in 15 Orders were from SM. CM is the place with the greatest vegetation coverture from the three field places while SM is the smallest and more disturbed what could have influenced on the less frequency of insects collected in the later. Four Orders summed 78.59% of all insects: the O. Lepidoptera was the most abundant (1641 individuals, mostly larvae -28.27%), followed by O. Coleoptera (1166 individuals - 20.09%), O. Hymenoptera (997 individuals, mostly ants - 17.17%), and O. Heteroptera (758 individuals - 13.06%). By place, in CM O. Lepidoptera was the most abundant, followed by O. Hymenoptera, O. Coleoptera and O. Heteroptera; in PV O. Lepidoptera was the most abundant, followed by O. Coleoptera, O. Heteroptera, and O. Hymenoptera; and in SM O. Coleoptera was the most abundant, followed by O. Lepidoptera, O. Hymenoptera, and O. Heteroptera. O. Psocoptera had higher frequency (n=162) in SM than in CM (n=95) and PV (n=49). In conclusion, it seems that insects could have a good potential to be used as disturbance bioindicators.

Index terms: Lepidoptera; Coleoptera; Hymenoptera; Heteroptera; bioindicators.

[1949] CONSUMPTION AND UTILIZATION OF THREE SPECIES OF EUCALYPTUS BY THYRINTEINA ARNOBIA (LEPIDOPTERA: GEOMETRIDAE)

A.L.T. Oltati¹ & <u>C.F. Wilcken¹</u>, ¹Dept. Plant Production, FCA/UNESP, Campus of Botucatu, P.O. Box 237, Botucatu, SP, 18603-970, Brazil, E-mail: aottati@fca.unesp.br

Food intake and utilization indices are indicators of an insect's alimentary behavior and some of its relationships with respective host plants. Thyrinteina arnobia is considered one of the most important Eucalyptus pests in Brazil. This experiment was conducted considering the economic importance of this defoliator and the need of alternative means of its control (other than the chemical). The main objective was to compare the above mentioned indices in insects fed with three Eucalyptus species (E. camaldulensis, E. dunnii and E. urophylla), for two consecutive generations. Leaves used in the experiment were collected at the FCA/UNESP (Botucatu, São Paulo state) campus and the studies were cariied out at the Entomology Laboratory of the Plant Production Department (FCA/UNESP). under a temperature of 25 \pm 1^o C, relative humidity of 70 \pm 5% and photophase of 13 hours. The experimental design was a completeley randomized design, with 3 treatments and 100 replications. Data were submitted to analysis of variance and means separated by Tukey test. Results showed that the relative consumption rate (RCR), the efficiency of conversion of ingested food (ECI) and digested food (ECD) were not influenced by the three host plant species. The relative growth rate (RGR), relative metabolic rate (RMR) and approximate digestibility (AD) were lowest for the caterpillars fed with *E. urophylla* in the first generation. For the second generation, RCR, RGR, RMR and AD were highest for the caterpiliars fed with *E. camaldulensis* and *E. urophylla*, ECI was similar for the three host plants and ECD was higher under E. dunnii. We also verified that the performance of T. amobia in the second generation under E. dunnii was worser than when compared to the first generation insects; caterpillars fed with E. camaldulensis kept the same performance while insects fed with E. urophylla had in improve in its performance, when compared to their first generation. Index terms: Forest pest, integrated management pest, eucalypt

[1948] EFFICIENCY OF DIFFERENT INSECTICIDES IN CONTROL OF NURSERY FLY SCYTHROPOCHROA SP. (DIPTERA: SCIARIDAE) IN EUCALYPTUS SEEDLINGS

C. Orlato¹, C. F. Wilcken¹, C. C. Ortiz² & J. C. Augusti², 1Dept. of Crop Production, FCA / UNESP – Campus of Botucatu, P. O. Box 237, Botucatu, SP, 18603-970, BR, Email cwilcken@fca.unesp.br; 2Bahia Sul Celulose S.A., Rod. BR 101, Km 880, Teixeira de Freitas, BA, 45995-000, BR.

The flies of family Sciaridae have been occurred since 1990 on many of Brazilian eucalyptus nurseries. Scythropochroa sp. larvae causes damages to the root system of seedlings obtained by vegetative propagation, causing plant mortality. The larvae take 5 mm long in the last instar and it develops in the substratum of the seedlings. This work was carried out at the Bahia Sul Celulose S.A. eucalyptus nursery, in Mucuri - BA -Brazil. Into one of the greenhouses were settled two pest control experiments using manual drench in the substratum as the way of products application: just with one application (test 1) and with two applications (test 2). The insecticides treatments were: Vectobac AS (Bacillus thuringiensis var. israelensis) in the dosages of 280 and 560 ml c. p. /1001 of water (treatments 1 and 2); Trigard 750 PM (Cyromazin) in the dosages of 15 and 30 g of c. p. / 100 l of water (treatments 3 and 4); Decis 25 CE (Deltamethrin) in the dosages of 20 and 40 ml c. p. / 100 l of water (treatments 5 and 6) and the check (treatment 7). Both experiments were carried out in the 10^{th} day after stalking, but one day before (9^{th} (ay) the attack was previously evaluated. In the test 2, the plots of each treatment with insecticide received the second application, at 7 days after the beginning of the test, using the same first application dosages. Both experiments were evaluated in each 3 days, taking out in random 10 stalks per each tray and verifying the larvae number and its level of damage in each stake. The statistical delineation used for each experiment was randomized, with 7 treatments and 10 repetitions. The obtained results were submitted to the analysis of variance and the averages compared by Tukey's test to the level of 5% of probability. In the test 1, the treatments that were pointed out through rooting period were Vectobac AS 560 ml / 100 l (T2) and Decis 25 CE 40 ml / 100 l (T6), exhibiting respectively at the final control evaluation 77,9 % and 62,3 % of efficiency. In the test 2 pointed out Vectobac AS (T2) and Decis 25 CE (T6) again, reaching 100% of control in the evaluations after 9 and 12 days (T6) and 12 and 15 days (T2), of the beginning of the test. In the final evaluation (28 days into greenhouse) was detected the importance of the second application, showing how efficient are the biological insecticide BTi (E = 97,2 %) and deltamethrin (E = 95.5 %).

Index terms: nursery fly, forest nursery, greenhouse, chemical control, biological control.

[1950] MONITORING OF LEPIDOPTERA DEFOLIATORS OF *EUCALYPTUS* IN NIQUELÂNDIA, STATE OF GOIÁS, BRAZIL

J. M. M. Pereira, T. V. Zanuncio, J. C. Zanuncio, & M. A. Guimarães, Dep. de Biologia Animal, Univ. Federal de Viçosa, 36.571-000, Viçosa, MG, BRASIL. E-mail: zanuncio@mail.ufv.br.

Population fluctuation of Lepidoptera primary and secondary pests of *Eucalyptus* was studied in Niquelândia, State of Goiás, Brazil from May 1991 to April 1996. Every fifteen days Lepidoptera species were collected with light traps powered by twelve volt batteries. Ten primary pest species with 3,846.90 individuals and 13 secondary pests with 137.85 individuals per light trap were collected. Most abundant pest species were: primary pests - *Thyrinteina arnobia* (Geometridae), *Sarsina violascens* (Lymantriidae), *Psorocampa denticulata* (Notodontidae); secondary pest species - *Idalus admirabilis* (Arctiidae) and Citheronia marion (Saturniidae); with 2,021.18; 842.27; 421.24; 44.16 and 28.92 individuals per light trap, respectivelly. Highest numbers of individuals of primary pest species were registered from May to June while secondary pest species should be done during this period which can be made with different methods such as cloths under *Eucalyptus* lpants, light traps or counting the number of caterpillars per branch of those trees. Population of pest species can be detected with these methods allowing a better control of them with less damage to *Eucalyptus* trees.

Index terms: Eucalyptus, Lepidoptera defoliators, monitoring

[1951] MANAGEMENT OF HEADWATER FOREST STREAMS: ISSUES OF INSECT DIVERSITY AND BIOMASS PRODUCTION FOR VERTEBRATE PREDATORS

R. A. Progar & <u>A. R. Moldenke</u>, Dept. of Entomology, Cordley Hall 2046, Oregon State Univ, Corvallis, OR, USA 97331 E-mail: progarr@bcc.orst.edu.

The riparian areas encompassing headwater streams comprise over fifty percent of federally managed land in the Pacific Northwest. Forest management practices and their consequences (for example, compaction or disturbance) are likely to have direct effects on the abundance and diversity of arthropods in these sensitive habitats, and indirect effects through the foodweb on vertebrates of concern. We examined the effect of stream flow (perennial vs. dry-season temporary), and canopy presence on the pre-harvest insect fauna collected from emergence traps in headwater streams at three sites in the conifer forests of western Oregon. Density and biomass of aquatic insects were higher in temporary streams in the spring, but higher in perennial streams during the summer. Taxon richness was continuously higher in perennial streams. The abundance of Chironomidae exceeded all other taxa during the spring, but was largely replaced by Mycetophilidae as the most abundant taxon during the summer, especially in temporary streams. Trichoptera and Ephemeroptera emerged in higher numbers from perennial than from temporary streams. These results are consistent with our hypothesis that the absence of vertebrate predators (fish and giant salamanders) allows the density of arthropods in temporary streams to flourish, serving as: (1) a potential source of colonization for perennial streams and (2) an important role in the terrestrial food web as an abundant food source for insectivorous We also examined the effect of canopy presence vs. clearcut on the insect vertebrates. fauna. Headwater streams flowing through clearcut uplands support higher densities, biomass and richness than forested streams. The proliferation of aquatic insects in headwater streams flowing through clearcuts is presumably due to the increased primary production from increased insolation, and higher diversity of allochthonous detritus. Pitfall sampling on transects perpendicularly across these streams clearly indicated that diversity and abundance are significantly greater at the immediate creek edge and 1-3 meters away within the riparian vegetation zone; all species characteristic of the upland forest floor occurred within the riparian zone as well.

Index terms: riparian management, emergence trapping, temporary stream, aquatic insects

[1952] VERTICAL DISTRIBUTION OF CLOUD FOREST PRONOPHILINAE BUTTERFLIES IN MONTE ZERPA, CORDILLERA DE MERIDA, VENEZUELA

T. W. Pyrcz¹, <u>J. Woitusiak</u>¹, ¹Zoological Museum, Inst. of Zoology, Jagiellonian Univ., R. Ingardena 6, 30-060 Kraków, Poland. E-mail: wojt@zuk.iz.uj.edu.pl

A method of sampling along elevational transects has been used to study vertical distribution of Pronophilinae butterflies (Nymphalidae, Satyrinae) on southern slopes of the Serrania de La Culata in Central part of the Cordillera de Merida, Venezuela, known as Monte Zerpa. Ranges of vertical distribution have been estimated for 20 species on the basis of 1100 records obtained from a series of collection sites set every 25 m from 2250 up to 3050 m. The ranges of only two species, Steromia bega and Erethris porphyria were as wide as the width of the entire cloud forest zone. The ranges of all the other were about 400 m on average. When superimposed on an altitude scale, ranges of Pronophilini revealed a characteristic pattern with the lover pool of species distributed within the zone of 2250-2750 m and the upper pool in the zone of 2500-3050 m. The highest biodiversity was found at middle elevation where ranges of the two pools overlap. Parapatric distribution was found for three pairs of closely related species, where Lymanopoda obsoleta, Pedaliodes montagna and Corades chelonis occured at lower elevations, whilst Lymanopoda dietzi, Pedaliodes ferratilis and Corades pax were replacing them at higher elevations. Possible factors which may play a possible role in the process of vertical range formation and maintainance of parapatric distribution in Pronophilini butterflies are discussed.

Index terms: Andes, altitudinal zones, cloud forest, butterflies, parapatry.

[1953] DEVELOPMENT OF *PSILOPTERA* SP. (COLEOPTERA: BUPRESTIDAE) IN STUMPS OF *PINUS CARIBAEA*, IN THE NORTHEAST REGION OF THE STATE OF BAHIA, BRAZIL

G. T. Ribeiro & J. C. Zanuncio, Dept^e. de Biologia Animal, Univ. Fed. Viçosa, 36571-000, Viçosa, MG, Brasil, E-mail zanuncio@mail.ufv.br.

Psiloptera sp. has been constantly damaging Eucalyptus seedlings of several species in many places of Brazil. Feeding of this insect occurs on the bark, on lateral branches and also on stems of young plants thus reducing their normal growth. Females of Psiloptera usually lay their eggs on the upper extremity of Eucalyptus stumps. After the incubation period larvae of this pest hatch and migrate to the roots or to deeper parts of the stumps. After emergence from the stumps adults of this pest prefer to attack young plants of Eucalyptus. Stumps of *Pinus* trees are preferred by *P. semipunctata* for egg laying and larval development in the northeast area of Bahia where constant attacks and damage by this pest on recently planted seedlings have been recorded. Occurrence of this beetle is, most of the time, associated to areas where Pinus trees were cut. Monitoring in areas with different types of vegetation near to areas with plants attacked or to places where Pinus trees were cut confirmed the presence of pupae and larvae of Psiloptera in stumps of this plant. Recently planted areas showed that the number of beetles increased near areas planted with Pinus. This indicates that plantations with Eucalyptus in areas previously planted with *Pinus* or close to plantations of this tree group are more likely to be attacked by *Psiloptera*. It is suggested that researches should be done aiming to quantify the number of stumps with larvae and the number of larvae of Psiloptera per stump before the use of land for planting. This could identify the occurrence and potential damage by Psiloptera in the area. These studies and others about the biological cycle of this insect can lead to development of better control methods of this pest in the field.

Words key: Wood borer of Eucalyptus and Pinus stumps; Psiloptera; larval development.

[1954] OCCURRENCE OF *PSILOPTERA* SP. (COLEOPTERA: BUPRESTIDAE) DAMAGING PLANTS OF *EUCALYPTUS* SPP., IN THE NORTHEAST REGION OF BAHIA, BRAZIL

G. T. Ribeiro & J. C. Zanuncio, Dept^e. de Biologia Animal, Univ. Fed. Viçosa, 36571-000, Viçosa, MG, Brasil, E-mail zanuncio@mail.ufv.br.

Successive attacks by the beetle Psiloptera sp. has been recorded in the last years in plantations of Eucalyptus in the northeast region of the State of Bahia, Brazil mainly in recently planted seedlings. Adults of this species feeds on bark, on lateral branches and also on young stems of Eucalyptus seedlings causing losses of the apical meristem and thus avoiding the normal development of the plant. Due to the severity of damage, which are not in many cases well evaluated companies with similar problem are adopting hand picking of this insect as a control strategy. During 1998 a total of 592.94 beetles/ha were collected in an area of 1012 hectares. This number was much higher than that of 1999 with 211.0 beetles/ha in an area of 1620 hectares. Such difference between 1998 and 1999 could be related to a higher rainfall during this last year. This could have represented a shorter period after planting for the bug to attack Eucalyptus seedlings. A faster development of seedlings in the field could also reduce the action of the beetles and to decrease damage to plants besides difficulting its location. During hand picking a total of 4.21% of the *Eucalyptus* blocks showed more than 1,000 beetles/ha being 1,215/ha the largest number of beetles collected per hectare; 14.74% of these blocks showed between 500 and 1000 beetles/ha; 42.26% of them had between 100 and 500 beetles/ha; and the remaining 35.79% of the blocks had less than 100 beetles/ha. Hand picking seems to be the best and more viable strategy to control this pest. Besides reducing damage by this pest when they are occurring in the area it can, also reduce risks of future outbreaks due to a sharp reduction of adults of this pest in the area and thus reducing population in the subsequent years. Even though hand picking presents satisfactory results it demands an intense labor activity which can turn it non-viable for large areas.

Words key: Psiloptera; damages in Eucalyptus, Control.

[1955] DESCRIPTION OF LARVAL TUNNELS AND PUPAL CHAMBERS OF CALYDON SUBMETALLICUM IN ROBLE PELLIN OF PATAGONIA, ARGENTINA

S. Rizzuto¹, ¹Cátedra de Zoología Forestal, Facultad de Ingeniería. Univ. Nac. de la Patagonia, Sede Esquel, Sarmiento 849, 9200 Esquel, Chubut, Argentina. E-mail: pautasso@cybersnet.com.ar

Cerambycids are one of the main groups of forest insects because of the damage they cause to the wood. During their development they make tunnels and galleries in the host plant, reaching vital tissues. Nothofagus forests (Deciduous Forest District, Sub-Antarctic Domain) range from Neuquén to Tierra del Fuego, and several species have economic interest; N. antarctica (ñire) and N. pumilio (lenga) are widely distributed. In the north of the district there are N. procera (rault) and N. obliqua (roble pellín) forests; these species have very precious wood. N. dombeyi (coihue) is found in the more humid zones in a narrow fringe close to Chile, in Neuquén, Río Negro and Chubut. These species are used for buildings, furniture or sometimes in posts and as firewood. Although some species of Nothofagus in Patagonia are attacked by cerambycids, there are no inventories and the biology of this group is unknown. This study describes larval tunnels and pupal chambers of Calydon submetallicum in N. obliqua. Dead wood of roble pellín was collected in Trevelin city (42° 06' S, 71° 28' W). It was put into wire cages outdoors for twelve weeks. Imaginal emergence was recorded in summer. Pupal chamber construction in cerambycids is a complex behavior that requires many succesive steps before the larva moves into pupa. Galleries produced by C. submetallicum are subcortical and pupal chambers are internal, constituting part of the sapwood.

Index terms: Cerambycids, Nothofagus obliqua, wood boring insects, Patagonia.

[1957] APHIDS (HOMOPTERA: APHIDIDAE: LACHNINAE: CINARINI) ON PINUS SPP. AND CUPRESSUS SP. IN SOUTHERN BRAZIL

S. M. N. Lazzari & <u>R. C. Zonta de Carvalho</u>, Depto. de Zoologia, Universidade Federal do Paraná, Curitiba, PR, BR. E-mail lazzari@bio.ufpr.br

Recent aphid outbreaks have been registered on Coniferae in southern Brazil, causing significant losses to the forestry, lumbering, and paper mill industry. The Cinarina Cinara pinivora (Wilson) and Cinara atlantica (Wilson) have been collected on Pinus elliotti, P. taeda, and P. caribaea. C. pinivora was first recorded in 1994, feeding preferentially on thicker branches, during the cooler months of the year. It spread from Santa Catarina to Rio Grande do Sul, Paraná, and São Paulo. C. atlantica was first collected in 1998, especially at the branch tips and buds. It has been found year round, in the South Region, São Paulo, and Minas Gerais. These Cinara species differ in a number of ways including the shape of the siphuncular sclerite and sclerotinization of abdominal terga. Other Cinara species on Pinus have been cited for Brazil: Cinara piniformosana (Takahashi), which has not been found lately and Cinara maritimae (Dufour). On Cupressaceae, two specie have been collected: Cinara tujafilina (del Guercio) on Thuja sp. and Cinara cupressi (Buckton) on Cupressus sp. The later was first collected in 1999, in Paraná, and can be distinguished from C. ujafilina by the color of the femur and tibia, and number and distribution of the hairs on the base of the antennal segment VI. The Eulachnina Essigella californica (Essig) and Eulachnus rileyi (Williams) have been observed associated with Cinara colonies on Pinus spp. The Californian pine needle aphid, E. californica, was first recorded in early June 1999, on slash pine P. elliotti and on Mexican weeping pine P. patula, in Paraná. It is characterized by the 5-segmented antennae, tarsal claws with double tips, and lime green color in life. E. rileyi has 6-segmented antennae, normal claws, color varying from dark olive green to gray, with a dusting of bluish-gray wax. Alate and apterous viviparae and nymphs of both species can be found on branch tips feeding on the needles, and moving quite rapidly. The damages of these Cinara species, and probably of the other associated pine species, are more visible after a couple of years of infestation. Chlorosis and premature needle dropping, stunting and malformation of trees, and extensive growing of sooty mold on the honeydew produced by the aphids, have been observed. Another indirect damage of Cinara is caused by the great amount of aphids that stick on collecting panels staining the resin with a reddish pigment. This damage results in loss of commercial value and credibility. Cinara eggs have been collected, although sexual morphs have not been found until the moment. More studies on biology, distribution, host plant-aphid-natural enemies relationships and control strategies are needed.

Index terms: Aphid outbreak; pine aphids; Cinara spp.; Essigella californica; Eulachnus rileyi.

[1956] CONSERVE OR NOT TO CONSERVE FOREST FRAGMENTS: CASE STUDY USING BUTTERFLIES AT THE KENYA COAST

L. M. Rogo, International Centre of Insect Physiology and Ecology, P. O. Box 30772, Nairobi, Kenya. Email: Irogo@icipe.org.

Throughout the tropics, deforestation is destroying the forest resource base, leaving only fragments of forests. A case in point is the eastern coastal forest of Africa, which once stretched from northern Natal to southern Somali. In Kenya only a few large tracks of this forest remain, such as the Arabuko-Sokoke (4,000 hecters) and Shimba Hills (14,000 hecters) forests. More common are the very small fragments like the Muhaka (180 hecters) and Mrima (350 hecters) forests. Species richness, diversity and composition of butterflies in two Kenya coastal forest remnants of Muhaka and Mrima hill were investigated to demonstrate the importance that forest fragments play in maintaining biodiversity. Sixty-three species were recorded from each forest remnant from a total of 1329 individuals. Species accumulation curves for both forests did not reach an asymptote with the likelihood that additional sampling effort could yield more butterfly species. High species similarity was recorded between the forest interior and the surrounding matrix, primarily due to invasion of the forest interior clearings by the savanna species. Despite their small sizes, these forest remnants were found to maintain viable populations of true forest butterflies. However, the number of species was less than half of that recorded from Shimba hills and Arabuko-Sokoke, located in the same larger forest reserves of geographical area. Records from Muhaka forest show species unique to it, not found in the larger forest reserves, underscoring the importance of small remnants in the preservation of forest biodiversity. However, in the event that conservation priorities were to be set, conservation efforts should be directed to larger forest reserves since they maintain more biodiversity. The high species similarity between the forest remnants implied that if habitat corridors were created, gene flow between these remnants and other larger forest reserves, would be possible. This would reduce the isolation of true forest butterfly populations within the remnants and potential local extinction.

Index terms: Forest remnants, species richness, species diversity, species composition, conservation.

[1958] BIOLOGICAL DATA AND POPULATION ABUNDANCE OF THREE SPECIES OF CASSIDINAE (COLEOPTERA: CHRYSOMELIDAE) IN A TROPICAL FOREST AREA IN BRAZIL

F.N. Sá¹ & J. Vasconcellos-Neto¹, ¹Universidade Estadual de Campinas - Inst. Biologia -Depto. Zoologia. Campinas, SP, Brasil, 13083-970. E-mail: fnsa@obelix.unicamp.br.

Few information is available on the biology and phenology of Chrysomelidae, unless if they are of economic interest. In this work we have followed the populations of Stolas chalybea, S. areolata and Anacassis phaeopoda for two years in order to obtain basic biological data on them and to know their occurrence throughout the year. We collected the data in fortnightly visits at the studied site by censusing host plants of studied Cassidinae. During each census, we have recorded the group sizes and position of egg and larval clusters and adults on their host plants. We also recorded their numbers. In an attempt to recognize the factors that influence the abundance of Cassidinae, we correlated that with temperature and rainfall at the study area, with some plant size parameters and also considered the relative abundance of different pheno-phases of the host plants. We observed that after emerging from the eggs, larvae of the three studied species remained aggregated, although the size of the groups decreased as the larvae developed. Egg clusters and larvae of the two Stolas species were more frequently found on the underside of leaves of their host plants; nevertheless, mature larvae of S. areolata were only observed on the upper side of leaves. Adults of the three species were always isolated and both Stolas species were more frequently found on the upper side of leaves. S. chalybea and S. areolata seemed to have the same pattern of occurrence throughout the year: they became active with the end of the dry season, reproduced more intensely during the rainy season and reduced their activity around June, during the beginning of the period of lower temperature and rainfall. A. phaeopoda showed a similar pattern, but it could be observed at the field earlier than the other two species. The three species also showed a lower peak of egg laying at the end of diapause of adults, what can suggest that females overwinter fertilized already. Larvae could be observed approximately from november until April or May. This pattern of occurrence was very similar to the occurrence of leaves on their host plants. Significant positive correlations between Cassidinae numbers and temperature showed that this parameter can influence ovipositing and mating activities. The number of new branches on the host plant was the most common trait that was significantly related to Cassidinae presence. Other parameters like number of branches and number of leaves were also related to the abundance of Cassidinae.

[1959] SCOLYTIDAE AND ASSOCIATED INSECTS IN PONDEROSA PINE STANDS UNDER DIFFERENT STRUCTURAL CONDITIONS IN NORTHERN ARIZONA

G. Sanchez-Martinez¹ & M.R. Wagner¹, ¹School of Forestry, College of Ecosystem Science and Management, Northern Arizona University P. O. Box 15018, Flagstaff, AZ 86011-5018, USA, E-mail gs8@spruce.for.nau.edu

Bark beetle (Coleoptera: Scolytidae) outbreaks are commonly associated with unhealthy forest conditions. In general, overstocked stands are considered more susceptible than open grown stands. However, because epidemic levels represent extreme values, bark beetle outbreaks may indicate unhealthy forest condition mostly from just one perspective. Forest management today requires more understanding of ecosystem components and ecological processes. Different bark beetle species create a variety of structural conditions within a given forest which, according to our management objectives and forest values, may be classified as healthy or unhealthy. Thus, from an ecosystem-oriented approach, a forest with high bark beetle infestations can be as unhealthy as a similar forest, but with no infestations at all. The objective of this study was to explore the association between the structure of ponderosa pine (Pinus ponderosa Dougl. ex Lawson) forests of the Coconino Plateau in northern Arizona and the diversity of Scolytidae and other important bark inhabiting insects. Although many dense stands with unhealthy conditions occur in this area, no significant bark beetle outbreaks have occurred for several decades. Four stand conditions were evaluated: 1) Dense stands with no management during the past 20-30 years, 2) Thinned mature even-age stands with >30% of hasal area (BA) removed between 1987-94, 3) Thinned mature even age stands with >30% of BA area removed by thinning with a prescribed burn 3 to 4 years after thinning, and 4) Formerly dense stands with no management which had been burned by stand replacing wildfires with >90% of BA removed by fire. Bark beetles and associated insects were sampled with Lindgren funnel traps baited with attractants (1998-1999). Dendroctonus brevicomis was the only aggressive species found in this study. It was more abundant in thinned stands and barely present in unmanaged stands; however, population levels of this species seem to be insufficient to cause outbreaks. D. valens was present in low levels in all stand types as well as Ips pini. Wood borers (Coleoptera: Cerambycidae) were more abundant in unmanaged and thinned only stands. Sevaral insect predators were well represented in all stands. Our preliminary results indicate a low diversity of bark inhabiting insects and suggest either: lack of suitable hosts or high efficiency of natural enemies. The lack of bark beetle attacks on susceptible stands could mean tree stagnation, interruption of natural disturbances, and poor habitat diversity.

Index terms: Pinus ponderosa, forest health, bark beetles.

[1960] *CTENARYTAINA EUCALYPTI* (HEMIPTERA, PSYLLIDAE) HOST EVALUATION

<u>D. L. Q. Santana</u> & R. V. C. Higa, *Embrapa Flerestas*, Estrada da Ribeira, Kml11, Colombo, PR. E-mail francis.santana@bbs2.sul.com.br.

On its natural environment (Australia) Eucalyptus is a host of several insects from Psyllidae family. Ctenarytaina eucalypti has a large distilution and it is considered among then, the most harmful. The species was first observed in Brazil in 1988 in Eucalyptus dunnii in a nusery. Leaf and stem deformity, growth delay, apical bud death, accessory bud development and seedling lost have been recorded. In order to evaluated C. eucalypti host preferential 1534 seedlings of 20 Eucalyptus species were produced in plastic tube, placed next to each other and they were infested with the pest. Insects number per plant was count when seedlings were around 20 cm high. E. camaldulensis, E. nitens, E. dunnii, E. benthamii, E. cinerea and E. viminalis had 100% of seedlings infested by C. eucalypti, on the other hand, E. grandis, E. pilularis, E. maculata, E. saligna, E. pellita, E. tereticornis, E. citriodora, E. resinifera, E. robusta, E. deanei, E. urophylla, E. microcorys and an hybrid ("Cambiju") were not infested. It was found an average of 6, 5, 20, 12, 20 and 3 C. eucalypti nimphs on E. camaldulensis, E. nitens, E. dunnii, E. benthamii, E. cinerea e E. viminalis respectively. It was observed that glaucous leaves were more susceptible to the insect attack.

Index terms: Eucalyptus spp., eucalypts pests

[1961] INSECTS ASSOCIATED WITH SEEDS OF THREE NATIVE SPECIES OF BRAZILIAN ATLANTIC FOREST

D. L. O. Santana¹, A. C. S. Medeiros¹, C. S. Ribeiro-Costa² & A. F. Santos¹, ¹Embrapa Florestas, Estrada da Ribeira, Km 111, Colombo, Paraná, Brasil, E-mail francis.santana@bbs2.sul.com.br;²Departamento de Zoologia, Univ. Federal do Paraná, C. P. 19020, 81.531-990, Curitiba, Paraná, Brasil. E-mail stra@bio.ufpr.br.

A Brazilian Institution, Embrapa Florestas placed at Colombo (Paraná), created in 1999 an active seed bank for the species of native forests in order to provide seeds for uses such as refforestation programs, reclamation of degraded ecosystems, etc. Fruits of three brasilian native species (Enterolobium contotisiliquum, Bauhinia forficata and Cordia trichotoma) were collected from Capitão Leônidas Marques, Paraná State. In order to evaluate the quality of seeds for storage in the Embrapa seed bank, 100 fruits for each species were processed and the seeds dissected to examine damages. Relating to Enterolobium contotisiliquum (timbaúva) presented average of 3.7 seeds per fruit and 21.8 % of them were damaged by a bruchid beetle, Merobruchus bicoloripes. In this plant it was also observed specimens of an Hymenoptera parasitoid belonging to the subfamily Braconinae. The fruit of Bauhinia forficata (pata-de-vaca) showed average of 4.5 seeds per fruit and 31.3% of the total number of seeds consumed by the bruchid Gibbobruchus speculifer. 5.1% specimens of G.speculifer were parasitized by the Eulophidae, Horismenus missouriensis and Pteromalidae sp. The damage in seeds of Cordia trichotoma was variable depending on the lots. One sample of Rio Grande do Sul had 95% of seeds damaged by the bruchid Amblycerus profaupar. Specimens of an unidentified Hymenoptera were also observed parasiting larvae of this bruchid. Considering the diversity and abundance of the insects species observed on these seeds lots it is necessary to conduct a careful observation of the seeds of the quoted species of plants to prevent infestation in the seed bank.

Index terms: Merobruchus bicoloripes, Gibbobruchus speculifer, Horismenus missouriensis, Amblycerus profaupar, seed pests

[1962] INFLUENCE OF STRIPS OF NATIVE VEGETATION IN PLANTATIONS OF FUCALYPTUS CLOËZIANA ON POPULATION OF OXYDIA VESULIA

<u>G.P. Santos</u>¹, **T.V. Zanuncio²**, **J.C. Zanuncio² & R. Pinto²**, ¹EPAMIG/CTZM, Vila Gianetti, 47, C. Postal, 216, 36570-000 Viçosa-MG, Brasil, E-mail: germi@mail.ufv.br; ²Dept. de Biologia Animal, Univ. Federal de Viçosa, 36571-000 Viçosa-MG, Brasil, Email: zanuncio@mail.ufv.br.

Eucalyptus species are planted in the majority of reforested areas in Brazil. These species of the Myrtaceae family are being damaged by insects from native hosts including Lepidoptera such as Oxydia vesulia (Lep.: Geometridae). This species is a primary pest of Eucalyptus being responsible for significant damage to this plant in reforested areas of Brazil. Eucalyptus plantations are characterized by extensive and contiguous areas which offers abundance of food and shelter for harmful insects and creates conditions for more frequent and harmful outbreaks of Lepidoptera pests. The establishment and preservation of native remnants of vegetation have been proposed as a strategy for pest management because it can increase ecological diversity and, consequently, favors the development and reproduction of natural enemies. Such strategy has been used in regions of the Savannah in the State of Minas Gerais, Brazil, where 25 meters wide strips of Savannah linked to each other and to forest remnants are used every 500 meters of *Eucalyptus* plantation. Lepidoptera individuals were collected in two different situations representing a Eucalyptus plantation with strips of native vegetation and another one without such strips. Five light traps were used in each plantation at two meters height and turned on at 6:00 to 7:00 P.M. and turned off between 8:00 and 9:00 A.M. the following day. These traps were located as: number 1- inside an area of Savannah at 100 meters from its border; 2- in the transition between the Savannah and the Eucalyptus plantation; 3- inside the Eucalyptus plantation at 250 meters from the Savannah; 4 in the center of a Savannah strip at approximately 500 meters from the border of the Savannah or between two blocks of *Eucalyptus* in the system without strips; and 5- inside the *Eucalyptus* plantation at 750 meters from the Savannah border. A faunistic analysis was made using frequency, constancy and diversity indexes for O. vesulia. A total of 329 individuals of this pest were collected with higher abundance in the plantation without strips where 266 individuals were collected and only 63 individuals were collected in the other system. This species was constant in the system without strips and accessory in the one with strips with frequency of 1.15 and 1.66% in these two systems, respectively. A large number of individuals of O. vesulia were collected in both plantations from the second period of February. The plantation with strips showed higher number of individuals of this pest inside the Eucalyptus plantation at 250 meters from the border of the Savannah with 31 individuals while in the one without strips O. vesulia showed higher number of individuals in the point at 750 meters from the border of the Savannah.

Index terms: insect monitoring, defoliator Lepidoptera, native forest

PREDATION RV [1963] SEED **CTENOCOLUM** CROTONAE (COLEOPTERA:BRUCHIDAE) IN LONCHOCARPUS MUEHLBERGIANUS (LEGUMINOSAE)

L.T.Sari ¹, C.S.Ribeiro-Costa¹, A.C.S.Medeiros² & D.L.Q. Santana², ¹Dept. of Zoology, Univ. Fed. of Parana, P.O.Box 19020, 81531-990, Curitiba, Parana, Brazil, Email stra@bio.ufpr.br; 2 EMBRAPA Florestas, Estrada da Ribeira, Km 111, Colombo, Parana, Brazil, E-mail dalva@cnpf.embrapa.br.

Lonchocarpus muchlbergianus (rabo-de-bugio) is a Brazilian native tree recorded from Minas gerais, Mato Grosso do Sul until Rio Grande do Sul. The beautiful lilac flowers arising from October until January are the reason for their use as an ornamental tree. In order to evaluate the seed predation by insects, fruits were collected from two specimens of this plant placed at Tres Barras, Parana, Brazil. A sample of 500 g of fruits was selected and processed in laboratory resulting in 2353 seeds. Usually the fruits are composed by two seeds, rarely by three or four seeds. It was registered 77.39 % of healthy seeds, 10.24 % of shriveled and 12.36 % damaged by insects. A bruchid species, Ctenocclum crotonae, was detected in this material. The genus Ctenocolum is composed by eight species registered from South and Central America; C. crotonae is the only recorded from Brazil. Species of Lonchocarpus are common host plants of this genus. The host plants of C. crotonae are L. hondurensis, L. margaritensis, L. nitidus, L. pentaphyllus, L. rugosus and Piscidia carthagenensis. In fact, this is the first record of L. muehlbergianus as a host plant of C. crotonae. This species was registered from Mato Grosso and, in this paper, the geographical distribution is amplified including the Parana state. Other immatures of Tenebrionidae and Curculionidae were detected feeding the seed contents but theirs damages were indistinguishable; both groups represented a loss of 2.84 % of the total number of seeds. A parasitoid belonging to the family Eulophidae, Horismenus missouriensis, was observed inside seeds probably developing in larvae or pupae of the Coleoptera species. This Hymenoptera was already recorded parasitizing bruchid species, as Amblycerus submaculatus, A. hoffmanseggi and Gibbobruchus speculifer. As the hole left by the adult bruchid in the seed is larger than the hole of the parasitoid, it was possible to differentiate both species. The parasite emmerged from 4.63 % and C.crotonae from 4.88 % of the total number of seeds.

Index terms: beetle, biology, damage.

[1964] OCCURRENCE OF WOOD BORING BEETLES IN THE NATIONAL FOREST MÁRIO XAVIER, RJ, BRASIL

V. M. Schermack¹, <u>A. G. Carvalho¹</u>, A. M. Lunz¹, J. G. N. Wendt¹, J. M. Pinto² & S. R. S. Ventura¹, ¹Depto. Produtos Florestais, Univ. Fed. Rural do Rio de Janciro, Seropédica, RJ 23851-970, Brasil. E-mail: schermack@ufrrj.br; ²Depto. Fitotecnia, Univ. Fed. Rural do Rio de Janeiro.

For counting with a wide diversity of species, the order Coleoptera is associated to several alimentary habits among its representatives. Considering the economic importance, they stand out in this order the wood-boring species that caused damages to the forest species, making perforations and galleries that degrade and they serve as entrance for agents degradadores of the wood, as the mushrooms Ambrosia. The families Scolytidae and Platypodidae are common in alive, reviled or recently abated trees; the family Bostrichidae is seen in wood in drying process, and the family Cerambycidae lives in several wood types embracing alive trees, even deteriorated logs. Seeking to establish the incidence and the frequency of the families of Coleoptera above-mentioned in the area of the National Forest Mário Xavier, km 50, Seropédica, RJ, twelve impact window-traps were installed, model Carvalho-47, made with recyclable material and adapted starting from the model Marques-Pedrosa, to a height of 1,5 m of the soil. The collections are weekly being accomplished starting from July of 1999, with end forecast for July of 2001. Three types of snares were distributed by vegetation, in the following areas: native vegetation, mixed plantation, "sapucaia" and Eucalyptus spp. Until January of 2000, 30 collections were accomplished. Of the 4694 collected insects, 4447 (94,74%) belong to the family Scolytidae, 190 (4,05%) Cerambycidae, 53 (1,13%) Bostrichidae and 4 (0,09%) Platypodidae. For the different vegetation types, the area of mixed plantation indicated the largest incidence with 2373 (50,55%) collected individuals, proceeded by the native forest with 805 (17,15%), Eucalyptus spp, 743 (15,83%) and "sapucaia", 773 (16,47%).

Index terms: Scolytidae, Cerambycidae, Bostrichidae, Platypodidae, Window-traps.

[1965] WOOD BORING BEETLES IN PLANTATION OF SAPUCAIA, LECYTHIS PISONIS (LECYTHIDACEAE), IN THE NATIONAL FOREST MÁRIO XAVIER, SEROPÉDICA, RJ, BRASIL

V. M. Schermack¹, A. G. Carvalho¹, A. M. Lunz¹ & S. R. S. Ventura¹, ¹Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica RJ. 23851-970, Brasil. E-mail: schermack@ufrrj.br.

Seeking to establish the incidence and the frequency of the families of wood degrading beetles that happen in homogeneous plantations with native essences, three snares model Carvalho-47 were used, in a area of Lecythis pisonis (Lecythidaceae), in the National Forest Mário Xavier, Seropédica, RJ, in the period of July of 1999 to January of 2000. The snares were installed to a height of 1,30 m of the soil, being used as attractiveness the alcohol 96% that it was renewed weekly, after the collection of the insects. The samples, in a total of thirty, were taken to the laboratory of Forest Entomology of the Institute of Forests, Department of Forest Products (DPF) of UFRRJ, where the insects were quantified and identified the family level. The total of wood degrading beetles collected belonged to 773 individuals, and the frequency of the family Scolytidae corresponds to 725 individuals (93,79%), with a population pick in the month of August of 1999, frequently of 159 (20,57%); proceeded by the family Cerambycidae with 32 (4,14%) and family Bostrichidae with a 16 (2,07%), both reached population pick in the month of September of 1999 with 11 (1,47%) and 8 (1,03%), respectively. Doubled attention should be given to these families, once its species presents quite varied alimentary habits, feeding of medullas, phloems and xylems. It was ended that there is incidence of wood degrading bettes in sapucais, *Lecythis pisonis*, represented by the families Scolytidae, Cerambycidae and Bostrichidae, in decreasing degree of frequency, respectively. Index terms: Scolytidae, Cerambycidae, Bostrichidae, Window-traps.

[1966] NON-HOST SIGNALS INHIBITING FEEDING IN HYLOBIUS PINE WEEVILS: LABORATORY ASSAYS AND FIELD TESTS

F. Schlyter, E. Marling, P. Månsson & J. Löfqvist, Chemical Ecology, Plant Protection SLU. P.O. Box 44, SE-230 53 ALNARP. Science. http://www.vsv.slu.se/cec/ce.htm

Anti-feedants as a protection against herbivores have been described in many plants, wellknown is the 'neem' tree Azadiractica indica. In conifers, defense is quantitative, based on less toxic oleoresin compounds. In small, stressed conifers like the seedlings planted on clear-cuts in forestry, the quantitative defense is weak. These seedlings have been proected by insecticides like DDT and pyrethroids against the feeding by pine weevils Hylobius abietis (causing a 100 million US\$/year damage in Sweden), but use of insecticides will finally be banned in 2003. Our work follows two lines: 1) The screening of synthetically available anti-feedant compounds and related structures, mainly of plant origin. 2) The search for antifeedants in non-host plants. The development of laboratory bioassays has been a prerequisite for the project. Initially, Klepzig & Schlyter (1999) modified a twig technique of Salom *et al.* (1994). Later, to test small amounts of synthetics and extracts, we developed a micro feeding assay using TLC-plates. Presently, we are modifying an olfactometer to investigate the mode of action (taste/smell) of synthetics. For one active compound, carvone, a mainly olfactory mode of action is indicated. Field tests in 1997 and 1998 demonstrate that formulated carvone may protect seedlings for months. The long-term formulation of antifeedants, their mode of action, and finding of lower volatility compounds remain our goals. Index terms: Hylobius abietis, pine weevil, antifeedant, DDT.

[1967] ECOLOGY OF SCOLYTIDAE (COLEOPTERA) IN FORESTRY REMNANTS BELONGING TO CHAMPION Co. IN MOGI GUAÇU, SP, BRASIL

C. A. M. Silva¹ & A. G. Carvalho¹, ¹Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: carlmont@floresta.ufpr.br and acacio@ufrrj.br.

This work investigated the populations of bark and ambrosia beetles (Coleoptera: Scolytidae) in three belonging native forestry remnants belonging to the Agricultural Chamflora Ltda., in the municipal district of Mogi Guaçu, Itapira and Martinho Prado Júnior, state of São Paulo. In the period of January of 1998 to January of 1999 was studied the composition of the scolytids species, by means of biweekly collections in nine snares ethanol's model Carvalho-47, being obtained the fluctuation for each specie in the three native forest fragments of different sizes, forms and historical of disturbance. It was used the index faunistics: frequency, constancy, individual dominance of the species, richness, association among the species, similarity between communities and diversity. Thirty-eight species were collected, where four of them were not identified, only one was identified at the genus level. The 34 identified species are distributed in 12 genus and 5 tribes. Hypothenemus eruditus, Microcorthylus minimus, H. obscurus, Xyleborus retusus, Corthylus schaufussi and Premnobius cavipennis were the most abundant species. Six species were represented, each one, with just a specimen in the collections. H. eruditus was just aimed as constant and dominant in the three studied forest fragments. It was ended that there were differences in the composition of the species among the studied forest fragments, such differences suggest that the measure that the habitats suffers alterations, they happen changes in the density patterns and in the composition of the species, however the scolytids diversity was larger in the fragments with larger level of environmental interference. This suggests that some species of this family can be used as indicative of wide environmental changes and of long reach.

Index terms: Indicators, Bark beetles, Ambrosia beetles.

119691 USE OF ATTRACTANTS FOR SURVEYING DIPTERAN POPULATIONS IN A RAINFOREST AREA IN NORTHEASTERN BRAZIL

D. F. Silva¹, A E. Eiras² & S. D. Vasconcelos¹, ¹ Mestrado em Biologia Animal, Depto. de Zoologia, Universidade Federal de Pernambuco. Av. Prof. Moraes Rego, s/n, Recife-PE, 50670-420, BRAZIL. E-mail: simao@npd.ufpe.br.². Depto. de Biologia, Universidade Federal de Minas Gerais

Chemical communication is one of the most remarkable ways of information transmission among members of the Class Insecta. Despite the importance of chemical compounds in triggering specific behaviour such as aggregation, escape, oviposition and sexual attraction, there are few field studies which investigated the substances involved in insect attraction. In this study, a set of substances combined with CDC light traps were tested for the attraction and capture of Culicidae and Psychodidae adults in a remainder of rain forest in the State of Pernambuco, Northeastern Brazil. The following treatments were used: octenol (in an open glass vial); octenol with a single wick; octenol with double-folded wick; CO2 (released as commercial bread yeast); living bait (mouse), and deionized water (control). Four traps separated from each other for 100m were placed in the forest for 12 hours, from 5pm-5am, during which the temperature in the sampled area was about 30°C and the relative humidity around 84%. Four replicates were used, in separate days; each replicate being considered the capture of the four traps combined. From all the Phlebotominae collected, 56% were collected in the CO_2 traps, 19% with the octenol and 25% were caught in the control traps. From all the Culicidae collected, 65% were collected in the control traps, 20% in the bait trap and 15% in the octenol traps. The different proportions of adults of Culicidae and Phlebotominae captured suggest differential responses in germs of substances involved in their attraction and communication.

[1968] COMPOSITION OF SCOLYTIDAE (COLEOPTERA) IN THREE FOREST MACROHABITATS OF SEROPÉDICA, RJ, BRASIL

C. A. M. Silva¹, <u>A. G. Carvalho¹</u> & L. A. Pereira², ¹Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: acacio@ufrrj.br and carlmont@floresta.ufpr.br; 2Depto. de Ciências Ambientais, Univ. Fed. Rural do Rio de Janeiro.

This study compared the composition of bark and ambrosia beetles (Coleoptera: Scolytidae) in three different forest macrohabitats in the municipal district of Seropédica, RJ: Pinnus elliotti (Pe), Eucalyptus citriodora (Ec) and Secondary Forest (Ms). Those three areas frequently suffer the action of the fire. In each macrohabitat it was installed, to 40 cm of height of the soil, an impact snare, being used ethanol 96% as attractive. The collections were accomplished during the months of April of 1988 to January of 1989, totaling eleven samplings. With relationship to the preferences for macrohabitats of the two more abundant species, 60% of the Xyleborus hagedorni happened in on Pe, 32% in Ec and 8% in the Ms ones. Those preferences were shown significant for the Test X2 (P <0,05). X. affinis showed preferences in the occurrence of 52% of the total of its species in the Ms ones, remaining 26% in Ec and 22% in the Pc. Of the total of 8221 analyzed Scolytidae, 38% happened in the Pe, 33% in Ec and 29% in the Ms ones. Seven species were shown more abundant in on Pe: X. hagedorni, X. obliquus, X. ferrugineus, X. brasiliensis, Hypothenemus opacus, H. bolivianus and Coccotripes palmarum. Other six were more abundant in Ec: Premnobius cavipennis, Cryptocarenus hevea, C. seriatus, C. diadematus, X. spinulosos and H. obscurus and the two species X. affinis and H. eruditus were only shown more abundant in the Ms. Using the Index of Percentile Similarity in the comparisons among the three communities were obtained in decreasing order: Pe x Ec = 75,24%; Ec x Ms = 53,90% and Pe x Ms = 46,40%. The largest value obtained among the two researched vegetable monocultures suggests a habitat-specific tendency of most of the species of boring-beetles occurred in those three macrohabitats. The diversity of Scolytidae for macrohabitat, evaluated through Shannon Weaver Index (H', with log of base 10) it shows, in decreasing order: H'Ec = 0,77 (H'máx. = 1,18 and J' = H' / H'máx. =0,65); H'Ms = 0,65 (H'máx. = 1,14 and J' = 0,57); and H'Pe = 0,63 (H'máx. = 1,18 and J' = 0,53). There was not significancia (P>0,05) in the differences among the diversities through the Test t of Student, applied in the comparisons of the variances of the three researched macrohabitats.

Index terms: Diversity, Macrohabitat, Ambrosia beetles, Bark beetles.

[1970] A POPULATION SURVEY OF PHLEBOTOMINAE IN REMAINDERS OF RAINFOREST IN NORTHEASTERN BRAZIL

D. F. Silva & S. D. Vasconcelos, Mestrado em Biologia Animal, Depto. de Zoologia, Universidade Federal de Pernambuco. Av. Prof. Moraes Rego, s/n, Recife - PE, 50670-420, BRAZIL. E-mail: simao@npd.ufpe.br

Insects from the genus Lutzomyia (Diptera: Psychodidae) occur in the neotropical region and have great medical importance for they are vectors of leishmaniasis. Around 350 species of this genus are found in Brazil, from which around 30 have been registered in the State of Pernambuco, in the Northeast of Brazil. Apparently, few of these play a role in disease transmission, although the extent to which this is related to their abundance is still unclear. The objective of this study was to survey the Lutzomyia populations in areas of rainforest conservation in Pernambuco. Additionally, the influence of temperature and relative humidity on population fluctuations in a three month period was investigated. Two areas were sampled, Mata do Curado and Mata de Dois Irmãos, both characterised by high plant diversity and slight variations in altitude. Four traps separated from each other for 100m were placed in the forest for 12 hours, from 5pm-5am. The Lutzomyia adults collected were distributed as follows: 22% Lutzomyia choti, 14,6% Lutzomyia walkeri, 14,6% Lutzomyia anduzei, 14,6% Lutzomyia evandroi, 12,2% Lutzomyia sordelii, 9,8% Lutzomyia umbratilis and 12,2% Lutzomyia sp. From all the insects identified to the species level, none is referred to as a leishmaniasis vector.

[1971] SCOLYTIDAE ASSOCIATED EUCALYPTUS SPP. IN A FRAGMENT OF DECIDUAL SEASONAL FOREST

T.E.F. da Silva¹; <u>E.C.Costa</u>²; T.M.B. Vianna³; M.A.G.Costa², ¹ Rua Jorn. Maurício Sirotski Sobrinho, 85 – CEP 97020-040 – Santa Maria, RS – Brasil, e-mail: thomas.freitas.luz@zipmail.com.br.² Depto. de Defesa Fitossanitária, Centro de Ciências Rurais – Universidade Federal de Santa Maria, Campus Universitário, prédio 42, 1º andar, 3225 – CEP 97105-900 – Santa Maria – RS – Brasil – e-mail: eccosta@ccr.ufsm.br; ³ Depto. de Biologia. Ciências Naturais e Laxatas - Universidade Federal de Santa Maria.– Santa Maria, RS – Brasil - e-mail: a9670087@alunop.ufsm. br.

A survey of Scolytidae (Coleoptera) insect was carried out, in an area covered by *Eucalyptus* spp. in a fragment of Decidual Seasonal Forest in a District of Itaara, RS – Brazil. The traps settled at a certain point of 1,3 meters of soil were "Marques/Pedrosa" type. The quantitative and qualitative data was correlated with temperature, air relative humidity and precipitation. The populational evaluation was done using frequency, constance, abundance, dominance and diversity rate. The delimitations of communities was estimated by the quotient and similarity rate. The results revealed the existence in two communities of 37 species Scolytidaes's family belonging to 12 genus from 380 species coleted. *Corthylus antenarius, Microcorthylus minutissimus, Xyleborus gracilis* and Xyleborus paraguaiensis were the most frequent, abundant and dominant in both communities. The quotient of similarity were 0,75 and the similarity rate whe 53,9%. The diversity rate was the same to both communities. Genus Xyloborus presented a hight species number in the two communities. The fluctuation of population in a total collected of escolideos in Eucalyptus spp., showed a 99,95% correlation in the average of monthly minimum relative humidity.

Key words: population available; forest; insect

Symposium and Poster Session

[1973] UTILIZATION OF FLORAL RESOURCES BY MELIPONINEOS (APIDAE:MELIPONINI) IN A FOREST FRAGMENT, BELO HORIZONTE, MG, BRAZIL

S. M. Soares, <u>Y. Antonini</u> & R. P. Martins, Laboratório de Ecológia e Comportamento de Insetos, Departamento de Biologia Geral, ICB, UFMG, Cx Postal 486 CEP: 31140-390 Belo Horizonte, MG, Brazil E-mail: antonini@mono.icb.ufmg.br

The bees are flower visitors for excellence, and constitute the most important group of pollinators. The meliponini are the most efficient pollinating bees in the tropical region. To verify the diversity of meliponini in a forest fragment, the bees were searched on the plants with flowers once a week from July to December/1999, between 6:00 and 13:00. The bees were then collected with an entomological net. We collected 490 individuals distributed among 11 different species. Of these, 198 were T. spinipes, 173 Trigona fulviventris, 31 Tetragonisca angustula, 28 Paratrigona subnuda, 21 P. lineata, 21 Plebeia sp., 11 Melipona quadrifasciata, 5 Nannotrigona testacoicornis, 1 Paratrigona sp. and 1 Leurotrigona mulleri. Trigona spinipes was the most abundant and generalist, visiting 30% of the registered plants, however both species prefer to visit Malpighiaceae and Melastomataceae. Paratrigona species only Byrsonima sp. (Malpighiaceae) was visited by all 10 bee species. The other most visited plants were Hyptidendron sp. (Labiata), Cellis sp. (Ulmaceae), Thunbergia sp. (Acanthaceae), Aureliana velutina (Solanaceae). All bee species visited the Malpighiaceae and Acanthaceae and the majority of them visited Sterculiaceae, Fabaceae, Labiatae, Ulmaceae and Solanaceae. These data show that the different species of meliponini use the nectar and available pollen in a similar mode.

[1972] UNDERSTANDING THE INTRODUCTION AND SPREAD OF SIREX NOCTILIO IN THE SOUTHERN HEMISPHERE

B. Slippers', G. Hunter', T.A. Coutinho', B.D. Wingfield' & <u>M.J. Wingfield'</u>, Dept. of Microbiology & Plant Pathology, Forestry and Agricultural Biotechnology Inst. (FABI), Univ. of Pretoria, Pretoria, 0002, Republic of S. Africa, Dept. of Genetics, Univ. of Pretoria, Pretoria, 0002, Republic of S. Africa

Exotic pine species have been established with great success in plantations in the tropics and subtropics of the Southern Hemisphere. Part of this success can be attributed to the separation of these trees from their native pathogens and pests. These pests are, however, steadily being introduced and the introductions often lead to severe and damaging outbreaks. An example of one such a pest is Sirex noctilio. It is not considered a primary pest in the Northern Hemisphere, but has caused substantial losses to softwood plantations in Southern Hemisphere countries, where it has been introduced. Understanding the epidemiology and population dynamics of this insect is important in preventing further spread and in controlling the pest where it has already become established. In this study we report on the use of phenotypic and DNA-based studies of Amylostereum areolatum, the obligate fungal symbiont of S. noctilio, to determine the diversity and relationship of isolates from different countries in the Southern Hemisphere. Results show that the genetic diversity of isolates of A. areolatum from Southern Hemisphere wasps is small and uniform. This indicates that Sirex has spread between continents of the Southern Hemisphere after initial introduction at the beginning of the 20th century. Fungal isolates from South Africa and Brazil are the most closely related of all isolates, indicating a common origin of Sirex in these two countries. These techniques and data now enable us to monitor and characterise S. noctilio populations and to plan future biological control strategies.

Key words: Sirex, Amylostereum, Insect/fungal interactions

[1974] TROPHIC PATTERNS IN AN INSECT COMMUNITY OF PINE FOREST AND SAVANNA ECOSYSTEMS

M. El Souki¹, R. Candia[†] & L. Bulla¹, ¹Inst. de Zoología Tropical, Fac. de Ciencias, Univ. Central de Venezuela, Apdo. Postal 47058, Los Chaguaramos 1041-A, Caracas, Venezuela, melsouki@latinmail.com.

Besides traditional land use of Venezuelan savannas for agriculture and cattle, a recent impact on the natural savannas being increasingly employed during the last 30 years is the cultivation of timber species of *Pinus caribaea* and *Eucalyptus* sp. The area cultivated in the southeastern savannas covers today more than 5,000 km² and is currently expanding. Our research is about the impact assessment of pine forests on the native arthropod community of the savanna. The present study focuses on the most relevant temporal (seasonal and successional) changes occurring in the savanna insect community. The sampled plots representing natural savannas were three uncultivated plots: S1, Trachypogon sp. dominant; S2, Trachypogon sp dominant, but surrounded by mature pines (island); and S3, Axonopus sp. dominant. The cultivated plots were: P1, 4 year old pines; P2, 12 year old mature pines; B1, recently harvested pines, and B4, 4 year old field (last two are set-aside). Insects were captured using attraction yellow plates (6 per plot) and were divided into five trophic groups: herbivores, predators, parasitoids, saprophytes, and omnivores. The relation between species number and abundance from a total of 789 species and 6,927 individuals, respectively, was herbivores 277:3,435, predators 113:2,011, parasitoids 280:602, saprophytes 68:733, and omnivores 51:147. Herbivores, predators, and parasitoids showed their greatest richnesses in the pine plots and their lowest in B1; with slight variations, their richnesses in B4 are similar to those in the savannas. Saprophytes and omnivores showed few between-plot differences. Abundances of herbivores and parasitoids showed a preference for pines. Predator abundance in pines was similar to that in savannas, except in S3. Almost all trophic groups showed similar abundances between set-aside plots and savannas, except in S1. During the wet season, total, green, and green/dry rate biomasses, and vegetation cover showed a significant positive correlation with total insect, omnivore, herbivore and saprophyte richnesses and abundances, whereas vegetation evenness showed a significant positive correlation with both total insect and predator abundances. During the dry season, vegetation richness, evenness, and diversity showed a significant positive correlation with total insect, herbivore, predator and parasitoid richnesses and abundances. These results suggest that richness and abundance patterns are determined by the quantity of resources in the wet season, but by the variety (diversity) of vegetation resources in the dry season. The more important trophic group relationships found were between herbivore and parasitoid richnesses and abundances in both seasons. This work was financed by the ISC Programme of the European Commission, Project CT 94-0099 VE.

[1975] DISTRIBUTION OF BARK AND WOOD-BORING INSECTS IN MARITIME PINE TREES INFECTED WITH BURSAPHELENCHUS XYLOPHILUS IN PORTUGAL

E. M. Sousa, P. M. Naves & L. P. Bonifácio, Dept. Prot. Florestal, EFN, Quinta do Marquês, 2780 Oeiras, Portugal. E-mail: dpf.efn@mail.telepac.pt

The Pine Wood Nematode Bursaphelenchus xylophilus (Nematoda; Aphelenchoididae) was found for the first time in Portugal and Europe in 1999, being confined to Setúbal peninsula, south of Tagus river. The biology and behaviour of the nematode and its insect vectors is not known in Europe, although some cerambycid and scolytid species that occur in this region are considered potential vectors. Maritime Pine (Pinus pinaster) trees infected with B. xylophylus were found to be quickly colonised by several bark and woodboring beetles and an intensive survey was conducted on 30 recently infected adult trees with an average 97,4 cm DBH, involving all trunk and branches debarking with capture of all insect development stages present. The results revealed a big under-bark insect diversity formed by scolytid (7 species), cerambycid (3), curculionid (1) and buprestid (1) beetle species. The scolytids were the most frequent group, particularly Orthotomicus erosus being present in the trunk and branches of all studied trees in high densities. Hylurgus ligniperda was found on 50% of the pines, while the other five scolytid species (Hylastes ater, H. linearis, H. attenuatus, Ips sexdentatus and Tomicus piniperda) were present in less than 33% of the pines. Regarding the cerambycid family, the three longhorn beetle species were common (more than 50% infested trees): Arhopalus syriacus larvae were present in all surveyed trees in high densities; Acanthocinus griseus was detected in 83% of the trees while larvae of Monochamus galloprovinciallis, the most probable nematode vector in Portugal, appeared in 50% of the pines. The only curculionid species, the pine weevil Pissodes castaneus was collected from 75% of the trees and the buprestid Chrysobothris chrysostigma in 33% of the pines. The within tree distribution revealed a spatial competitive exclusion pattern between the different species, with special emphasis to A. syriacus, H. ligniperda, H. ater, I. sexdentatus and T. piniperda in the lower sections of the trunk, while M. galloprovinciallis and P. castaneus were found mainly in the branches and in the upper part of the trunk. Regarding O. crosus and A. griseus no spatial distribution pattern was found, with this species present throughout all the trunk and branches

Index terms: Bursaphelenchus xylophilus, Pinus pinaster, bark and wood-boring beetles, Portugal

[1976] DEADWOOD IN COMMERCIAL FORESTS: A SOURCE OF INCREASED BIODIVERSITY AND OF OUTBREAKS OF PEST SPECIES?

W. Topp & R. Haeusler, Dep. of Zoology, Univ. of Cologne, D-50923 Koeln, Germany

This study examines the saproxylic insect fauna of a commercial mixed oak-beech forest situated in the Westerwald of Germany (50° 26'N / 07° 50'E, 325m above sea level) in which nature-oriented forestry has been practiced for the last 10 ten years. Using eclectors, insects were collected from the deadwood of oak and beech trees. Our studies concentrated on different types of decaying wood: 1. Deadwood, which has accumulated near the forest floor in the center of the forest in shady areas and which was different in respect to dimension (twigs, branches, logs) and phase of decomposition. 2. Living wood, which prior to sampling had been freshly cut and exposed either to sunny or shady areas for the length of one year. In total we collected insects from 8.5 m³ wood, equaling about 170 m². About 140,000 insects were found. The most dominant groups were dipterans (61,000 ind.) and coleopterans (25,000 ind.). Each "milieu type" of dead wood supported characteristic species. However, the fauna of decomposed logs was most diverse. In the shady area bark beetles but also predators of bark beetles were the most common coleopterans, so that there is no fear of mass occurrence of pest species in the center of the forest. Based on our data we recommend for this forest type an accumulation of 40 m² dead wood per ha, which is enough to supply the prerequisites for a diverse fauna and even for rare and endangered species, which live in shaded areas near the forest floor. In the area of study this amounts to about 5% of the amount of living wood. The actual numbers of the different beetles species were always higher in areas exposed to more sunlight compared to shaded areas. However, the abundance of individuals in the sunny areas outnumbered those of the shaded areas, but only when their development has taken place in branches with diameters > 7 cm. Remarkably high emergences were found for bark beetles (i.e. 850 ind./m² for Taphrorychus bicolor) from branches which have been exposed to strong sunlight. In a commercial forest in which nature-oriented forestry is practiced and an accumulation of dead wood will occur, the cultivation of graded forest edges is also recommended. This will reduce the amount of deadwood exposed to strong sunlight and thus minimize the outbreak of pest species.

This study was supported by Forstliche Versuchsanstalt Rheinland-Pfalz.

[1977] DEAD WOOD AND BEETLES: A CASE STUDY IN FLANDERS (BELGIUM)

V. Versteirt, K. Desender, G. Geudens & P. Grootaert, Dept. of Entomology, RBINSc., Vautierstraat 29, 1000 Brussel. E-mail: veerle.versteirt@kbinirsnb.be

There are only few data available on xylobiont beetles associated to dead wood in Flanders. In this contribution we present the first results from detailed samplings, performed in four forests in the surroundings of Brussels and Tongeren, within the framework of a study on terrestrial invertebrates in woodlands of the region of Flanders. Special attention was paid to sampling methodology. The following techniques were used on each sampling site: three pitfall traps, three white and three yellow pan traps, a large window trap, a dung baited trap and a tree eklektor, completely enveloping a large standing dead beech tree between 1.5m and 2m of height. Sampling was performed during a complete year cycle. On the whole, about 200 beetle species were obtained (some 8000 individuals), many of which are of high faunistic value. Preliminary analysis of the beetle diversity suggests lower values for a large and rather homogeneous forest. This pattern can also be explained by the presence of many additional species from surrounding open landscapes in smaller forests. The importance of dead wood for xylobiont arthropods is well known. Dying and dead trees provide essential habitats for a number of animals (like insects). In order to maintain this biodiversity it is important to consider the aspect of dead wood in managed forests. The quality of the species thereby seems more important than the observed number of species, because species richness not only is influenced by habitat quality but also, especially in small forests, by edge effects due to accidental immigration of species with a high dispersal power.

Index terms: woodland, beetle diversity, forest management.

[1978] LEPIDOPTEROUS ASSOCIATED TO TWO FOREST COMMUNITIES IN ITAÁRA, RS - BRAZIL

T.M.B. Viana¹; <u>E.C.Costa²</u>, ¹ Depto. de Biologia. Ciências Naturais e Exatas. Universidade Federal de Santa Maria.– Santa Maria, RS – Brasil - e-mail: a9670087@alunop.ufsm. br. ² Depto. de Defesa Fitossanitária, Centro de Ciências Rurais – Universidade Federal de Santa Maria, Campus Universitário, prédio 42, 1º andar, 3225 – CEP 97105-900 – Santa Maria – RS – Brasil – e-mail: eccosta@ccr.ufsm.br.

Aiming at analyzing the behavior of lepdopterous population in two communities, are constituited of planting field of Eucalyptus spp. with small plants in formation and another of a fragment of Decidual Seasonal Forest, weekly collections were made by using light trap. This work was develop in Itaára, RS - Brazil, from May 1997 to May 1998. In order to study the populations, lepidopterous fluctuations were analyzed, according, to the meteorological elements (temperature, air relative humidity, pluviometric precipitation) and faunal rates represented by frequency, constancy, abundance, dominance and diversity. In the communities delimitations were apply the quotient and similarity rate. Were collected 73 species of the large planting field of Eucalyptus spp., being 63,01% species of identified as infrequent and, in the fragment of Decidual Seasonal Forest 77 specieswere collected being 57,14% of them infrequent. The constant species, dominance and very abundance were: Sarcina violascens (Lymantriidae) found in the planting field of Eucalyptus spp. and Bronchelia puellaria (Geometridae) and Iscadia aperta (Noctuidae) in the fragment of Decidual Seasonal Forest. With relation of diversity rate to lepdopterous family, this higher in the fragment of Decidual Seasonal Forest, than in a large planting field of Eucalyptus spp. The quotient and percent of similarity changing with the studied ecossistem and with the species. In both forest communities the fluctuation of lepdopterous species influenced of the meteorological elements. Key words: light trap; forest; insect; faunal rates

[1979] EVALUATION OF THIAMETHOXAM ON COSTALIMAITA FERRUGINEA (COLEOPTERA: CHRYSOMELIDAE) CONTROL IN EUCALYPTUS PLANTATIONS

C.F. Wilcken¹, N.S. Bezerra Jr.¹, E.B. Couto¹ & C. Orlato¹, Dept. Plant Production -FCA / UNESP - Campus of Botucatu - P.O. box 237 - 18603-970, Botucatu - SP. E-mail: cwilcken@fca.unesp.br

The eucalyptus yellow beetle Costalimaita ferruginea is one of the eucalyptus main pests in Brazil, occurring at October - December and limiting the plants growth up to 1 year old. Nowadays, there is a total absence of insecticides for forest use to control of this pest and the need to new products is pressing. This work was carried out to verify the insecticide thiamethoxam efficiency on C. ferruginea control in eucalyptus plantings. The experiment was installed in planting area of Eucalyptus hybrid, in Itapeva - SP - Brazil. The experimental design was in randomized blocks, with 5 treatments and 4 blocks, with 50 plants per plot. The treatments were: thiamethoxam (Actara) in dosages of 12.5; 25 and 50 g a_i./ha, deltamethrin (Decis 25 CE) in dosage of 5 ml of a.i. /ha and check. The number of insects / plant was evaluated at 1, 3 and 6 days after application, and the plant height at 10 and 55 days. The results indicated that thiamethoxam was efficient in C. ferruginea control in all tested dosages, being comparable to the control provided by deltamethrin. However, thiamethoxam control residual period was superior compared with deltamethrin, could imply in reduction in spraying quantity in eucalyptus plantings attacked by eucalyptus yellow beetle. It was not observed phytotoxicity symptom in treated plants. Index terms: Forest pest, chemical control, insecticide, eucalyptus yellow beetle

[1981] PRELIMINAR OBSERVATIONS OF CULICIDS (DIPTERA:CULICIDAE) ASSOCIATED TO PHYTOTELMATA IN A VERY HYMUD TROPICAL FOREST IN CHOCO-COLOMBIA

<u>M. Wolff¹</u>, S. Perez¹, J. Betancur², P. Duque¹, & C. Porter³, ¹ Dept. Biology, Univ. Of Antioquia, AA 1226. Medellín-Colombia, E-mail: Erro! Indicador não definido. ² Ins. Ciencias Naturales, Univ. Nacional of Colombia, AA 7495 Santafe de Bogotá Colombia; ³ Center for Disease Control and Prevention (CDC) 4770 Buford Highway Atlanta, Ga 30341-3724 USA.

The association between Diptera of the Culicidae family and phytotelmata in the department of Chocó (Colombia) was studied in the Ensenada de Utría National Park (bmh-T) in the understorey of mangrove swamps and heterogeneous forest. 18 species of phytotelmata were collected in seven families; Bromeliaceae, Maranthaceae, Heliconiaceae, Bignoniaceae, Rubiaceae, Palmae-Arecaceae and Caesalpinaceae. 1661 culicids were found in the above plants and were classified in the following genera: Wyeomyia, Culex, Anopheles, Trichoprosopon, Orthopodomyia, Toxorhynchites and Haemagogus. 10 new morphospecies belonging to the genus Wyeomyia and the subgenera Hystatomyia and Microculex were found as well as a new species report for Colombia, Anoedioporpa corrigani. The Principal Component Analysis (PCA) based on a presence - absence matrix showed two groups of plants that gather the hosts according to the species sheltered by them, and two groups of insects: the first one more generalist and the second a more selective group.

[1980] EVALUATION OF TWO TRAP CARDS TO MONITORING OF SCYTHROPOCHROA SP. (DIPTERA: SCIARIDAE) IN EUCALYPTUS SEEDLINGS NURSERY

C. F. Wilcken¹, C. Orlato¹, C. C. Ortiz² & J. C. Augusti², ¹Dept. of Crop Production, FCA / UNESP – Campus of Botucatu, P. O. Box 237, Botucatu, SP, 18603-970, BR, Email cwilcken@fca.unesp.br; ²Bahia Sul Celulose S.A., Rod. BR 101, Km 880, Teixeira de Freitas, BA, 45995-000, BR.

The nursery flies of the family Sciaridae (genera Bradysia, Sciara and Scythropochroa) have been causing damages in nurseries and greenhouses where is carrying out the vegetative multiplication of eucalyptus seedlings. The monitoring of flies infestations at greenhouses had origin in Europe and North America, where these insects are important pests in cultivation of ornamental plants. The monitoring was installed in 10 greenhouses at the eucalyptus nursery of Bahia Sul Celulose S.A., in Mucuri - BA - Brazil. Were tested two types of trap cards with useful area of 100 cm²: 1) acetate plates, recovering both sides with a mixture of engine oil + grease, on proportion of 50% each, 2) yellow stick cards (AgriSenseTM) especially developed to capture small insects. Were shared 6 cards for each greenhouse, been installed 5 cm high above stalks and 8.90 m distant among the cards. Evaluations were made in 7^{th} , 14^{th} , 21^{th} and 28^{th} days in the rooting period, counting the fly number per card and calculating the average for each greenhouse. Different dates concerning the 2 rooting cycles for each of 10 greenhouses were evaluated. The results showed that the best option to monitoring the Scythropochroa sp. population was the use of yellow stick cards. The high advantage of these traps, beyond the capture efficiency, was the durability of your glue, what allowed the fulfillment of 4 evaluations in the same card. The limit (accumulated) of good visualization to the counting of fly numbers was 200 adults per card. When this number was exceeded, the card was changed. The monitoring must be done during the whole year, suspending the activity only when were observed constant low infestations in every greenhouses, showing number below 10 flies per greenhouse in each weekly evaluation. The operational cost of both trap cards was also evaluated, been observed that the yellow stick card cost was much lower than acetate card, turning its utilization economically viable.

Index terms: Forest pest, nursery fly, greenhouse, rooting period, operational cost.

[1982] SPECIES MIXTURE OF BIRCH AND CONIFERS DECREASES DAMAGE BY A DIPTERAN MINER OF BIRCH STEMS

T. Ylioia¹ & T. Lapveteläinen², ¹Punkaharju Research Station, Finnish Forest Research Institute, Finlandiantie 18, FIN-58450 Punkaharju, Finland, E-mail tiina.ylioja@metla.fi; ²European Forest Institute, Torikatu 34, FIN-80100 Joensuu, Finland.

Females of *Phytobia betulae* (Diptera: Agromyzidae) lay eggs within the soft tissue of young shoots in the crowns of birch (*Betula pendula* and *Betula pubescens*). The larvae mine downward for several meters through the zone of differentiating xylem in the birch stems. The resulting tunnels become filled with brown parenchyma tissue, which reduces the aesthetic value of the light coloured birch wood and causes considerable expense to the forest products industry. There are presently no known ways to control Phytobia. We hypothesized that growing birch mixed with conifers would decrease *Phytobia* infestations by interfering with their ability to locate hosts. This hypothesis was tested by comparing infestation levels in stands of pure birch and stands that were a mix of birch and conifers (Picea abies and Pinus sylvestris). We sampled four birch stands (15 - 25 years of age) within each of six municipalities in southeastern Finland: one pure birch stand and three stands with about 20%, 60% and 80% of coniferous trees (altogether 24 stands). We established eight circular sample plots along systematic survey lines in each stand and counted the percentage of coniferous and birch trees. For one focal tree within each sample plot, we measured tree height, diameter, the number and length of branches, and canopy crown class (dominant, co-dominant, or intermediate). We also measured distances to the five nearest coniferous and birch trees (or ten birch trees in pure birch stands) and the canopy crown class and diameters of these neighboring trees. We collected two stem disks per sample tree. A disk from ground level was used to measure the age of the tree and a disk from 1.3 m height was used to count larval tunnels in five latest annual rings and measure the corresponding radial growth. There were fewer larval tunnels in birch trees in stands that included only about 20% of birch. The number of larval tunnels was almost the same in stands that included 60% of birch as the number of larval tunnels in pure birch stands. Fast growing trees in dominant canopy classes had the greatest number of larval tunnels. The stands with only 20% of birch trees contained more co-dominant and intermediate birch trees than the other stands. Silvicultural practices that favor mixed stands might limit birch infestations by Phytobia, but the proportion of coniferous trees must be high (at least 70%), which limits the total volume of birch that can be harvested. Index terms: Phytobia betulae, Diptera, Agromyzidae, Betula, species composition.

[1983] STEM BORING AND PUPATION OF A DIFFERAN MINER OF BIRCH STEMS

T. Ylioia, Punkaharju Research Station, Finnish Forest Research Institute, Finlandiantie 18, FIN-58450 Punkaharju, Finland, E-mail: tiina.ylioja@metla.fi.

Larvae of Phytobia betulae (Diptera: Agromyzidae) bore within the differentiating xylem tissue of birch trees (Betula pendula and Betula pubescens). Larvae (three instars) mine several meters within the stem, from the crown to the base of the tree. Larval tunnels are filled with brown parenchyma tissue that causes pronounced degradation of the birch wood used for furnishing. However, the biology of *Phytobia* is not well known and there are no known methods for control. In late summer, larvae exit the tree (through the bark at the base or in the roots) and pupate in the soil. In this study, we aimed to determine how fast larvae of Phytobia move through the differentiating xylem during the growing season and how much time the pupation takes. Every other day beginning on 10 June 1997, we examined randomly selected branches and small trees (up to 3 m high) from an open sunny birch stand to determine when the first eggs were laid. The first egg was found on 23 June 23. On 3 - 7 July, the first larval tunnels were 3 - 17 cm long. Beginning at this time, we conducted repeated sampling of 12 taller trees (11 - 16 m). On 9 July, tunnel lengths varied from 0.01 - 2.5 m. By 14 July, second instars had created tunnels that were 8 - 10 meters in length. The mining speed of Phytobia seems to be tremendous. Tunnels of the largest diameter (presumably created by the largest larvae) usually continued to the roots. In August, we carefully removed the outer bark from the base and the roots of young birch trees (158 trees) and collected the larvae found under the bark (22 larvae on 13 August from *Betula pendula*, and 34 larvae on August 15 from *Betula pubescens* and *B*. pendula). Each larva was placed within an individual vial containing a mixture of sand and peat. Nearly half (46%) burrowed into the soil within 10 hours (at room temperature) and began to pupate. Altogether 59% of the larvae pupated. Our study revealed no times during the life history when insecticide application is likely to be effective. Larvae are protected within their host trees while feeding and are only exposed for a few hours prior to burrowing into the soil for pupation. Potential control measures are further complicated by asynchrony in the timing of larval development and pupation.

Index terms: Phytobia betulae, Diptera, Agromyzidae, Betula, larval tunnel.

[1984] LEPIDOPTERAN COLLECTED IN AN *EUCALYPTUS* PLANTATION IN GOIÁS, BRAZIL, FROM MAY 1995 TO APRIL 1996 - EFFECT OF TEMPERATURE AND RAINFALL ON POPULATION DYNAMICS

<u>J. C. Zanuncio¹</u>, E. T. Lopes², T. V. Zanuncio¹ & J. F. Gonçalves¹, ¹ Dep. de Biologia Animal, Univ. Federal de Viçosa, 36.571-000 Viçosa, MG, BRAZIL. E-mail: zanuncio@mail.ufv.br; ² Dep. de Engenharia Florestai, Univ. Federal de Viçosa, 36.571-000, Viçosa, MG, BRAZIL.

Lepidopterans are considered in Brazil as an important group of *Eucalyptus* pests due to severe losses in wood production. Biweekly collections were made in the State of Goiás, Brazil aiming to study population dynamics and the effect of temperature and rainfall on Lepidoptera pests of *Eucalyptus*. Lepidopteran were collected with five light traps installed at two meters high with black light and powered by 12 volt batteries. These insects were divided in groups according to their importance as pests to *Eucalyptus*: group 1: 11 primary pests; group 2: 10 secondary pests; group 3: 64 species without defined importance to *Eucalyptus*; and group 4: non-identified species. Among the primary pests, *Thyrinteina arnobia* (Geometridae), *Eupseudosoma aberrans* (Arctiidae) and Sarsina violascens (Lymantridae) were the most frequent ones, the last two being constant and the first one accessory. *Idalus admirabilis* (Arctiidae) and *Eacles imperialis magnifica* (Saturniidae) were the most frequent secondary pests, the first being constant and the second accessory. Most of the Lepidoptera species were collected during the coldest and driest months, which shows that these conditions could favour the occurrence of Lepidoptera outbreaks. For this reason, population monitoring of these species should be intensified during these periods.

Index terms: Lepidopteran defoliators, Eucalyptus, insect monitoring

[1985] EFFECT OF FEEDING ON THREE EUCALYPTUS SPECIES ON THE DEVELOPMENT OF BRONTOCORIS TABIDUS (HET.: PENTATOMIDAE) FED WITH TENEBRIO MOLITOR (COL.: TENEBRIONIDAE)

J. C. Zanuncio¹, T. V. Zanuncio¹, R. N. C. Guedes¹ & F. S. Ramalho², ¹Dcp. de Biologia Animal, Univ. Federal de Viçosa, 36.571-000 Viçosa, MG, BRAZIL, E-mail: zanuncio©mail.ufv.br; ²Empresa Brasileira de Pesquisa Agropecu-ria – EMBRAPA, Caixa Postal 174. 58.107-720 - Campina Grande, PB, BRAZIL.

Brontocoris tabidus (Heteroptera: Pentatomidae) is an important predator of defoliating Lepidoptera in Brazil, which has been mass produced and released against defoliating caterpillars in Eucalyptus plantations. We aimed to improve the mass production of this predator by providing eucalypt seedlings, besides an alternative prey, for its development. The effect of three *Eucalyptus* species on the development of *B. tabidus* fed with Tenebrio molitor L. (Coleoptera: Tenebrionidae) pupae was studied at a temperature of 25.0 ± 2.5 °C; a relative humidity of 70.0 ± 10.0% and a photophase of 12:12 hours (light: dark). Pupae of T. molitor was provided in each of the following feeding treatments: treatment 1- Eucalyptus urophylla seedlings; treatment 2 - Eucalyptus camaldulensis seedlings; treatment 3 - Eucalyptus grandis seedlings; and treatment 4 - no seedling (only pupae of T. molitor). Duration of the nymphal phase of the predator was similar in all treatments with plant and prey. It was observed that adults developed from nymphs fed on T. molitor only had deformed wings and a small abdomen. B. tabidus fed during their nymphal and adult stages with prey together with Eucalyptus seedlings, had improved longevity, higher egg viability and a larger number of eggs and nymphs, than those insects fed only with prey. Therefore, it seems advisable to rear B. tabidus with prey and seedlings of one of the Eucalyptus species studied to improve the mass production of this predator for biological control of defoliating caterpillars of eucalypt plantations. Index terms: Plant feeding, predatory bug, alternative prey

[1986] KEY FACTORS AFFECTING POPULATIONS OF SCHIZOTETRANYCHUS NANJINGENSIS, APONYCHUS CORPUZAE AND ACULUS BAMBUSAE IN FUJIAN BAMBOO FORESTS DURING DIFFERENT SEASONS: AN ANALYSIS USING METHODS OF GREY SEQUENCE

Y. X. Zhang¹, J. Z. Lin¹, Z. Q. Zhang², M. G. Song³, J. Ji¹ & Q. Y. Liu⁴, ¹Institute of Plant Protection, Fujian Academy of Agricultural Sciences, Fuzhou, 350013 China, E-mail zyxlj@pub3.fz.fj.cn; ²Landcare Research, Private Bag 92170, Auckland, New Zealand; ³Nanping City Forest Protection Office, Nanping, Fujian, China; ⁴Laboratory of Forest Protection, Fujian Forestry Bureau, Fuzhou 350002, China.

The key factors affecting the population dynamics of mite pests on the moso bambooin Fujian, China. Schizotetranychus nanjingensis Ma & Yuan. In spring, temperature was an important factor influencing mite population growth in a big harvest year, but in a small harvest year predation was the key factor. In Summer, Relative humidity was most important to the population development of this species in a big harvest year, but in a small harvest year, predation was the key factor (except in 1996 when rainfall was the key factor). In Autumn, temperature was the key factor for mite population development in a big harvest year, but in a small harvest key factor was either rainfall or relative humidity. In Winter, temperature and predation were more important than other factors in a big harvest year, but relative humidity was the key factor in a small harvest year. Aponychus corpuzae Rimando. In Spring, The relative humidity was an important factor in a big harvest year, but in a small harvest year, predation was the key factor. In Summer, predation was the key factor in a big harvest year, but in a small harvest year, temperature was the most important factor. In Autumn, relative humidity was the key factor influencing its population in a big harvest year, but in small harvest year, rainfall was the most important factor. In Winter predation was the key factor in a big harvest year, but rainfall was the most important factor in a small harvest year. Aculus bambusae Kuang. In Spring, relative humidity was the key factor influencing its population in a big harvest year, but in a small harvest year, predation was the key factor. In Summer, predation was the key factor influencing its population in both big and small harvest years. In Autumn, relative humidity was the key factor in a small harvest year of 1996 and big harvest year of 1997, but predation was the key factor in the small harvest year of 1998. In Winter, rainfall was the key factor in a small harvest year, but predation was the key factor in a big harvest year.

Index terms: Pest mites, climatic factors, Typhlodromus bambusae, Grey Sequence.

[1987] OPHIOSTOMATOID FUNGI ASSOCIATED WITH THREE BARK BEETLES IN SOUTH AFRICA

X. D. Zhou¹, Z. W. de Beer², <u>M. J. Wingfield¹</u> & B. D. Wingfield¹, Dept. of Genetics, Forestry and Agricultural Biotechnology Inst. (FABI), Univ. of Pretoria, Pretoria, 0002, Republic of S. Africa; Dept. of Microbiology & Plant Pathology. Univ. of Pretoria, Pretoria, 0002, Republic of S. Africa

Ophiostomatoid fungi, for example, Ophiostoma, Ceratocystis and Ceratocystiopsis, are economically important because they cause blue stain in lumber and logs, thus reducing the value of export wood. These fungi are often associated with bark beetles (Coleoptera: Scolytidae). Three species of exotic bark beetles, Hylastes angustatus, Hylurgus ligniperda and Orthotomicus erosus occur on mature Pinus spp. in South Africa. Hylustes angustatus also damages pine seedlings during its maturation feeding stage. Despite extensive research on these three bark beetle species in South Africa, little is known about the fungi associated with them. The aim of this study was to determine the extent to which these three bark beetle scontribute to the blue stain problem, and to identify their fungal and 000 beetle galleries from trapping logs, infested stumps and root collars of Pinus patula and Felliottii trees in the eastern parts of South Africa, and about 600 fungal isolates were collected. Forty additional isolates were identified based on morphology, rDNA sequencing and mating studies. At least 12 different ophiostomatoid species have been found to be associated with these three bark beetles. The dominant fungal associates were *Leptographium serpens*, L. lundbergii, Ophiostoma ips, and Graphium sp. Ophiostoma galeiformis and L. procerum are reported here for the first time from South Africa.

[1990] VIRUSES

J. L. Flexner, Dupont Agricultural Products, Stine-Haskell Research Center, Newark, Delaware

Viruses have been isolated from more than a thousand species of insects from at least thirteen different insect orders. Entomopathogenic viruses from almost a dozen viral families have been isolated: Ascoviridae, Baculoviridae, Birnaviridae, Iridoviridae, Nodaviridae, Parvoviridae, Picornaviridae, Poxviridae, Reoviridae, Rhabdoviridae, and Tetraviridae. However, the number of currently registered viral insecticides is made up of a relatively small number of entomopathogenic viruses exclusively from the family Baculoviridae. All of these commercially available baculoviruses are targeted for lepidopteran hosts with the exception of one forestry product for sawfly control (Hymenoptera: Diprionidae). Most are very specific, infecting one or several slowly, sometimes taking 7 to 10 days to kill larger instars. All baculoviruses are extremely susceptible to degradation under UV light, making them ephemeral in direct sunlight when applied as insecticides without protective formulations. Recently, the nucleopolyhedroviruses such as AcMNPV have been genetically modified for an increased killing speed. The most promising of these genetically modified viruses encode and express insect-selective toxins and have resulted in an approximate 20 to 50% reduction in the killing time of their insect hosts. Several of these genetically modified baculoviruses have been field tested but none are currently being commercialized. The first viral insecticide was the single-nucleocapsid Nucleopolyhedrovirus of Helicoverpa (Heliothis) zea (HzSNPV) registered in 1971. This virus was developed by the USDA in the mid-1960s for control of Heliothines (e.g. Tobacco Budworm (Heliothis virescens), Corn earworm (H. zea), and Heliothis armigera) on cotton, row crops, fruits and vegetables and is still currently produced and marketed. By far the most successful viral insecticide used to date is the multinucleocapsid Nucleopolyhedrovirus of Anticarsia gemmatalis (AgMNPV) applied to over 1 million hectares annually for control of the velvetbean caterpillar, A. gemmatalis, in Brazil. This section will describe the commercial importance of baculovirus insecticides and the recent advances that have been made in formulation technology, mass production and genetic manipulation. Safety of genetically modified baculoviruses will also be discussed. In addition, this discussion will focus on areas of baculovirus research that have been neglected that could possibly advance the potential of this group for commercialization.

Index terms: biological control, microbial control, insect viruses, Baculoviruses, Nucleopolyhedroviruses

[1991] MICROBIAL CONTROL: DREAM OR REALITY FUNGI: ADVANCEMENTS AND SUCCESSES

J.C. Lord, Grain Marketing and Production Research Center, US Dept. of Agriculture, 1515 College Ave., Manhattan, KS 66502, USA, E-mail: lord@usgmrl.ksu.edu.

Commercial mycoinsecticides have been registered and used on all of the continents except Antarctica. Beauveria bassiana and Metarhizium anisopliae are prominent, but registered products exist for at least five other species. Successful use patterns involve selection of targets by biological and sociological factors. The systems in which mycoinsecticides are most successful include systems wherein there is a highly susceptible key target pest, systems of special concern for avoidance of synthetic toxins crops grown by cooperatives, and high value crops, especially in protected agriculture. Perhaps most importantly, mycoinsecticide can only succeed in those systems that allow delivery into contact with the target. Registrations do not ensure success. Market-driven products rarely succeed. Failures are often due to business plans built on large acreage, low value crops such as corn, cotton and soybeans. Technical staff sometimes fuels unrealistic expectations with optimistic predictions of performance. Unfortunately, there are past and future failures that are due to poor quality products and inadequate use rates. Advances in production, formulation, and storage are important factors in the successes. Production improvements are primarily engineering achievements. It is now practical to convert 10% of the weight of grain substrates into nearly pure conidia. Mixing and stability properties have been improved by the use of oil-based formulations. Optimization of water content of conidia and gas exchange in packaging has allowed storage of some commercial products for more than a year at moderate ambient temperatures for without significant loss of activity. Improvements in understanding and quantification of spore delivery have contributed to improved performance. Interestingly, selection of strains for virulence has contributed little to the success of mycoinsecticides, but selection for prodigious conidiation is an economic imperative. Five successful cases to be discussed are: M. anisopliae for control spittlebugs in sugarcane and pasture in Brazil, Verticillium lecanii for aphids, whiteflies and thrips in Europe, B. bassiana for coffee berry borer in Latin America, B. bassiana for control of miscellaneous pests in the United States and Mexico, and B. bassiana for control of Masson's pine caterpillar in the Peoples Republic of China.

Index terms: mycoinsecticide, microbial control, Beauveria bassiana, Metarhizium anisopliae, Verticillium lecanii

[1992] MICROBIAL PESTICIDES: DREAM OR REALITY ENTOMOPATHOGENIC FUNGI VS. AGRICULTURAL PESTS

D. R. Sosa-Gómez, Embrapa Soja, Cx. P. 231, Londrina, PR, 86001-970, Brazil. Email sosa@cnpso.embrapa.br

Since 1888, when Krassilstchik based on the work of Metschnikoff produced Metarhizium anisopliae to control the sugar-beet weevil, there has been a dream to control pests with fungi. The microbial control foundation lays on the deep knowledge of the epizootiological aspects. Frequently, the epizootiological process has been simplified to the trilogy pathogen-host-environment. But in nature, an epizootic on a single host can be caused by an arrangement of different fungal genotypes infecting an array of different insect genotypes, feeding on a changing substrate in a changing environment. Far from a reality-based strategy, the traditional approach has been single strain application. Furthermore, the complexity of behavior and unstable nature of fungi have made them not easily produced on a massive level. Also due to the size of their genome, the complete knowledge (sequences and functions) of their genetic codes will take time to be accomplished. Therefore, many aspects should be understood before reaching the stage where fungi can be used as reliable control agents in a variety of agricultural systems. Mycopathogen epizootics occur in several agricultural and forest systems, but man has not been successful in reliably inducing epizootics. Nowadays there is incomplete knowledge about which are the biochemical and/or genetic determinants of the complex and multigenic fungal virulence. The interactions with different hosts make each case, a unique study. Although production methods have been improved in the last years, the relationship cost/benefit still is very high. Frequently, there is the need of several applications or the use of a high dosage approach to get adequate control. These facts limit mycoinsecticide use expensive commodities. Among the different aspects that need more research efforts, application technology appears to be the most neglected area. Not much progress has been made in this area to improve control. Soil inhabiting pests possibly demand more work than aerial or exposed pests, since the soil is a complex environment where homeostatic forces tend to diminish fungal impact. Additionally, in the soil several, organisms act in antagonistic ways, and a more elaborated inoculum delivering technology is required. Presently, Beauveria and Metarhizium species have been used in emerging and declining microbial control programs. However, the use of other entomopathogenic fungi might go a long way toward fulfilling the desired dream. Index terms: entomopathogenic fungi, biological control, microbial control

[1993] PERSPECTIVES AND LIMITATIONS ON THE COMMERCIAL DEVELOPMENT OF ENTOMOPATHOGENIC NEMATODES

S. Franceschini, Biochem s.r.l., Via Virgilio 1 Corbetta (MI), Italy,

The efficacy of entomopathogenic nematodes to control soil inhabiting insect pests has been extensively shown against many insect pests. However these biocontrol agents are currently used only on niche market mainly in cases where chemical has no effect. In order to reach an extensive commercial applications a number of tasks have to be addressed. Perspectives for the commercialization of these materials are very significant, mainly due to the high efficacy, exemption for registration and market requirements. The limitations to their further applications are on the other hand the consequence of erratic field results, particularly under unusual climatic conditions, also their relative high cost and lack of stability limit the use of these products. The development of new products that can solve these problems could significantly increase the use of EPN as biopesticides agents. Production costs have to be reduced significantly in order to increase the competitiveness of the EPN with chemical where there is an alternative. This can be accomplished by developing adequate fermentation processes for EPN mass production in which particular attention has to be paid to the establishment of efficient bacteria and nematode inoculum train for the preparation of seed fermenters. Increase of fermentation volumes, reduction of media ingredient expenses, reduction of fermentation time, increase of fermentation yields as well as recovery of the final product could be the key elements for the increase of EPN market share. Fermentation process has to be scaled up to an adequate volume to fulfill the market requirements. EPN are very delicate microorganisms not able to survive the handling stress of severe production processes resulting in organisms with poor field performance. In order to avoid these problems standard equipment has to be adapted for the production process. Formulation stability remains probably the main problem needed to overcome. Product shelf life has to be significantly improved in order to increase product storage at room temperature and avoid the development of contaminants. Good methods for quality control capable to discriminate the quality of single production batches as well as predict their field performance are also critical parameters to consider. EPN have the potential to take a significant portion of the market provided that the consumer expectations are fully met. Index terms: fermentation, formulation, shelf life.

[1994] GENETICS AS A MEAN TTO IMPROVE ETNS TOLERANCE TO ENVIRONMENTAL STRESS

I. Glazer

ABSTRACT NOT RECEIVED

[1995] GENETIC IMPROVEMENT OF ENTOMOPATHOGENIC NEMATODES

R. Gaugler, Department of Entomology, Blake Hall, Rutgers University, New Brunswick NJ 08901-8524, USA, E-mail Gaugler@rci.rutgers.edu.

Thirty years ago, the idea of using nematodes to control insects was a vague concept held by the handful of researchers working with these obscure insect parasites. Today nematodes are no longer a laboratory curiosity but have begun to be used in niche crops, including citrus, mushrooms, turfgrass, and home and garden.

Despite impressive strides in nematode use, further progress may require technological solutions to reduce the gap twixt nematodes and conventional insecticides in stability, reliability, cost, ease-of-use, and efficacy. Entomopathogenic nematodes are well suited for genetic manipulation due to their simplicity, transparency, ease of culture, short generation time, and small genome size, attributes that entomopathogenic nematodes share with the intensively studied nematode, Caenorhabditis elegans. Molecular insights generated with this closely related free-living nematode are now being applied to entomopathogenic species. This paper begins by summarizing the available classical and molecular genetic information relevant to entomopathogenic species. Efforts made at genetic manipulation including hybrid vigor, selective breeding, mutagenesis, and genetic engineering are discussed with emphasis on future prospects and remaining obstacles. Traits offering promise for modification and molecular tools required to accelerate efforts are identified. Case studies will focus on enhancing heat tolerance, desiccation tolerance (i.e., shelf-life), and the anti-immune response (i.e., enhanced efficacy) by overexpression of potentially useful genes. The use of interference RNA, a powerful new molecular tool developed to study gene regulation will be treated. This fast and simple procedure permits the disruption of gene expression and the creation of null mutants. The paper concludes by reviewing the potential that transgenic strains offer to enhance the broader study of entomopathogenic nematode biology. As one example, molecular markers expressing green fluorescence protein in posterior ganglia have been previously generated in heterorhabditid nematodes, but have been too indistinct to use for other than molecular purposes. New advances in expressing markers throughout the nematode cuticle coupled with the easy availability of fluorescent stereomicroscopy offers the ability to quickly screen large populations. The relevance of this advance to nematode field ecology will be discussed.

Index terms: mutagenesis, selection, genetic engineering.

[1996] USE OF PATHOGENIC NEMATODES AND THEIR SYMBIOTIC BACTERIA FOR THE CONTROL OF SLUG PEST

<u>R. A. France</u>, M. E. Gerding, S. Espinoza & E. Vivanco, INIA - Quilamapu, P.O. Box 426, Chillán, Chile.

Slugs are important pest over a wide range of climatic and agronomic conditions. Some agricultural practices, like mulching or reduced tillage favour slug reproduction up to levels capable to produce severe damage to monocots plants and make broadleaf cropping impracticable. Until now, slug control has been based in toxic baits, which are easily damaged by high humidity after application, and with active ingredients unfriendly to the environment. Biological control of slugs has been a complicated task mainly due to the presence of few natural enemies. However, the discovery of Phasmarabditis hermaphroditu, a parasitic nematode of slugs and snails, in the UK in 1988, provided a new alternative to slug control. This nematode has been found also in Chile (1996), following a fortuitous slug sampling. The nematode is an effective parasite, which enter into the slug either through the shell cavity or respiratory pore. Like entomopathogenic nematodes, P. hermaphrodita releases symbiotic bacteria that are pathogenic to slugs. These bacteria are responsible for producing a marked swelling of the mantle, inducing feeding inhibition and body disintegration. Moreover, the bacteria associated with the Chilean nematode also produces mouth and reproductive system prolapsing. The main differences between both isolates are in their symbiotic bacteria. The UK nematode was found to be associated with ninc bacterial isolates, however, only one was the most effective in killing slugs (Pseudomonas fluorescens) while another specie was capable to support nematode reproduction (Moraxella osloensis). On the other hand, the Chilean isolate has only two associated bacteria (P. fluorescens and Serratia fonticola), both of them capable to kill slugs and support nematode reproduction. Also, each one of the individual bacteria or their by-products when used as toxic bait for slugs' control produced similar symptoms to the ones observed with the nematode-bacteria combination. Also, it was observed that the field applications of the nematode not only killed the slug pest from the treated soils but also had a positive effect in the following crop. The UK P. hermaphrodita is currently commercialised by Microbio in Europe, but only as a garden biopesticide. Price is the main restriction for their use in farmland. Efforts should be made in order to find a more effective nematode-bacteria combination with improves nematode rearing efficiency and better storage capabilities. The potential of using the isolated symbiotic bacteria or their metabolites, either for slug control or source of novel products should be explored.

Index terms: Deroceras reticulatum, Phasmarhabditis hermaphrodita, parasitic nematcdes, slugs, biological control.

[1997] BIOPESTICIDES BASED ON ENTOMOPATHOGENIC NEMATODES: DREAM OR REALITY?

B. Fridlender, Biotech M.A.H. Headquarters Brurim M.P. Shikmim 79837 Israel, Email: tolof@hazera.com

The capabilities of insect and other parasitic nematodes to serve as biocontrol agents have been know for a long time. However, despite their effectiveness, the application of these very interesting biopesticides has remained limited to certain niches markets. Parasitic nematodes, as most biocontrol agents, are living organisms that have very specific requirements in order to remain healthy and retain their capabilities to effectively reach their target host pest. Nematodes activity, in contrast to other more simpler biocontrol agents, are based in a complex living system formed by the nematode and its symbiotic bacteria. The complexity of this biological system as well as the lack of full understanding of the physiological interaction of these components with their target pests, have probably been one of the most significant limiting factors in the extensive use of these biopesticides. The importance of the symbiotic bacteria and the main role played by them in the control of insects and other pests has been recognized only in the last couple of years. Nematodes probably act mainly as vectors of these bacteria with the capability to deliver their lethal load into the right place of the target pest. It could be that they also play another role in this complicated control system, however, it is still not fully clear how this is done. It is the complexity of the system what has made so difficult the mass production of these biopesticides at a costeffective price. The main limitations of available products are their short shelf life and lack of state of the art formulations. However, the efficacy demonstrated for the different strains of nematodes available and their wide spectrum of activity against many different pests fully justifies development efforts needed to obtain better and more readily available products. The development of future products should have a much less conventional approach and it should take into consideration the great deal of knowledge becoming available from the different genomic programs. New information being derived from the understanding of the function of the nematodes as well as their symbiotic bacterial genetic composition could be very significant for production and stability purposes. Nematodes capable to persist in wider ranges of environmental conditions associated with bacteria with increased pathological capabilities are just a couple of examples of characteristics that can improve the existing products. There is hope that the dream will be converted in reality. The use of the vast amount of functional genetic information arising from around the world could make the difference.

[1998] BACULOVIRUS PRODUCTION IN VITRO - RECENT DEVELOPMENTS

S. Reid & S. Weiss, Dept. Chem. Engin., Univ. of QLD., Brisbane, Q, 4072, Australia

In Australia, due to resistance by *Heliothis* larvae to nearly all available chemical sprays, an *in vivo* produced baculovirus product, Genastar[®], is finding a ready market on a range of crops. Recently we have demonstrated the ability to produce a Helicoverpa armigera singly enveloped nucleopolyhedrovirus (HaSNPV) in vitro using a Helicoverpa zea cell line which shows comparable activity to Gemstar in the field (Chakraborty et al., 1999). Currently a fed - batch process is being developed at pilot scale using a low cost medium (LCM) to further demonstrate the commercial potential of the HaSNPV fermentation product. Fed - batch studies have shown the potential to produce up to 1.2 g/L of B-Galactosidase using the Spodoptern frugiperda, SI9, cell line and a recombinant Autographa californica nuclear polyhedrosis virus, (Chan et al., 1998). It should be possible therefore to eventually produce 1.2 g/L of the HaSNPV virus (each virus particle is composed primarily of 0.5 picograms of polyhedral protein). At such yields, at the current application rates of 5 x 10¹¹ HaSNPV particles/Ha, a good buisness plan can be established for this product. While the development of LCM (less than \$4/L) and process models (Power et al., 1994), for insect cell/baculovirus systems are at an advanced stage, the stability of HaSNPV isolates over at least 10 passages (required to scale the process to the necessary 5-10,000 L scale) in culture, is proving problematic. This talk will review the status of our process research into the development of a baculovirus fermentation product.

[1999] POTENTIAL IN AUSTRALIA FOR A HELICOVERPA BACULOVIRUS

D.A.H. Murray, R.J. Lloyd & J. Boddington, Department of Primary Industries Po Box 102 Toowoomba Q 4350 Australia.

Helicoverpa armigera is a scourge for producers of fibre, grain, fodder and food crops in Australia, costing an estimated A\$225M annually in chemical control and lost production. Reliance on conventional synthetic insecticides has turned a full circle. More than 20 years ago a Helicoverpa nucleopolyhedrovirus (NPV) made a foray into the Australian insecticide market. Eventhough it had many of the attributes of a successful biopesticide, it did not compete in the market place with the new synthetic pyrethroids and carbamates. Insecticide resistance to these insecticide groups has changed the outlook as control of H. armigera is unreliable using conventional chemistry. There are also increasing pressures to adopt sustainable insect pest management approaches that embrace a responsible attitude towards the environment and the community. In late 1998, a Helicoverpa NPV, under the trade name Gemstar® was registered in Australia for Helicoverpa spp. control on grain sorghum and chickpea, Registration on cotton was approved in January 2000. The imported product costs about A\$60/L and is used at rates from 100 to 500 niL/ha. There has been an amazing uptake of Gemstar in the marketplace as pest managers recognise the potential contribution of this product. Limited use on a suite of other crops is allowed under permit. The adoption of Gemstar has been accompanied by a growing acceptance that total pest control is not achievable nor necessary in many of today's crops. Conservation of natural enemies is fundamental to this approach. Gemstar has delivered the goods, but it should not be used like any other insecticide. Education and understanding how Gemstar works are crucial, as are application and timing. Much of the current effort with Gematar is to improve its performance and broaden the The addition of milk powder has repeatedly improved field registration suite. performance of Gemstar. Various other additives have been evaluated, but none of these were equivalent to milk powders. Increasing persistence of NPV through the use of UV protectants has not been delivered, and in some crops multiple low rates are viewed more favourably than a single high rate application. Ultra low volume application has demonstrated its potential for cost effective Helicoverpa management in grain sorghum. An in vitro NPV was equivalent to Gemstar in initial field trials. The future for Helicoverpa NPV in Australia is very promising. It has cemented a niche in the marketplace, and this will invariably expand as users fully understand its capabilities. A locally produced in vitro product will also strengthen its share in a competitive insecticide market. An exciting time is dawning as finally some successful IPM programs are being developed. Just as before, the threat lies in new chemistry that provides a 'simple, quick fix' solution.

[2000] POTENTIAL FOR FUNGAL BIOPESTICIDES IN TROPICAL AGRICULTURE: THE AUSTRALIAN EXPERIENCE

R.J.Milner, CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia.

Research in Australia on entomopathogenic fungi over the past decade has concentrated on the genus Metarhizium. This fungus is easily isolated from soil and there are now about 1000 isolates preserved in the CSIRO Insect Pathogen Culture Collection. This fungus is genetically very diverse with some isolates being specific for certain targets and others with a wide host range. For example, isolates from acridids recently named M. anisopliae var. acridum are only known from acridid grasshoppers in nature while isolates identified as M. anisopliae var. anisopliae often attack a wide range of hosts in the laboratory, though their host range in nature is unknown. Isolates also vary in their response to temperature with *M. anisopliae* var. acridum growing well at temperatures up to 3° C and poorly below 15 °C, while some isolates of *M. flavoviride* var. *flavoviride* grow well at 10 °C but poorly over 30 °C. These factors need to be taken into account when selecting an isolate to develop as a biopesticide. At least 2 commercial companies are producing strains of Metarhizium as biopesticides in Australia. However only one product, BioGreen for use against redheaded pasture cockchafer, *Adoryphorus couloni*, produced by Bio-Care Technology Pty. Ltd. is registered at present. A second product, BioCane, for use against sugarcane scarab larvae is expected to be registered soon. This product is effective against Australia's most severe sugarcane pest, the greyback canegrub, Dermolepida albohirtum, and applied as conidia soon after planting. The conidia are produced by solid substrate fermentation on sterile broken rice and used directly as a natural granule. In 1999, some 9 tonnes of product were used in commercial trials under experimental use permit. Also nearing registration is Green GuardTM, an oil formulation of M. anisopliae var. acridum (isolate FI-985) for control of locusts and grasshoppers. This has also been extensively field trialed under an experimental use permit and a dose of 1×10^{12} conidia/ha has proved effective over a range of weather conditions for control of Australia's worst locust pest, Chortoicetes terminifera. The expected cost of this dose is comparable with chemical pesticides and given current concerns about chemical residues in Australia and the expansion of organic farming, it is likely to be widely used for preventative control of locusts. Other potential targets include termites, crickets, flies and various soil insects. *Metarhizium* seems to be poised to become a major biopesticide in Australia over the next few years. Index terms: *Metarhizium*; locusts; sugarcane scarabs; biopesteides; *Adoryphorus*

couloni, Chortoicetes terminifera, Dermolepida albohirtum.

[2001] IS SOLID STATE FERMENTATION THE BEST OPTION TO PRODUCE FUNGAL BIOPESTICIDES?

<u>S. Reid¹</u>, D.A. Mitchell² & A.Mordocco¹, ¹Dept. Chem. Engin., Univ. of QLD., Brisbane, Q, 4072, Australia; ²Depto de Solos, UFPR, Rua dos Funcionários 1540, Juvevê, Curitiba 80035-050, Paraná, Brazil, E-mail mitchell@agrarias.ufpr.br

Entomopathogenic fungi have been studied widely for use as biological control agents against many Australian pests. Conidia can be produced directly by solid state fermentation (SSF), or alternately, submerged liquid fermentation (SLF) can be used to produce mycelia that are then placed in trays to induce sporulation (diphasic production). A model organism, Metarhizium anisopliae, was chosen for this study. Conidia of M. A model organism, incluming an inspirate, was closed to us study, comma or main anisopliae were initially produced in jars using parboiled rice as a substrate. Studies showed the organism to be sensitive to agitation, with an optimal conidia yield of 2.57×10^9 conidia g⁻¹ rice obtained without agitation. When hand agitation (days 4-14) was incorporated a small decrease in yield to 1.97×10^9 conidia g⁻¹ rice was produced. This yield decreased even further to 1.09×10^9 conidia g⁻¹ rice with 5 min agitation, day 4-14 at 7 rpm, and 9.14 x 108 conidia g-1 rice with 15 min agitation, day 4-14 at 7 rpm. In fact, any form of agitation was detrimental to conidia production. This presents a problem for large-scale production of this organism as agitation would be required at large-scale to encourage oxygen transfer and to promote heat removal, homogeneity and the uniform distribution of water added to the substrate during the fermentation. Based on the decrease in conidia yields in an agitated system, even if the agitation was infrequent, it was decided that SSF would be problematic at large scale, and therefore an alternative production technique was sought. Another feasible technique for the production of conidia was to use SLF to produce biomass and then produce conidia using SSF. This two-step production method is referred to as a diphasic process. The process decided upon was one in which no additional substrate was added during the SSF step when the vegetative biomass was the introduction of the state of mycological peptone and 10 g L¹ of yeast extract, giving a biomass yield of 20.90 g dry biomass L⁴. Conidia production by the biomass harvested from the SLF occurred only 48 h after placement on an agar plate surface with a yield coefficient of 1.4 x 1010 conidia g' dry biomass. The efficiency of the conversion process from biomass to conidia was low for this process at approximately 17% w/w but with further work this may be improved. Bioassays showed that the biological activity of the conidia produced by the SSF method and the diphasic method were equivalent

[2002] FUNDAMENTAL ISSUES THAT LIMIT SCALE UP OF FUNGAL BIOPESTICIDES USING SOLID STATE FERMENTATION PROCESSES

<u>D. A. Mitchell¹, O. F. von Meien², A. Maccari Jr¹ & N. Krieger³, ¹Depto de Solos,</u> UFPR, Rua dos Funcionários 1540, Juvevê, Curitiba 80035-050, Paraná, Brazil, Email mitchell@agrarias.ufpr.br; ²Depto de Engenharia Química, UFPR, Cx. P. 19011, 81531-970 Curitiba, Paraná, Brazil; ³Depto de Química, UFPR, Cx. P. 19081, 81531-990 Curitiba, Paraná, Brazil.

Fungal biopesticides have potential for use against many insect pests, however, their production at large scale can be problematic, especially when spores are the active agent. The production of these spores usually must be done in solid-state fermentation (SSF), because the fungi involved typically do not sporulate well in liquid culture, and even if they do, fungal spores produced in submerged liquid culture are usually more sensitive, less stable and less virulent than the aerial spores produced in the environment provided by SSF. However, despite the superiority of SSF, it has a major limitation: little is known about how to design and operate bioreactors for large scale SSF processes. As a result, relatively few fungal biopesticides requiring SSF technology have been successfully commercialized. Most commercial processes operate on relatively small scales, involving production in multiple trays or bags. However, it is difficult to use this production technology in batches of greater than a tonne of substrate because such processes are very labor intensive and therefore expensive at these scales. This presentation will explore the challenges in the development of large scale SSF bioreactors and current research being undertaken tomeet these challenges. It will show that several bioreactor designs can be used for SSF processes, but that even with the most efficient designs there is always a problem: due to the poor heat and mass transfer characteristics of solid beds, it is very difficult to maintain the bed temperature and the oxygen and water levels at values optimal for growth of the fungus. It is especially difficult to remove the waste metabolic heat generated by the fungus during growth at a rate sufficient to prevent the temperature of the substrate bed from increasing to values which are deleterious to growth and sporulation. Furthermore, large temperature gradients can occur within the bed. These can be prevented by agitating the solid substrate, but this usually decreases spore yields even further because it damages reproductive hyphae. Without presenting mathematical details, the presentation will show how mathematical models of fungal growth and the heat and mass transfer processes within the bioreactor are essential tools guiding how SSF bioreactors should be designed and operated. The establishment of rational model-based strategies for the design and operation of large scale SSF bioreactors will have significant benefits for the production of fungal bionesticides

[2003] CURRENT STATUS ON MICROBIAL CONTROL OF TERMITES IN AUSTRALIA

R.J.Milner, J.A. Staples and M. Lenz, CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia.

Subterranean termites are major urban pests in Australia. The most damaging species belong to the genus Coptotermes and form discrete nests in trees or in the ground. Termites can also cause problems in horticulture (Mastotermes darwiniensis). Current termite management measures are based on chemical controls, physical barriers and the imposition of the Australian building standard for termite management. Among the more novel methods for controlling active infestations in buildings are the use of bait systems and also nematodes of the genus Steinernema for Coptoternes spp. In 1983, Hänel and Watson showed that conidia of the hyphomycete fungus, Metarhizium anisopliae, could be applied to feeding sites of Nasutitermes exitiosus and the disease would transfer to the colony causing some adverse effects. However due to "unknown factors" the colonies often recovered and no epizootic developed. Over the past 10 years, we have been undertaking research to elucidate these "unknown factors" and hopefully develop a commercial microbial control product based on the conidia of M. anisopliae. An extensive survey was undertaken to assess the significance of Metarhizium as a natural mortality factor in Australian termite colonies. This survey resulted in over 100 isolates being obtained from termite contraits in was concluded that the fungus did not normally cause epizootics in termite colonies. Screening of the isolates resulted in the selection of FI-610 a strain with a wide host range which is highly pathogenic for all species of termites tested. This strain developed well under the temperature and humidity conditions normally found in termite nests but when introduced into a mound resulted in avoidance behaviour and the walling off of the applied conidia. It is now thought that these behavioural responses are the "unknown factors" of Hänel and Watson. Strategies for use of *Metarhizium* as a microbial control agent include killing the nest with a large dose of conidia blown directly into the centre of a nest, the use of the conidia as a prophylactic barrier by treatment of the surface of wood or of the soil, the use of a dust to eliminate termites from active galleries in damaged buildings and, recently, the possible use of conidia in baits. Problems and progress with baits will be discussed. We have an agreement with SGB Pty. Ltd. in Albury to commercialise Metarhizium for termite management in Australia.

[2004] MICROBIAL CONTROL OF TERMITES IN BRAZIL

S.B. Alves¹, J.E.M. Almeida², P.J. Neves³ & A. Moino Jr.⁴¹ESALQ/USP, C.P.9,13418-900,Piracicaba/SP-Brazil.E-mail sebalves@carpa.ciagri.usp.br; ²CEIB, C.P.70, 13001-970,Campinas/SP-Brazil. jemalmeida@uol.com.br; ³UEL, C.P.6001,86051-970, Londrina/PR-Brazil.E-mail pmojneve@uel.br; ⁴UFLA,C.P.37,37200-000,Lavras/MG-Brazil. E-mail alcmoino@ufla.br

In Brazil termites are considered important agricultural and urban pests. Several crops, such as sugarcane, pastures, forests and citrus are frequently attacked by termites. In urban areas, these insects attack trees, buildings, furniture and even phone cables. To replace chemical control, studies were developed on microbial control (MC) of Heterotermes tenuis in sugarcane using baits ("Termitrap"), in which individuals are contaminated with control agents. These agents are later transmitted to other insects by contact or trophallaxis. The baits contained entomopathogenic fungi in association with chemical insecticides. Strains of Beauveria bassiana and Metarhizium anisopliae were selected for the control of H. tenuis in the laboratory and a higher than 90% inortality rate was observed. Also, B. bassiana associated with several insecticides caused similar mortality levels. The baits were also used for bioecological studies of H. tenuis in sugarcane to evaluate population level and foraging area. These studies showed that cultural practices in the sugarcane crop influence the termite populations, and that the use of 30 to 35 baits/ha is sufficient to monitor these populations. In field tests, the insecticide triflumuron, mixed or not with the entomopathogenic fungi, caused reduction of the termite population at 0.1, 0.15 and 0.2% concentrations. Similar results were obtained when the entomopathogenic fungi were used alone. Preliminary studies showed efficacious control of small and medium mound termite nests, Cornitermes cumulans with B. bassiana and M. anisopliae applied in an inundate strategy. However, this strategy was not very effective for the control of large nests. Further studies associating entomopathogenic fungi with im

[2005] MICROBIAL CONTROL OF TERMITES IN THE USA IN THE UNITED STATES

B.T. Forschler, Dept. of Entomology, Univ. of Georgia, Athens, GA 30602, USA

The potential for biological control using predators, parasites and pathogens has not been thoroughly investigated for termite control. Vertebrate and invertebrate predators have not been seriously considered because of a variety of biological constraints and the zero tolerance action thresholds used in termite control (Grace 1997. Agri. Entomol. 14:281-189). Insect parasitic nematodes have been investigated but were found to repel termites from the point of application rather than effect serious termite population reductions (Mix 1986. Pest Control 53:48-54; Epsky & Capinera 1988. J. Econ. Entomol. 81:21-30). Bacterial pathogens have been screened but effects on termites in laboratory bioassay were not promising (Grace and Ewart 1996. L. Appl. Microbiol. 23:183-186). No viral pathogens have been examined. Biological control of subterranean termites in the United States has been directed toward survey and laboratory bioassay of entomopathogenic fungi (Lai et al. 1982, J. Invertebr. Path. 39:1-5; Zoberi and Grace 1990. Mycologia 82:289; Jones et al. 1996. Environ. Entomol. 25:481-487). Intuitively, Rhinotermitidid termites have co-evolved with and therefore should have defenses against fungal epizootics. Experimentally it has been shown that termites have physical and social barriers to fungal infection (Boucias et al. 1996. Pflanzenschutz-Nachr. Bayer 49:103-145; Rosengaus et al. 1998. J. Chem. Ecol. 24:1697-1706). Our research has indicated that several isolates of three species of fungi are repellent in the spore or conidial stage while they are non-repellent in the blastospore or mycelial stages and they were ineffective in reducing reproductive potential (Forschler & Jelks 1998, Proc. Nat. Conf. Urban Entomol. pp. 102) It would appear that fungi are best suited for application to infested structural lumber as a repellent (Forschler 1998. Proc. 6th Siconbiol. pp. 100-105) rather than a subterranean termite population management tool. The greatest potential for a biological control agent probably lies with the little studied entomopathogenic viruses. Theoretically, a latent virus could be disseminated in a termite population via social contact before it expresses its lethal effects. Therefore, large-scale population impacts are possible and by knowing the stress factor that would 'turn on' a latent virus one could plan or predict the timing of termite population reductions. Screening termite populations for viral pathogens should yield candidates for intensive bioassay.

Index terms: biological control, subterranean termites, Rhinotermitidae, fungi, viridaeloprid at low concentrations resulted in a 4X reduction of the amount of conidia used, and in control levels greater than 80% for large *C. cumulans* nests. Microbial control of *Nasutitermes sp.* using *B. bassiuna* was also effective when the fungus was applied inside the nests. Despite the advances of MC in Brazil, studies are needed to evaluate its effectiveness and define strategies for its use in wide scale. It is important to continue studies with new insecticides in association with entomopathogens and the investigation of possible factors that affect the MC in the field, especially the action of antagonistic microorganisms in the soil. Index terms: *Heterotermes tenuis, Cornitermes cumulans*, entomopathogens

[2006] INTRODUCTION OF A PROTOZOAN FOR CONTROL OF IMPORTED FIRE ANTS IN THE USA

David H. Oi & <u>David F. Williams</u>, U.S. Dept. of Agriculture, Agricultural Research Service, Center for Medical, Agricultural & Veterinary Entomology, P.O. Box 14565, Gainesville, FL, 32604, USA, E-mail doi@gainesville.usda.ufl.edu.

Protozoan infections in fire ants have been reported infrequently since the 1970's. Thelohania solenopsae was the first protozoan (microsporidia) to be observed in fire ants, specifically the red imported fire ant, Solenopsis invicta, by Buren in 1973. Extensive studies in the mid-1990's by Briano et al., of T. solenopsae infections in the black imported fire ant, S. richteri, have established the potential of this protozoan as a biological control agent for fire ants. In 1996, T. solenopsae was discovered in Florida, USA from S. invicta by Williams et al. Imported fire ant Icolonies have been infected with T. solenopsae collected from Florida via the introduction of infected brood. Artificial inoculations of laboratory colonies have resulted in infected queens with reduced queen weights and oviposition rates. This has resulted in significantly less brood (88%) and lower queen survivorship than in uninfected colonies. To examine the potential host range of the Florida collected T. solenopsae, infected fire ant brood was introduced into laboratory colonies of seven species of ants. Infections were detected only in S. richteri colonies obtained from Argentina. Examinations of field collected colonies of 7 non-S. invicta ant species were also negative for T. solenopsae infection. Field inoculations were initiated in Florida in 1997, and 4 of 5 inoculated colonies became infected. Infections were detected in non-inoculated fire ant nests on subsequent sample dates suggesting that infections had spread. By 1999, infections have been detected in over 85% of the colonies sampled at this study site, and reductions in fire ant populations of over 60% also have been observed. Additional introductions were made in ten states to document the potential impact of T. solenopsae on imported fire ants in different geographic areas of the southern USA. Infections have been detected in seven of these states. Field infections in the USA have been predominately found in polygynous fire ant populations. The first field infections in the monogynous form of S. invicta have been detected among these introductions. T. solenopsae has been detected in 93% of the males and 75% of the females alates initiating nuptial flights. It is possible that infected reproductives will fail to establish new colonies, thus impeding the spread and continual reinfestations by fire ants.

Index terms: Solenopsis invicta, Formicidae, Microsporidia, biological control

[2007] MICROBIAL CONTROL OF ANTS WITH FUNGI

<u>I.L. Stimme</u>, Dept. of Entomology and Nematology, Univ.of Florida, Natural Area Drive, P.O. Box 110620, Gainesville, FL 32611-0602, USA, E-mail jls@gnv.ifas.ufl.edu.

Entomopathogenic fungi can infect and kill a wide variety of arthropod species but their role in the dynamics of social insect populations and communities is not well defined. The discovery in 1985 of a naturally occurring strain of the white muscardine fungus, Beauveria bassiana, in populations of Solenopsis invicta in Mato Grosso, Brazil spawned interest in the possibilities of using fungi as biological control agents for ants. Field studies in Brazil confirmed that B. bassiana has natural epizootics in fire ant populations in Mato Grosso and suggested that this microbial agent is an important factor in the regulation of abundance and distribution of fire ants in South America. Isolate 447 of Beauveria bassiana was selected as a candidate for evaluation as a microbial pesticide against ant species. Studies were conducted to evaluate the efficacy of the fungal strain for a variety of ant species including: (1) Red Imported Fire Ant, Solenopsis invicta; (2) Carpenter Ant, Camponotus floridanus; (3) Pharaoh Ant, Monomorium pharaonis; (4) Crazy Ant, Paratrechina longicornis and (5) Ghost Ant, Tapinoma melanocephalum. A bait formulation of the fungus was tested in comparison with three chemical pesticide products. Results showed that the fungal bait was significantly efficacious for all ant species tested and that performance of fungal bait was equal to or superior to chemical bait products for most of the ant species. These results indicate that a non-toxic biological control for social insects is not only possible but also feasible. The fungal strain was tested for eight other ant species and was found to be very pathogenic. However, the efficacy of fungal formulations appears to be dependent upon ant foraging and recruitment behaviors as is also the case with chemical bait products. The 447 strain is being developed as commercial products for ant control by SafeScience, Inc. and this strain also has potential for control of termites.

[2008] CHALLENGES FACING MICROBIAL CONTROL OF SOIL-DWELLING PESTS

T. A. Jackson, AgResearch, PO Box 60, Lincoln, New Zealand. Email: jacksout@agresearch.cri.nz.

Soil dwelling insects are hosts to a wide variety of pathogens and the soil, being rich in microbes, should be an ideal environment in which to practise microbial control of insect pests. Difficulty arises in implementation of microbial control as the soil is a highly complex, competitive environment, placement of microbes in the correct position in the soil profile is difficult and survival of applied microbes is by no means assured. In addition, soil dwelling pests appear to show a high level of resistance to many pathogens and microbial toxins. In spite of these difficulties, some significant successes in control of soil dwelling pests have been achieved. Most have involved a microbe that is highly specific for the particular target species which also has the ability to persist in the soil, either through the inherent stability of the organism or from recycling through the host population. This specificity of micro-organisms for soil dwelling pests poses some problems in developing and managing microbial control systems. Pest outbreaks can be sporadic and mixed-species pest populations can be damaging to a particular crop. Specificity precludes use of microbial control agents as broad-spectrum controls, but does have the advantage of limiting non-target effects. Correct identification of the pest species and a thorough search for pathogens should be the first stages of any programme. Several of the successful microbial control programmes of soil insects are based on unique, specific micro-organisms and undoubtedly many more useful microbes await discovery. Microbial strains should be selected for both pathogenicity and environmental persistence. While strain selection is the essential first step in microbial control of soil dwelling pests, it must be followed by development of efficient production systems and delivery systems backed by quality control measures to ensure application of a standardised, high quality product. Although particular microbes may vary in their production and survival characteristics, there is an opportunity for application of generic systems for formulation and delivery to speed progress in microbial control development. To bring these factors together in a package remains a major challenge for the broad-scale implementation of microbial control for soil dwelling pests.

[2009] BEHAVIORAL RESPONSE OF SOIL ARTHROPODS TO FUNGAL PATHOGENS

<u>M. G. Villani¹</u>, L. L. Allee² & R. I. Brandenburg³, ¹ Dept of Entomology, NYSAES, Cornell University, Geneva NY 14456, USA, email: mgv1@nysaes.cornell.edu; ²Dept of Entomology, NYSAES, Cornell University, Geneva NY 14456, USA, email: lla1@cornell.edu ³Dept. of Entomology, North Carolina State University, Raleigh, NC 27695, USA, email: rick_brandenburg@ncsu.edu

The Japanese beetle, Popillia japonica Newman, and the tawny mole cricket, Scapteriscus vicinus Scudder, are important soil dwelling pests of turfgrass in eastern United States. Inundative field applications of fungal pathogens Metarhizium. anisopliae and Beauveria bassiana have given inconsistent results against these two soil pest species. Changes in Japanese beetle grub feeding site selection on sod roots, movement patterns, and survival in Metarhizium. anicopliae inoculated soil were examined in greenhouse studies and through the use of radiographic analysis in the laboratory. Our studies indicate that the application of mycelial particles in soil affected the behavior of Japanese beetles larvae. Japanese beetle grubs avoided soil that contained high concentrations of pathogen for up to 20 days after application..Further studies have shown that a simple formulation of M. anisopliae sporulating on rice also elicits avoidance in Japanese beetle. Similarly, M. anisopliae grown on rice or a commercial preparation of Beauveria bassiana. incorporated into the upper level of the soil profile in a microcosm alters the highly stereotypic tunneling of the tawny mole cricket, with an accompanying deterioration of tunnels in the conidia-iucorporated soil. Preliminary field studies with liquid formulations of B. bassiana indicate that reverse rate responses often occur with higher rates providing less control. This may be the result of avoidance behavior associated with higher rates. This behavior would allow the mole crickets to avoid the fungal pathogen until it becomes inactive and then resume tunneling, causing increased damage. The avoidance response seen in laboratory experiments may be evidence of an evolutionary adaptation to avoid infected insects and areas of soil with high concentrations of conidia. While avoidance entomopathogenic fungi in the soil may seem to thwart efforts to directly control arthropod pests with pathogens, more in depth study of the parameters of this behavior may provide new control strategies.

Symposium and Poster Session

[2010] DISEASE/HOST MODELS FOR SOIL-DWELLING PES7S

N.D. Barlow¹, T.A. Jackson¹ & H.C.J. Godfray², ¹AgResearch, PO Box 60, Lincoln, New Zealand, E-mail barlown@agresearch.cri.nz, ²NERC Centre for Population Biology, Silwood Park, Ascot, Bcrks, UK

The usual approach to modelling insect/pathogen interactions is the 'classic' Anderson/May model, which divides the host population into categories according to their disease status and uses differential equations to represent changes in densities of the categories. These models have provided the foundation for most theory to date and helped to develop insights into the dynamics of host/pathogen systems. For example, long-lived, highly pathogenic infectious stages can cause cycles in forest insects, and non-infectious pathogen reservoirs can regulate hosts at low density. More complex versions of the models have been successfully applied to a number of specific case studies. Here we discuss two new models. One is a development of the Anderson/May model, applied for the first time to a soil insect/disease system and including not only a pathogen reservoir but also competition between pathogenic and non-pathogenic bacterial strains. The other represents an alternative approach, using discrete models analogous to those commonly applied to parasitoid/host and predator/prey systems. Such models are simple and easily fitted to typical insect and disease sampling data. The models are applied to two case studies, the New Zealand grass grub/Serralia spp. and the European chafer/Bacillus popiliae system. For grass grab, they show that naturally occurring bacteria contribute to but are not solely responsible for regulation of numbers, suppressing populations by around 17% on average, at a prevalence of 12%. If this is raised to 40% by augmentative biological control, grub populations are suppressed by 67%. Improvements in biological control may be achieved by enhancing saprophytic ability of the bacteria rather than virulence. For European chafer in New York State, existing *B. popilline* has little effect on grub density; however, a single inundative addition of bacteria can give a 50% reduction in the year of application. If biocide use is sustained then, as for grass grub, the impact of successive increases in disease prevalence is non-linear. In this case there is little effect up to prevalences of about 60%, then chafer densities drop rapidly with higher levels of sustained disease.

[2011] THE DEVELOPMENT OF *METARHIZIUM*-BASED BIOPESTICIDES FOR USE AGAINST SUGARECANE WHITEGRUBS IN AUSTRALIA

R.J.Milner¹ & <u>P.R.Samson²</u>, ¹CSIRO Entomology, GPO Box 1700, Carberra, ACT 2601, Australia and ² BSES, PMB 57, Mackay Mail Centre, Qld. 4741, Australia.

The most serious insect pests of sugarcane in Australia are the larvae of scarabaeid beetles, known as sugarcane whitegrubs. There are 19 species which can cause economic damage by feeding on the roots and thus reducing the yield of sugar harvested and the ability of the crop to ratoon. The beetles normally fly in October/December, with the complete lifecycle taking 1 to 3 years depending on the species and the latitude. Pathogens are important as natural control agents in some areas and one of the most significant of these are various strains of the hyphomycte areas and one of the most significant of disc of the disc and one of the most significant of disc of the disc of t Dermolepida albohitrtum, in the North Queensland tropics and M. flavoviride var. flavoviride and Beauveria bassiana being dominant in the Rhopaea grubs of temperate northern New South Wales. Two isolates of Metarhizium FI-1045 from greyback canegrub and FI-147 from negatoria canegrub, Lepidiota negatoria, have been selected for commercialisation as biopesticides. FI-1045, with the trade-name BioCane is being manufactured by BioCare Technology Pty. Ltd. at Somersby, New South Wales, is most advanced with registration expected by the middle of 2000. In 1999 some 9 tonnes of a rice-based granular product with conidia as the active ingredient was used in commercial trials against greyback canegrub mostly in the Burdekin region of Queensland. The material is applied at the rate of 33 kg $(6.6 \times 10^{13}$ conidia/ha) before fill-in of the planting furrow and provides 50-60% control in the first season. The conidia can persist in the soil for at least 2-3 years and it is expected that a single application will provide protection for several years. FI-1045 also shows promise for control of two other species, southern one-year canbegrub, Antitrogus consanguineus and picticollis, Lepidiota picticollis. The other isolate, FI-147, is ineffective against greyback canegrub, but very effective against negatoria and French's canegrub, L. frenchii. Field trials are currently underway with a combination of FI-1045 and FI-147 in the hope of controlling mixed infestations. Initially it is expected that these biopesticides will be used where chemical control measures are ineffective or undesirable, however they have the advantage of recycling in the canegrubs and thus the inoculum building up in the ratoon crops. It is hoped that this advantage will outweigh the problem that control can be too slow to prevent damage in the year of application. Metarhizium.

Index terms: sugarcane; whitegrubs; scarab beetles; Metarhizium, Beauveria;Dermolepida albohirtum; Lepidiota; Rhopaea; Antitrogus.

Symposium and Poster Session

[2012] AN INTEGRATED APPROACH TO MANAGE THE ANDEAN POTATO WEEVIL, PREMNOTRYPES SPP. (CURCULIONIDAE)

A. Lagnnoui, J. Alcazar & F. Cisneros, International Potato Center, Apartado 1558 - Lima 12 - Peru.

The potato production in the Andean area is essential for food security of the inhabitants of the Andes, particularly those in rural areas. Unfortunately, many pests (insects, pathogens, nematodes and weeds) are known to affect potato production in this region, causing severe losses. In the Andes, the most damaging potato pests are the Andean potato weevils, most in the genus *Premnotrypes* and often referred to as the Andean potato weevil complex. Despite the heavy use of insecticide in that region, the weevils are still causing severe losses to the potato crop. The Andean potato weevil is an endemic pest in the Andean countries that causes considerable losses. Over the years, CIP scientists developed an integrated management strategy based on locally produced entomopathogenic fungus, *Beauveria brogniarii*, to control weevil larvae. This naturally occurring insect killing fungus is now used in Peru, Colombia, and Bolivia to control the most serious insect pest of potato in highland areas. It is most prevalent among small, resource-poor farm families. The fungus has been found to be effective against larvae, pupae, and adult weevils. Use of the fungus is low-cost, effective and particularly attractive to poor farmers, relieving them of the high costs and undesirable effects of toxic insecticides.

[2014] PATHOGENS OF TARO BEETLES AND THEIR POTENTIAL USE IN PEST MANAGEMENT IN THE SW PACIFIC

R. Masamdu¹, N. Simbiken¹, I. Alloali³¹², W. Theunis³ & <u>T.A. Jackson⁴</u>. ¹EU/SPC Taro Beetle Project, PO Box 1639, Lae, Papua New Guinea. Email: SPC spetaro@datec.com.pg; ²EU/SPC Taro Beetle Project, PO Box 912, Honiara, Solomon Islands: ³PO Box 226, Zamboanga City 7000, Philippines; ⁴AgResearch, PO Box 60, Lincoln, New Zealand.

Seven species of taro beetles in the genera Papuana and Eucopidocaulus (Coleoptera: Scarabaeidae) are important soil dwelling pests of taro Colocasia esculenta and other cultivated aroids Xanthosoma sagittifolia, Alocassia, Cyrtosperma and Amorphophallus species in six countries in the South Pacific.; Papua New Guinea, Solomon Islands, Vanuatu, Fiji, Kiribati and New Caledonia. Surveys of pest populations in Papua New Guinea have shown that taro beetles are naturally infected by an entomopox virus, bacteria (Paenibacillus popilliae and Serratia marcescens), fungi (Metarhizium anisopliae and Cordyceps sp.), protozoans (Nosema sp., Vavraia sp. and a neogregarine) and nematode (Steinernema sp.). In addition, Papuana spp. are susceptible to Oryctes virus isolated from the rhinoceros beetle, Oryctes rhinoceros. Several pathogens have been tested as microbial control agents for taro beetle in the laboratory and field. Both larvae and adults of Papuana uninodis were susceptible to entomopathogenic nematodes (Steinernema glaseri, S. feltiae, S. carpocapsae and Heterorhabditis zealandica) in the laboratory, but field results were inconclusive and nematodes could not be recovered from the soil three months after application. Paenibacillus popilliae type A1 was found to be highly pathogenic to P. uninodis in the laboratory and infected larva were found in the field one year from application on Kiribati. A highly virulent strain of Metarhizium anisopliae was selected in the laboratory and has been tested in the field producing infections over a prolonged period. Adult beetles artificially infected with *Oryctes* virus have been released into the field and the virus has been shown to persist in the beetle population at one of the release sites. The ability of pathogens to persist, spread and reduce taro beetle populations and damage to taro will be discussed in relation to beetle biology and the potential of microbial control for taro beetle evaluated. Index terms: Papuana, Eucopidocaulus, Colocasia, microbial control

[2013] PATHOGENS FOR CONTROL OF NORTH AMERICAN SCARABS

M. G. Klein, USDA, Agricultural Research Service, 1680 Madison Ave., Wooster OH 44691, USA, E-mail klein.10@osu.edu

Scarab larvae and beetles are serious pests of turf, nursery, flower, and food crops throughout most of N. America, and are of increasing quarantine concerns. Introduced species such as the Japanese beetle, Popillia japonica, oriental beetle, Exomala orientalis, and European chafer, Rhizotrogus majalis, are of primary concern in the northeast and midwest, while native June beetles, Phyllophaga spp. and masked chafers, Cyclocephala, spp., predominate elsewhere. Even though microorganisms play a major role in the natural suppression of scarabs, no pathogens are commercially available against adult beetles, and few are available for larval control. This situation will probably change little in the next few years. Viruses are an important component of scarab control in some parts of the world, but are almost non existent in N. America. Several genera of protozoa, Adelina, Pseudomonocystis, and Ovavesicula for example, play an important role in natural suppression of scarabs, and are among the few agents infecting adult beetles, but they are unavailable for control programs. Infections from another protozoan, Nosema spp., are found much less frequently in N. America than Europe and Australia/New Zealand. Milky disease bacteria were the first microorganisms registered in the U.S., but their use has been severely limited by a lack of commercial products, the natural distribution of the bacteria, and the slow and erratic performance of products in the field. Recently, the genus of these bacteria has been changed from Bacillus to Paenibacillus, and the characteristic formation of parasporal bodies to separate species was shown to be unreliable. In addition, concerns have been raised about the release of a vancomycin resistant organism (P. popilliae in N. America) into the environment. Entomopathogenic nematodes, particularly those in the genus Heterorhabditis, are available for use against scarab larvae. The extent of their use in the future will depend on the availability of high quality products and dependable delivery systems to end users. The generalist insect killing fungi, Metarhizium and Beauveria spp. have a potential for increased use against scarab pests. Strains of these fungi with high scarab activity have been identified. Field tests using Japanese beetle traps, modified to facilitate auto-dissemination of the fungus by adults to larval populations, have been highly successful in the Azores and N. America. This delivery method offers hope for using fungal pathogens in areas that are otherwise difficult to treat.

Index words: Scarabaeidae, milky disease, nematodes, Paenibacillus popilliae

[2015] MANIPULATION OF SPRAY PARAMETERS TO IMPROVE EFFICACY OF MYCOINSECTICIDES AGAINST INSECT PESTS OF FIELD CROPS

<u>S. P. Wraight¹</u>, M. E. Ramos¹ & C. A. Bradley², ¹USDA, ARS, U. S. Plant, Soil, and Nutrition Laboratory, Tower Road, Ithaca, NY 14853 USA, E-mail spw4@cornell.edu; ²Mycotech Corp., 2500 Continental Dr., Butte, MT 50702-4109, USA, E-mail cbradley@mycotech.com

Most entomopathogenic fungi establish infections by direct penetration of the host's exterior body wall. The infectious units must therefore be applied directly onto the target insect or onto substrata in the host habitat where inoculation can be effected indirectly during locomotion or feeding. This mode of dose acquisition puts these agents at a marked disadvantage compared to many synthetic chemical insecticides whose vapor activity or capacity for systemic or translaminar movement obviates the need for precisely targeted spray applications. This paper reviews and compares results of field studies designed to evaluate the effects of various spray application methods on the field efficacy of Beauveria basssiana against Bemisia argentifolii (silverleaf whitefly) infesting cucurbits and Leptinotarsa decemlineata (Colorado potato beetle) infesting potatoes. In whitefly trials, efficacy of B. bassiana applications from a hydraulic sprayer configured to spray straight downward from 20 cm above the crop canopy was significantly improved by lowering nozzles to within a few cm of the crop canopy, orienting them downward at a 45° angle, and increasing hydraulic spray pressure over the range of 3.5 to 28.1 kg/cm². Compared to overhead sprays, efficacy of applications against early-instar potato beetle larvae was increased by mounting nozzles on lateral drop tubes and directing them upward at a 45° angle. These configurations effectively targeted the abaxial leaf surfaces, where young insects were feeding in a microenvironment shielded from sporicidal solar radiation and with greater than ambient relative humidity. Unexpectedly, however, use of the drop-nozzle configuration to spray third-instar potato beetle larvae had little effect on efficacy. Parallel greenhouse studies suggested that secondary acquisition of conidia by potato beetle larvae feeding on contaminated foliage was limited and that direct inoculation of larvae with a high dose of conidia was necessary to achieve control. This work indicates considerable potential for improving efficacy of foliar applications of B. bassiana through manipulation of various spray parameters and underscores the importance of precise targeting of mycoinsecticide sprays. Index terms: Entomopathogenic fungi, Beauveria bassiana, Bemisia argentifolii, Leptinotarsa decemlinenta, application technology, microbial control

[2016] DEVELOPMENT OF MYCOPESTICIDES FORMULATIONS AND APPLICATION TECHNIOUES

Alves¹ & R. P. Bateman², ¹Brazilian Agriculture Research Corporation -EMBRAPA Cerrados, Caixa Postal 08223, CEP 73301-970, Planaltina, DF, Brazil, E-Mail: ralves@cpac.embrapa.br; ²CABI Bioscience, Silwood Park, Buckhurst Road, Ascot, Berks, SL5 7TA, U.K.

A successful spraying technique needs to achieve the target; to be used on correct time under favorable environmental conditions; to be applied with the most appropriate equipment and volume application rate; with an effective formulation of the active ingredient and sprayed in the droplet size range to achieve that particular target. There is a great interdependance between the application technique and the pesticide formulation to achieve a successful insect pest control. Mycoinsecticide formulation refers to the resultant composition when an entomopathogenic fungus is mixed with other ingredients. The ingredients should contribute to the viability, stability, virulence, and efficacy of the microbial control agent and the acceptance of the product by the user. Successful results were obtained using oil-based fungal formulations against insect pests showed the potential of some oils for use as carrier to overcome or to decrease the effects of adverse conditions. Experimental results also showed that adjuvants can enhance the fungal infectivity and improve the mycoinsecticide application. The process of an effective mycopesticide application is consisted of some steps: mixing (some products are applied directly as formulated); atomisation; transport; collection; deposit formation; interaction with pest; and biological action. If all of the previous steps have been successfully completed, and if a sufficient dose has been delivered to the pest properly and in an active state, the desired result will likely to happen. This is the goal of an effective mycopesticide application and can be achieved only if all of the previous steps have been successfully completed. It is also necessary to increase the knowledge on pesticide application techniques within the farming, governmental and commercial sectors of all countries.

Index terms: emulsifiable adjuvant oil, controlled droplet application, Metarhizium spp.

[2017] FUTURE TRENDS IN CODLING MOTH CONTROL IN INTEGRATED PARTICULAR **EMPHASIS** PRODUCTION ON FRUIT WITH GRANULOVIRUS

E. Dickler, Federal Biological Research Center for Agriculture and Forestry, Institute for Plant Protection in Fruit Crops, Dossenheim, Germany

Opening statements in this presentation will discribe a wide spectrum of non chemical methods currently in use or in development for the control of codling moth. Presentations given by the speakers will deal with specific microbial control agents. The codling moth, Cydia pomonella, is a key pest in pome fruits and walnuts. In the Upper Rhine Valley of Germany, where this pest is bivoltine, it was for several decades the limiting factor in integrated control programmes, requiring 3-4 treatments each season with organophosphorus insecticides. This was more than half of all insecticide applications used in this area. In western Europe in the mid 80s, azinphosmethyl and other OPs were replaced by insect growth regulators (IGRs) which are less hazardous to the orchard ecosystem. They became of central importance in IFPprogrammes. However, in the early 90s, resistance to diflubenzuron, triflumuron, fenoxycarb etc. due to over-use and over-dosing of these chemical products was reported by several authors from the South Tyrol region of Italy, south eastern France, south west Germany and other central European fruit growing areas. In addition nowadays, organo-phosphorous insecticides, due to their acute human toxicity, have received worldwide criticism. Furthermore, the majority of these products are "existing active subtances", for which no ecotoxicity data are available. Manufacturing firms are not interested in supplying this information for re-registration. For these reasons, new strategies for codling moth control are needed, and around the globe, programmes were started to develop systems based mainly on the use of non-chemical products and techniques for sustainable fruit production. The objective of my presentation at this meeting is to describe the environmentally sound products, methods and techniques available nowadays for IFP programmes and possibilities for their intelligent combination with particular emphasis on granulovirus.

Components for integrated codling moth control

Selective, chemical insecticides

Pheromones: mating disruption, attract and kill

Eradication: SIR

Microbials, granulovirus, Bacillus thuringiensis,

Beneficials: pesticides, safe to beneficials, release of beneficials, e.g. Trichogramma, entomopathogenic nematodes

Cultural methods: hand fruit thinning, summer pruning, ground cover management

Monitoring: pheromone traps, corrugated paper bands, computer-based phenological modelling

Index terms: Cydia pomonella, integrated control strategies, granulovirus

Symposium and Poster Session

(2018) BIOCONTROL OF LEPIDOPTERAN PESTS OF APPLE AND PEAR WITH MICROBIAL AGENTS AND NEMATODES

J. V. Cross, Horticulture Research International, East Malling, Kent ME19 6BJ, UK.

Microbial pathogens and entomopathogenic nematodes are important components of the natural enemy complex in orchards and more effort needs to be devoted to fostering them and exploiting them as biocontrol agents in biologically-based IPM programmes. They can often be mass produced at low cost and applied as sprays and are potentially ideal biocontrol agents. Important general characteristics are their comparative environmental and human safety, compatibility with IPM programmes and reproductive capacity. They tend to be effective in a narrower range of environmental conditions than pesticides, but they can be improved by formulation, strain selection and genetic manipulation. They are often host- specific and thus, offer restricted marketing opportunities, which is a barrier to commercialisation. Baculoviruses are important pathogens of several lepidopteran pests but other viral pathogens have not been investigated in depth and are little known. The granuloviruses CpGV and AoGV have been researched extensively and are exploited as biocontrol agents. Commercial development has been limited by high costs, slow action, short persistence and specificity. Resistance to insecticides and the desire to reduce pesticides will lead to an increase in CpGV use. Future R&D approaches include genetic manipulation, formulation (to reduce UV sensitivity) and development of cheaper mass production techniques (possibly in vitro). A systematic search for other viruses is needed. The most important bacterial pathogen used as a biocontrol agent is Bacillus thuringiensis (B.t.). The HD-1 strain is widely used, but efficacy is moderate against lepidopteran orchard pests. Advances in biotechnology and genetic engineering provide opportunity for development of B.t. strains designed specifically to control orchard pests. Other approaches include the evaluation of new B.t. products developed for other markets world-wide and the bioassay of strains from B.t. collections. The main factor limiting the effectiveness of entomopathogenic fungi is the requirement for high humidities and moderate temperatures for spore germination and development. Pests which inhabit protected microenvironments should be targeted by improved formulation, the selection of low temperature-active strains, field evaluation and avoiding adverse effects of fungicides. The requirement for surface moisture for survival and movement of entomopathogenic nematodes means there are only limited prospects for using them as biocontrol agents for foliar pests. Pests overwintering in bark crevices close to the soil should be targeted.

Index terms: Cydia pomonella, Adoxophyes orana, Operophtera brumata

ENTOMOPATHOGENS FOR CONTROL OF USE OF [2019] LEPIDOPTERAN PESTS OF APPLE IN THE PACIFIC NORTHWEST OF THE UNITED STATES

L. A. Lacev, USDA-ARS-YARL, Wapato, WA 98951, USA

Control of insect pests of apple in North America has traditionally been accomplished using conventional chemical pesticides. Codling moth (CM), the primary pest insect of apple in the Pacific Northwest of the USA, has routinely been controlled with organophosphate insecticides. However, the use of conventional insecticides will be severely reduced in the near future due to implementation of the Food Quality Protection Act. Alternative interventions, such as the use of CM sex pheromone to disrupt mating (MD), will require low population densities of the moth in order to be effective. The use of microbial control agents could reduce CM population densities and complement MD while conserving beneficial insects. For the most part, microbial control of fruit tree pest insects has been underutilized. The combination of MD with the CM granulovirus (CpGV) and entomopathogenic nematodes (EPNs) offers promise for effective control of CM. The potential of CpGV for control of neonate larvae has been demonstrated by numerous researchers (Cross et al 1999), but the virus has not been routinely used in the USA. Overcoming problems associated with UV sensitivity will increase the attractiveness of CpGV to growers. The potential of EPNs for control of prepupal stages of CM has been elucidated by several authors (Kaya et al., 1984; Lacey and Chauvin, 1999; Lacey et al., 2000), but implementation in orchards will depend on keeping nematodes moist for six or more hours after application (Lacey et al. 2000). One consequence of the MD strategy has been the release of some secondary pests such as leafrollers that were incidentally controlled with conventional insecticides used for CM control. Bacillus thuringiensis, is regularly used in the Pacific Northwest for control of leafrollers, principally Pandemis pyrusana and Choristoneura rosaceana. The residual activity of Bt is relatively short necessitating reapplication. The recent discovery of a granulovirus in *P. pyrusana* (R. Pfannenstiel, unpub.) and a nucleopolyhedrovirus C. rosaceana will provide additional microbial options for control of these pests.

[2020] THE ROLE OF FORMULATION ADDITIVES IN INCREASING THE POTENCY OF CYDIA POMONELLA GRANULOVIRUS FOR CODLING **MOTH LARVAE**

J. Ballard¹, D.J.Ellis¹ & <u>C.C.Payne²</u>, ¹Horticulture Research International, Wellesbourne, CV35 9EF, UK; ²Dept. of Horticulture and Landscape, Univ of Reading, RG6 6AS, UK.

Studies were undertaken to improve the biological efficacy of the granulovirus (CpGV) of the codling moth, Cydia pomonella, by evaluating the performance of some formulation additives that might improve virus persistence and/or virus uptake by first instar larvae. Laboratory studies, using a leaf disc bioassay demonstrated that 15% cane molasses in a CpGV formulation significantly reduced the median lethal exposure time (LET₅₀) to CpGV for neonate larvae at a CpGV dosage rate of 10⁷ occlusion bodies (OBs)/ml. Laboratory screening of a range of other compounds showed that sucrose, fructose and sorbitol (at 10% concentrations) and extracts of apple flesh and skin also gave significant reductions in the LET₅₀ of CpGV formulations containing these ingredients. Pectin, malic acid, α -farnesene, skimmed milk and two artificial sweeteners containing aspartame and saccharin, did not significantly reduce the LET₅₀ in laboratory tests. In a field trial, molasses included at 15% (v/v) in a CpGV formulation, containing a dosage rate of 1042 OBs per hectare, gave as good control of codling moth damage as virus formulations containing 0.2% skimmed milk at dosage rates of 10^{13} and 10^{14} OBs/ha. Studies of CpGV persistence on foliage revealed no significant improvement of virus persistence on apple foliage using 10% or 15% molasses formulations conspared with formulations containing 0.2% skimmed milk. A second field trial demonstrated that 10% molasses, 10% sorbitol or 0.08% afornesene significantly reduced codling moth damage to fruit when these ingredients were added to formulations of pure CpGV. Substantial sooty-mould growth (*Cladosporium* spp.) was observed on apple foliage treated with formulations containing molasses, indicating that this formulation additive has secondary consequences that would need to be taken into account if molasses was to be used in commercial CpGV formulations. Nonetheless, these studies clearly demonstrate that major biological improvements in CpGV performance can be achieved by the incorporation of formulation additives, including molasses and several other compounds, that probably function as attractants and/or feeding stimulants for codling moth larvae.

[2021] CODLING MOTH (CYDIA POMONELLA) CONTROL WITH BACTERIAL AND VIRAL PREPARATIONS UNDER POLISH WEATHER CONDITIONS

R. W. Olszak & Z. Pluciennik, Research Institute of Pomology and Floriculture, 18 Pomologiczna, 96100 Skierniewice, Poland

For several decades pest control has been realized mostly with chemical pesticides many of are broadly destructive agents affecting harmful and beneficial inhabitants of plants indiscriminately. Insect pathogens are promising alternatives. They have the attributes of ideal control agents. Most are highly selective, affecting one or a few species of pests and are compatible with rules of integreted pest management (IPM) and integrated fruit production (IFP). They are used against codling moth in apple orchards. With the exception of Japan and some regions of far Eastern Asia, the codling moth occurs throughout the temperate regions of the world where apples are grown. In Europe, depend ing on the region, the pest has one, two or even three generations per annum. In Poland, the codling moth has two generations per annum, the second of which is usually less numerous (by 20-40%). For the past decades, OPs were mainly used against this pest, more recently (the last decade), a partial switch to IGRs has occurred. Experiments with insect pathogens were done in 1995 and 1998 with Bacillus thuringiensis (B.t.) applied as a market preparation "Biobite" and in 1992-1998 with - CpGV, applied as preparations "Carpovirusine" (Calliope Co., France) and "Granupom" (Hoechst Schering AgrEvo GmbH). The effectiveness of these biopreparations was assessed at harvest on the number of damaged fruits out of a sample of 800 fruits picked from trees and 200-400 dropped fruits from each treated plot. The results obtained were compared to a treatment with one of the standard pesticides (OP or IGR) and to the control plot, non- protected from codling moth. The preparations with B.t. were applied usually once or twice, whereas viral preparations were applied from two to five times depending on the programme. In all the experiments, both B.t. and the viral preparations significantly reduced the percentage of fruits damaged by codling moth caterpillars to below economic treshold level. The results were comparable to these of the standard pesticides. These results imply that, under Polish climate conditions, bacterial and viral preparations can maintain codling moth populations at a low level. Since they are safe to beneficial fauna and mammals, they can be recommended for use in orchards under an integrated management system as well as in other orchards that need to be sprayed against the 2nd generation during the summer when the pre-harvest interval excludes the use of many pesticides. Index terms: orchard, fruit, Cydia pomonella, baculovirus, Bacillus thuringiensis, granulovirus, biological control

[2022] GRANULOSIS VIRUS OF CODLING MOTH CYDIA POMONELLA: FROM LABORATORY TO FIELD

P.J. Charmillot. Swiss Federal Research Station for Plant Protection, Changins, CH-1260 Nyon, Switzerland, E-mail: pierre-joseph.charmillot@rac.admin.ch.

When tested by dipping apples in different product concentrations, Madex, a granulosis virus based product, had a LC_{50} of 0.3 ppm (mg/l) of formulated product, which is about 300 fold lower than that of Mimic (tebufenozid). Thus, the potential of the virus to control codling moth C. pomonella is exceptional. Biological tests in the laboratory on apples treated in the orchard indicated that granulosis virus had a good initial efficacy but a poor persistence due to a quick inactivation by UV light. In general, addition of products such as sugar, skimmed milk powder, Nu-Film-17 and Humin Vital increased slightly the persistence of the virus. Practical trials carried out during 7 and 8 consecutive years with 4 to 6 treatments per season allowed to maintain fruit damage at harvest and population densities of codling moth at a low level, even by reducing the dosage of virus to one half to decrease the cost of control.

Index terms: Cydia pomonella, lethal concentration, persistence, practical control

(CYDIA POMONELLA) AND THE USE OF [2023] CODLING MOTH GRANULOVIRUS IN ORGANIC AND INTEGRATED CONTROL

F. Polesny, BFL, Inst. of Phytoeind. Spargelfeldstr. 191, A-1220 Vienna, Austria fpolesny@bfl.at.

The CpGV product Carpovirusine was registered for control of codling moth in Austria some years ago. There are two nearly overlapping codling moth generations per annum in Austria. The egg laying period of the first generation lasts for about one and a half months. The egg laying period of the second generation lasts for more than a month. The use of CpGV against Cydia pomonella was evaluated in field trials. An effective treatment strategy using only CpGV requires a large number of applications during the whole period of larval hatching. Weekly applications are successful but applications at two week intervals results in an enormous decrease in efficacy. There are good opportunities to implement CpGV in integrated treatment strategies. There is no danger of cross resistance to other compounds used in Integrated Fruit Production. The combined use of CpGV with ovicidal insect growth gives good results and requires a reduced number of applications compared with traditional use of single compounds. The results of the different field trials are presented and discussed. Index terms: orchard, fruit, Cydia pomonella, baculovirus, granulovirus, biological control

[2024] CONTROL OF THE CODLING MOTH WITH $C_PGV\,\, DISSEMINATED$ by means of pheromone stations: 5 years of field trials

O. Pultar¹, F. Kocourek², J. Stara², J. Kuldova³ & <u>I. Hrdv</u>³, ¹Biola Laboratorics, Agricultural Cooperative, Chelcice, Vodnany 38901, Czech Republic; ²Research Institute of Crop Production, Drnovska 507, Praha 16106, Czech Republic; ³Institute of Organic Chemistry and Biochemistry, Academy of Sciences, Flemingovo 2, Praha 16610 Czech Republic, E-mail hrdy@uochb.cas.cz.

The method of attractant aided dissemination of *Cydia pomonella* granulosis virus (CpGV) was examined in field trials. Trials were performed on small as well on large commetcial apple orchards in Czech Republic, Central Europe. The aim of experiments which started in 1994, was to prove the following hypothesis: Males when attracted into pheromone station will be contaminated by virus, virus will be transferred to females during copulation and by ovipositing females directly on cggs and/or on fruits and leaves. Special pheromone station, i.e. modified tube trap coated inside with virus formulation and fluorescent paint and baited with codlemone dispenser was developed. Dissemination of virus formulation was assessed according to number of recaptured males in pheromone delta traps with sticky inserts. The pest situation on untreated plots, on plots treated by CpGV stations, by CpGV direct spraying and on plots under conventional insecticide treatment was compared. Efficacy of the new method was estimated by monitoring the population dynamics of coding infestation of fruits at least at two different terms (summer and autumn) during the season. The method of CpGV-pheromone stations was combined also with reduced number of direct CpGV sprayings. Factors affecting efficacy of the CpGV-pheromone station design,

virus formulation, persistence of virions, inunigration of non-contaminated males from surrounding plots, were evaluated. Dissemination of viral infection from CpGVpheromone stations into the field populations of the codling moth was confirmed. The advantage of the new method is in lower amount of virus preparation needed for treatment. The results imply the trends of decrease in population density and fruit damage, when compared to untreated control plots. The method may be efficient at initial low population densities of the pest and/or as complementary to CpGV sprayings.

[2025] VERTICAL TRANSMISSION OF CpGV AND IMPROVEMENTS FOR CONTROL OF CYDIA POMONELLA POSSIBLE EXTENSION TO CYDIA SPLENDANA IN APPLES, PEARS, WALNUTS AND CHESNUT CROPS

<u>M. Guillon¹</u> & G. Biache², ¹ Natural Plant Protection S.A., B.P. 80, Route d'Artix, 64150 Noguères, France, ² I.N.R.A. La Minière, Station de Recherche de Lutte Biologique, 78285 Guyancourt, France

Granulovirus (Carpovirusine) is produced by using larvae infected by a viral strain from Mexico, distributed by the B.B.A. (Darmstadt). It has been observed that a treatment of 10^{13} OBS per hectare every 10 days gives sufficient protection on condition that the destructive population level is weak to moderate. A study carried out on Codling moths which surved the treatment did not show any difference in weight between the variant pupae : untreated control, granulovirus, chemical insecticide and alternation of chemicals and granulovirus. Neither did the moths show any malformation of ovarioles. The study showed an increase in mortality and modification of the adult emergence curves. Vertical transmission of threated orchards. Index terms; Cydia pomonella, Cydia splendana, granovirus, vertical transmission [2026] PROGRESS IN THE GENETIC IMPROVEMENT OF GRANULOVIRUSES FOR THE CONTROL OF TWO IMPORTANT APPLE PESTS

D.Winstanley¹, S.L. Wormleaton¹, R. Finch¹ & G. J. Keane¹, Dept. of Entomological Sciences, Horticulture Research International, Wellesbourne, Warwick, CV35 9EF, UK.

Cydia pomonella GV (CpGV) is a fast killing GV, normally killing its host in the larval instar in which it is inoculated. In the case of codling moth the virus must be targeted against first two instars i.e. prior to their entry into the fruit. The GV has high infectivity for codling moth; the LD_{50} is one occlusion body (OB) for neonates. However, the speed of kill is relatively slow compared to insecticides, between 4 to 6 d for neonates. This results in continued damage to the fruit post inoculation of the larvae. It has been possible to increase the speed of kill of some nucleopolyhedroviruses by genetic manipulation using strategies such as gene insertion and gene deletion. Cell lines, permissive to CpGV, have provided a useful tool for *in vitro* studies on CpGV and have allowed the successful genetic manipulation of CpGV. Recombinant CpGV (CpGV-EGT), with a deletion in the ecdysteroid UDP-glucose transferase gene (egt) has been produced. In laboratory dietbased bioassays the efficacy of CpGV-EGT has been compared to the parent CpGV genotype, derived from the CpGV Mexican isolate, in first and fifth instar larvae. The nucleotide sequence of the CpGV genome has aided the construction of transfer nucleon the production of recombinant CpGVs expressing insecticidal toxins (e.g. the itch nute toxin) and /or lacking a functional egt gene. The CpGV genome sequence information in conjunction with the GV permissive cell lines will be used to identify genes involved in host range determination, infectivity, and speed of kill. A. orana GV (AoGV) is a slow killing GV, killing its host in the final instar. It is marketed for the control of summer fruit tortrix on apples and pears. Two baculoviruses, (a granulovirus and a NPV) were jointly isolated from diseased overwintering A. orana larvae collected in the UK in 1993. The biological activity of this AoGV has been assessed in different instars of A.orana. This virus has similar restriction endonuclease fragment profiles to the Japanese, Swiss and Italian isolates of AoGV. Genetic studies are being conducted on AoGV. The relatedness of slow and fast killing GV genomes will be compared both at a genomic and genetic level. Cell lines have been established from A.orana embryo's and the feasibility will be discussed of using these to look at gene function and for producing an improved recombinant AoGV. Finally the merits of using either a fast killing compared to a slow killing GV as a biological insecticide will be considered.

Index terms: Cydia pomonella, Adoxophyes orana, granulovirus, genetic manipulation

2027] THE SPATIAL AND TEMPORAL IMPACT OF ENDEMIC NATURAL ENEMIES ON THE MORTALITY OF CHRYSOMELID BEETLES IN EUCALYPT PLANTATIONS

G. R. Allen^{1, 2} & V. S. Patel², ¹ School of Agricultural Science, Univ. of Tasmania, GPO Box 252-54, Hobart, Tasmania, 7001 Australia, E-mail Geoff, Allen@utas.edu.au; ² CRC for Sustainable Production Forestry, GPO Box 252-12, Hobart, Tasmania, 7001 Australia.

The cucalyptus leaf beetle Chrysophtharta agricola has been identified as a major threat to plantations of Eucalyptus nitens in Tasmania. We set up a replicated natural enemy exclusion experiment, across 3 yr old plantations separated by at least 20 km, to examine the impact of natural enemies on the survival of C. agricola in the field. Beetle mortality was assessed at egg, larval and pupal stages using uncaged and 'entire' tree caged treatments. After assessment of egg mortality, six selected branches on all experimental trees were loaded with clutches of first instar beetle larvae (ca. 30 larvae per clutch). Overall mortality and spatial variability in mortality both within and between trees was regularly monitored until emergence of adult beetles. Pupal mortality was assessed using litter cages, dug prior to commencement of the experiment, under each tree. To identify the parasitoid complex and the host stages attacked clutches of 'sentinel' or trap larvae exposed for the duration of each instar were seeded on further treees within the plantation. At least three primary parasitoids (two tachinids and one bracoaid) and one hyperparasitoid were present in the parasitoid guild which showed temporal separation in their timing of attack. Overall mortality in uncaged treatments exceeded 99 % across all plantations and was spatially variable both within and between trees. Variability in uncaged treatment survival was greater within trees than between trees with spider predation having a large impact on intra-tree larval survival. Within a plantation average mortality of uncaged larvae was up to 10 fold greater than for controls with the majority of loss in control cages occurring within the first few days of larval establishment. Natural enemies were concluded to have a significant impact on populations of C. agricola. Since the majority of larval damage is done in the fourth or final larval instar, yet control decisions are made in earlier instars, beetle monitoring protocols that account for spatial variability and the temporal patterns of both natural enemy attack and parasitoid induced mertality may need to be devised. Landscape approaches to the management of leaf beetles and their natural enemies should also be considered. Index terms: Chrysophtharta agricola, parasitoids, tachinids, Chrysomelidae, forest insects

[2028] SETTING UP AN ENTOMOPATHOGENIC MICROORGANISMS COLLECTION AT THE CENTRO EXPERIMENTAL DO INSTITUTO BIOLOGICO/LABORATORIO DE CONTROLE BIOLOGICO, BRAZIL

J. E. M. Almeida², A. Batista Filho², A. G. Souza³, A. C. Fattori³, ² Lab. Controle Biológico, Centro Experimental do Inst. Biológico, P. O. Box 70, Campinas, SP, Brazil. 13001-970 e-mail: jemalmeida@uol.com.br.¹ Research financed by FAPESP.³ Student supported by CNPq.

Studies concerning entomopathogenic microorganisms emphasize the importance of isolate screening for research improvement. Isolates in the same microorganism species can possess different levels of virulence. So, their storage helps their manipulation for studies of pest control under laboratory and field conditions. We are setting up an entomopathogenic microorganism collection, including isolation and identification of these organisms, as well as by exchanging isolates with Universities and Reserch Institutes. The microorganisms were isolated from soils using the dodine method. Medium with dodine is selective for isolation of entomopathogenic and phytopathogenic fungi. Fungi found on dead insects were isolated by their inoculation on plates of potato-dextrose-agar medium. The isolates were stored in culture tubes with mineral oil or in eppendorfs. The soil samples were also processed by the L media method, which allows the isolation of bacteria of the genus Bacillus. Insects suspected being killed by bacteria had their viscera inoculated on plates of solid L medium. The bacteria have been stored in culture tubes with mineral oil. The viruses were isolated from insects by maceration of the host followed by centrifugation and then stored in sterile water. The collection has 205 isolates that have been stored on rice, culture tubes and eppendorf tubes. There are 197 fungal, 5 viral and 3 bacterial isolates. Thirty-five isolates were donated by other institutions.

Index terms: Collection, entomopathogenic, microorganisms, microbial control, biological control

[2029] VOLATILITY COMPARISONS OF DIFFERENT FORMULATIONS USED TO APPLY MYCOINSECTICIDES

R.T. Alves¹, R.P. Bateman², C. Prior³ & S.R. Leather⁴, ¹EMBRAPA/Centro de Pesquisa Agropecuária dos Cerrados (CPAC), Caixa Postal 08223, CEP 73301-970 Planaltina, DF, Brazil, E-Mail ralves@cpac.embrapa.br; ²CABI Bioscience, Silwood Park, Buckhurst Road, Ascot, Berks, SL5 7TA, UK; ³The Royal Horticultural Society, Wisley, Woking, Surrey, GU23 6QB, UK; ⁴Silwood Centre for Pest Management, Department of Biology, Imperial College, Silwood Park, Buckhurst Road, Ascot, Berks, SL5 7PY, UK.

The volatility of water-based formulations with different concentrations of emulsifiable adjuvant oils was evaluated and the volatilities of oil-based and conventional water-based formulations, used to apply mycoinsecticides, were compared with that of an emulsifiable adjuvant oil-based formulation. The formulations were applied onto filter papers and weighed at different time intervals. The evaporation of all formulations increased with time. The majority of all waterbased formulations and pure Shellsol evaporated during the first 30 minutes. The half lives of emulsifiable oil formulations were approximately 20 minutes. The mixture of 50 % Shellsol T plus 50 % Ondina EL satisfied the requirements of an ULV formulation. Emulsifiable adjuvant oil formulations retained approximately 10 % of the initial weight after evaporation. This is sufficient to allow an even spread and thereby enhances the fungal infectivity on insect pests. All these results demonstrate that emulsifiable adjuvant oil fungal formulations can perform similar to oil-based formulations. They can be sprayed with the existing delivery systems and used in large scale agriculture where currently water-based formulations are predominan

[2030] EVALUATION OF APPLICATION TECHNIQUES OF AN EMULSIFIABLE ADJUVANT OIL FUNGAL FORMULATION

R.T. Alves¹, R.P. Bateman², C. Prior³ & S.R. Leather⁴, ¹EMBRAPA/Centro de Pesquisa Agropecuária dos Cerrados (CPAC), Caixa Postal 08223, CEP 73301-970 Planaltina, DF, Brazil, E-Mail ralves@cpac.embrapa.br; ²CABI Bioscience, Silwood Park, Buckhurst Road, Ascot, Berks, SLS 7TA, UK; ³The Royal Horticultural Society, Wisley, Woking, Surrey, GU23 6QB, UK; ⁴Silwood Centre for Pest Management, Department of Biology, Imperial College, Silwood Park, Buckhurst Road, Ascot, Berks, SL5 7PY, UK,

The physical effects of water-based mixtures containing an emulsifiable adjuvant oil, with and without conidia of Metarhizium flavoviride were evaluated with a range of commercially available sprayers and nozzles. The influence of adjuvant concentration on viscosity, flow rate and droplet size spectra were measured together with conidial viability and conidial concentration after spraying. Flow rate was not affected when the concentration of emulsifiable oil was increased up to 10 %. Droplet size increased when the concentration of emulsifiable oil was increased for applications with a knapsack sprayer, but it decreased when applied with motorised mistblowers. Droplet uniformity (relative Span) increased when the concentration of emulsifiable oil was increased for most of the sprayers and nozzles. High droplet densities were obtained with some nozzles from the knapsack sprayer and from the two motorised mistblowers. None of the techniques applied affected the conidial viability. The problem of conidia sedimentation in tank mixtures was greatest with motorised mistblowers. The number of conidia sprayed was more affected by the sprayers when formulated in water plus 0.1 % Agral than in water plus 1 % Codacide⁹. These results should be helpful for researchers and farmers in order to select appropriate application equipment and to make the best use of emulsifiable adjuvant oils, while maintaining adequate spray coverage with reduced spray volumes to achieve high work rates.

Index terms: Metarhizium flavoviride, emulsifiable adjuvant oil, droplet size, sprayerst. Index terms: emulsifiable adjuvant oil, evaporation, fungal formulations.

[2031] HURRICANE FORCE STORM DAMAGE IN UK TEMPERATE WOODLAND BENEFITS INVASIVE LEAFHOPPER

J.S.Badmin, Coppice Place, Selling, Kent ME13 9RP, UK.E-mail jsb5@cant.ac.uk.

In the British Isles, the evergreen shrub Rhododendron ponticum has been widely planted in woodland habitats since its introduction in the mid-sixteenth century. It is highly invasive, spreading either by seed or vegetative expansion and is now fully naturalised throughout the British Isles. The Rhododendron leafhopper Graphocephala *fennahi*, which lays its eggs in the dodendron flower buds, was imported into Europe from North America in the middle of the last century. First recorded from England in 1936, it is now well established on naturalised rhododendrons throughout south-east England and has since spread through large parts of northern Europe. This study reports the effects on G.fennahi of the hurricane-force Storm which hit Perry Woods, Kent, south-east England in 1987. The woods suffered extensive damage: 67% of conifers were snapped or uprooted, c.50% of standard oaks and beech suffered major limb damage, and stands of chestnut coppice on less exposed ground suffered <5% loss. Large canopy lacunae allowed leafhoppers such as G.fennahi associated with rhododendron shrub, which was less severely damaged, to flourish. The most noticeable changes in leafhopper abundance occurred as a delayed response to changes in vegetational composition in large canopy gaps and areas cleared after the storm. The effects were more noticeable in large rather than small gaps. The open habitat surrounding rhododendron plants proved ideal for growth and flower bud initiation, with the result that more ovipositional sites became available for the leafhopper in succeeding years. Numbers of G.fennahi subsequently reached epidemic proportions in 1990 and 1991 with adults swarming and moving onto nearby vegetation. Subsequent population decline was due largely to destruction of oviposition sites by Rhododendron bud blast Pycnostysanus azalaea transmitted by the leafhopper and shading, caused by canopy closure, which reduced flower bud initiation.

Index terms: Graphocephala fennahi, invasive pest, canopy gaps

[2032] SYNERGISM OF ENTOMOPATHOGENS AND CHEMICAL INSECTICIDES: THEORY AND APPLICATION

W. L. Baiwa & M. T. AliNiazee, Department of Entomology and Integrated Plant Protection Center (IPPC)' Oregon State University, Corvallis, OR 97331-8530, USA.

Insects like other organisms, are more susceptible to diseases when they are under the influence of stress produced by crowding, malnutrition and environmental factors. Chemical insecticides at reduced/sublethal rates can act as stressors and make insects more susceptible to the action of microbial toxins, and can be additive or synergistic when combined with microorganisms. Healthy larvae of many species of insects can not be infected with entomopathogens unless they have been first treated with weak doses of insecticides. Potentiation has been documented for interactions using the Bacillus thuringiensis (Bt)/Beauveria bassiana (Bb) and several chemical insecticides against a number of insect pests on various crops. Laboratory and field tests have shown that the amount of chemical insecticide can be greatly reduced by integrating entomopathogens into spray program, without sacrifying crop. The effectiveness of Bt can be enhanced against several lepidopterous larvae by combination with chemical insecticides at low/sublethal rates. In many crops, reduced dosages [one-fifth (0.2X) to one-tenth (1.0X) of normal field rate (1X)] compared with standard rates of organophosphorous and pyrethroid insecticides enable sufficient survival of natural enemies. Low concentrations of several insecticides either do not affect bacterial growth or improved it. A general compatibility of δ -endotoxin with different chemical insecticides has also been established. This suggests that the target species can be controlled with reduced insecticide rates in combination with Bt without greatly affecting natural enemies. This would reduce the selection pressure and conserve the susceptible gene pool and can result in reduced or delayed insecticide resistance. Reduced dosage mixtures of Bt and chemical insecticides can also reduce the problem of pest resurgence, and would be highly compatible with IPM approach. This approach was tested in laboratory and field against codling moth (Cydia pomonella) for four consecutive years. The results showed that utilization of mixtures of Bt with low rates of insect growth regulator diflubenzuron (0.25-0.50X) or pyrethroids esfenvalerate and permethrin (0.1-0.2X) in the codling moth management is possible and indeed might be beneficial. Standard application rate (2 times/generation) and timing were found to be appropriate for Bt-pyrethroid mixtures. These mixtures were selective to most predatory insects, spiders, and Zetzellia mali, however, toxic to phytoseiid species causing outbreaks of many phytophagous mite species. Bt-diflubenzuron mixtures were suitable when applied 3 times/generation. These mixtures were environmentally safe and did not cause outbreaks of phytophagous mites. Index terms: Joint action, biopesticides, microbial insecticides, insect pathogens.

[2033] COMPARISON OF THE PATHOGENICITY OF THREE ISOLATES OF *METARHIZIUM* FOR WINGLESS GRASSHOPPER: EEFECT OF DOSE AND TEMPERATURE

L. Barrientos-Lozano¹ and R.J.Milner², ¹Instituto Tecnológico de Cd. Victoria. Blvd. Emilio Portes Gil No. 1301, Cd. Victoria, Tam. México 87018. ² CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia.

As part of a program to develop Metarhizium as a biopesticide for use against locusts and grasshoppers in Australia and Mexico, laboratory bioassays were undertaken to compare the pathogenicity of an Australian isolate (FI-985) of Metarhizium anisopliae var. acridum with two Mexican isolates (QF-001 and QF-002). All 3 isolates were derived from acridid locusts and have similar DNA fingerprints. However, the Mexican isolates have smaller more ovoid conidia than the Australian isolate and QF-001 grows faster at temperatures below 20°C and slower at temperatures above 30 °C than the other two isolates which have similar temperature responses. Adult wingless man the other two isotates which have a write inoculated individually on the mouthparts grasshoppers, *Phaulacridium vittatum*, were inoculated individually on the mouthparts with $0.2 \mu l$ of an oil formulation of conidia. The doses used were 10^3 , 10^4 , and 10^5 spores per insect and control insects were inoculated with the oil only. When applied as a biopesticide, it could be expected that the grasshoppers would receive a dose between 10^3 and 10^4 conidia. Insects were then incubated at each of 5 constant temperatures: 15, 20, 25, 30 and 35 °C for up to 17 days. All 3 isolates were pathogenic at the intermediate temperatures with the most effective being 30°C for all three isolates. At this temperature, two higher doses killed all insects after 5 or 6 days with all three isolates. At 20 and 25°C, mortality was high at the two higher doses but delayed. At 15 °C, FI-985 was the most effective causing 100% mortality at dose 1 after 17 days, the Mexican isolates killed 50% after 17 days at this temperature. FI-985 also performed well at 35 °C, causing 100% mortality at all doses after 8 days. At this temperature, cadavers were less likely to sporulate even thought they were incubated at high humidity at 25 °C. QF-001 was least effective at 35 °C, causing 100% mortality after 11 days at the highest dose. It is interesting that the two Mexican isolates which are morphologically and genetically indistinguishable and came from the same host, have different temperature responses. FI-985 was highly virulent over the entire temperature range suggesting that it might perform better under extreme weather conditions in the field. Recent field trials in Australia have confirmed that this isolate is very effective for control of Australian plague locust, Chortoicetes terminifera, during very hot weather.

Index terms: *Metarhizium*; biopesticide; locusts; grasshoppers; bioassay; pathogenicity; temperature

[2034] EXPERIMENTAL EVALUATION OF ADULT STAGE OF SPODOPTERA LITURA (LEPIDOPTERA : NOCTUIDAE) AS A POTENT HOST FOR ENTOMOPATHOGENIC NEMATODES, STEINERNEMA GLASERI

V. Baweia, Department of Zoology, University of Delhi, Delhi-110007, India

Entomopathogenic nematodes (EPN_a) have been shown to be virulent against soil insect pests and/or soil inhabiting stages of foliage insects, but it is slightly difficult in case of adult stage as the nematodes cannot survive in air for long. With the determination of managing the adult population of *Spodoptera litura*, a new method for alleuring the adults towards EPN, bait, was developed. The experiment was endeavoured in a cage (30x25x25 cm) under maintained laboratory conditions. Steinernema glaseri in various concentrations of honey (0% to 9%) was provided as food to the moths. Vitality of infective juveniles (IJs) of S. glaseri was ascertained in terms of number of undulations per minute subsequent to exposure to various concentrations of honey. It was noted to be significantly more (ca. 114 undulations/minute) at 0% and showed reducing trend towards high concentration (9%) of honey solution. Us could survive in all the tested honey solutions upto a period of four to five days till the liquid dried off. Adults were found to be susceptible to EPN, infection, they got parasitized and developed the characteristic ochre colour within three days. Susceptibility of female moths towards EPN, infection was assessed to be more in comparison to male moths. Per cent parasitization was observed to be maximum (ca. 100%) at 9% honey solution and it was significantly reduced (40%) at 0% honey solution. This might be primarily due to their preference to sugar rich food source. Various other parameters, which can manoeuver the suitability of adult stage of Spodoptera litura as an acceptable host for Steinernema glaseri are also discussed. Index terms: Entomophilic nematodes, EPN, bait, Biological control.

[2035] THE BENEFICIAL NEMATODE, HETERORHABDITIS MARELATUS : ITS PROMISE IN BIOCONTROL OF PESTS IN NURSERY AND FIELD CROPS

R. E. Berry¹, T.-H. Kim¹, J. Liu¹, P. W. Gothro¹, C. Armer¹ & <u>A. F. Moldenke¹</u>, ¹Dept. of Entomology, 2046 Cordley Hall, Oregon State Univ., Corvallis, OR 97330, USA. E-mail: alisonm@bcc.orst.edu.

The entomopathogenic nematode Heterorhabditis marelatus (Rhabditidae) was isolated from the coastal region of Oregon and successfully reproduces at lower temperatures than do many other nematodes used in biocontrol. It therefore holds promise for use in cooler climates where other beneficial nematodes are not effective. It also tolerates warm, dry conditions, increasing its versatility as a biocontrol agent. The nematode is an obligate internal parasite of insects. Infective juveniles invade the host through body openings or the cuticle and release symbiotic bacteria (*Photorhabdus luminescens*) that induce septicemia and kill the host. The nematodes then develop and reproduce in the host, usually passing two generations in the host before leaving as infective juveniles to begin the cycle again. We have found that H. marelatus effectively controls strawberry root weevil (Otiorhyncus ovatus) and black vine weevil (O. sulcatus) in strawberries and azaleas, mint root borer (Fumibotys fumalis) in peppermint, cranberry girdler (Chrysoteuchia topiaria) in cranberries, and Colorado potato beetle (Leptinotarsa decemlineata) in potatoes. It is somewhat effective against sciarid flies (Lycoriella spp.) in mushrooms. Although control is effective, poor rates of nematode reproduction in some of these hosts (e.g., Leptinotarsa) limits usefulness of II. marelatus as a self-sustaining biocontrol agent. Improving mass production techniques and investigating mechanisms underlying reproductive success or failure are among the ongoing projects of our group. Index terms: entomopathogenic nematodes, weevils, root borers, Colorado potato beetle, sciarid flies.

Symposium and Poster Session

[2036] TRANSMISSION OF *NUCLEOPOLYHEDROVIRUS* IN *BOMBYX MORI* L., 1758 (LEPIDOPTERA: BOMBYCIDAE)

R. M. C. Brancalhão¹, <u>L. F. A. Alves¹</u> & M. M. C. Carvalho¹, ¹UNIOESTE/CCBS, R. Universitária, 2069, Cascavel/PR, Brazil, CEP 85814-110, E-mail: elbranca@zaz.com.br.

In Brazil, sericulture is an important cottage industry, and contributes substantially to the rural economy. Paraná State contributes with 82% to the national production and employs nearby 8,000 farmer families. Silk production in Brazil, however, is low when compared with other countries. One significant problem in the sericulture production is the presence of silkworm diseases. Among these, the viral diseases occupy an important position. Prevention and control of these diseases are essential for good silk production. In a previous paper it was identified the occurrence of Nucleopolyhedrovirus-infected Bombyx mori in Paraná State. At present it was verified transmission of Nucleopolyhedrovirus in Bombyx mori (BmNPV). It was studied infected and healthy silkworm obtained from sericulture the industry. Purified BmNPV was sprayed on mulberry leaves in different concentrations (2,26 x 10⁶, 2,26 x 10⁵, 2,26 x 104), and sixty healthy fourth-instar larvae allowed to feed on treated leaves. The control larvae were fed with leaves sprayed with distillated water. The larvae were divided in four groups of fifteen organisms and maintained in a climate room until adult stage. Daily the insect were analyzed and at different stage of development some of them were prepared for observation at the optical microscope by the following techniques: larvae, pupa, adults and eggs were shacked in distillated water and afterwards it was filtrated with cotton plug, resulting the suspension. A smear of this suspension was stained with Azan adapted and viewed under optical microscope. We also prepared a smear of meconium and stained by the same technique. Occlusion bodies of BmNPV were observed in the slades prepared from larvae, pupa and meconium. Slades from adults and eggs not showed any sight of infection by BmNPV. Our observation showed an important mechanism of defense in B. mori where great quantity of BmNPV are eliminated in association with meconium. Meconium stored waste products of pupal metabolism, and the histolysis of the larval infected tissue ensure the presence of BmNPV in this structure. However, it is impossible to affirm that the BmNPV is not transmitted to the next generations because latent virus may be present and not demonstrable by this technique.

Index terms: Bombyx mori, Nucleopolyhedrovirus, meconium, development

[2037] DISPERSAL CAPABILITIES OF THE WHITEFLY PARASITOID, *EKETMOCERUS EREMICUS*

D. N. Byrne & D. E. Bellamy.

Dept. of Entomology, Univ. of Arizona, Tucson, AZ 85721, USA, E-mail byrne@ag.arizona.edu.

Short range dispersal (< 100 m) by insects is important biologically because it can provide the means to leave unsuitable habitats in search of more favorable situations. It is important agronomically because failure to take into account events such as movement by resistant individuals, vectors and natural enemies can lead to problems designing integrated pest management (IPM) programs. We are interested in movement by *Eretmocerus eremicus* Rose & Zolnerowich, a parasitoid of the sweet potato whitelly, *Bemisia tabaci*. This aphelinid has shown enough promise as a biological control agent that it has been incorporated into a large number of IPM programs backed by the public and private sectors. A better understanding of dispersal by *E. eremicus* will assist in designing release systems for this and other parasitoids. We have already learned that unmated female *E. eremicus* fly for significantly longer periods than male counterparts (10 versus 1 min). Using laboratory data, we have constructed models that predict that most males in cantalouge fields will be travel approximately 4.2 m from a release site for every 1 min of flight.

This model was verified in 1999 field experiments ($r^2 = 0.998$). Additionally, the

average rate of dispersal for males is 90.4 m² in a 4-h sampling period. Redesigned field experiments will allow us to generate the same models for female movement. Given differences in flight duration, females will likely disperse greater distances. We are also examining a portion of parasitoid fitness in the laboratory and field by measuring rates of parasitism following dispersal. Models describing female flight will be evaluated using field-generated data. These will help improve our ability to effectively deploy *Eretinocerus* spp. As well as serve as a basis for other natural enemy release programs.

Index terms: Aleyrodidae, Aphelinidae, Bemisia tabaci, migration

[2038] CHARACTERIZATION OF A *BACILLUS THURINGIENSIS* STRAIN TOXIC AGAINST LEPIDOPTERANS AND COLEOPTERANS

C. Berón, & G. L. Salerno, FIBA. Vieytes 3103. 7600 Mar del Plata. Argentina. Email: Errot Indicador não definido..

Bacillus thuringiensis is a spore-forming bacterium producing upon sporulation a parasporal crystal toxic to some invertebrates, mostly insects and nematodes. The parasporal inclusion body or 8-endotoxin, varying in quantity and type depending of the strain. The search for novel strains is important because new isolates more pathogenic than those commercialy available can be obtained, expanding the insecticide spectrum against resistant insects. In a project oriented to search for novel native strains in Argentina, the FBt 7 isolate was obtained from soil samples collected in the province of Córdoba. Phase contrast microscopy (1,000X) and scanning (15,000X) and transmission (25,000X) electron microscopy revealed the presence of a rounded inclusion which is morphologically different from the typical crystals found in kurstaki, tenebrionis and israelensis serovars. The crystals were purified by sucrose gradients (55-82 % w/v) and the apparent molecular masses of the toxin polypeptides were determined by SDS-PAGE. The electrophoretic pattern showed the presence of two major polypeptide bands at 80 and 130 KDa. The toxicological characterization of the toxin was performed using spore-crystal complex against larvae of two lepidopteran (Anticarsia gemmatallis and Spodoptera frugiperda), two coleopteran (Diabrotica speciosa and Tenebrio mollitor) and one diptera species (Aedes agypti). Mortality was observed in a preliminary assay against lepidopteran and coleopteran species. Molecular characterization by the PCR methodology support these results. Index terms: Bacillus thuringiensis, δ-endotoxin, Anticarsia gemmatallis, Spodoptera frugiperda, Diabrotica speciosa, Tenebrio mollitor

[2039] LARVAE OF *DILOBODERUS ABDERUS* (COLEPTERA, SCARABAEIDAE) PARASITED BY NEMATODES, IN ARGENTINA

N. B. Camino¹ & <u>L. C. de Villalobos²</u>, ¹ Centro de Estudios Parasitológicos y de Vectores, CEPAVE, 2 N°584, 1900 La Plata, Argentina. E-mail cepave@museo.fcnym.unlo.edu.ar; ² Facultad de Ciencias Naturales y museo, Paseo del Bosque s/n, 1900 La Plata, Argentina. E-mail villalo@infovia.com.ar

After two years of systematic studies made weekly on insecta plague of alfalfa in the Province of Buenos Aires, Argentina, a new species of nematodes (Thelastomatidae) of the genus *Leidynema*, was found in scarabeid larvae. The larvae of the scarabeid *Diloboderus abderus* (n=62), were collected manually in holes of 10 cm per 10 cm made with shovel in the area of cultivation and pericultivation. They were packed in plastic containers with soil of the place they were collected. In the laboratory, the larvae were dissected as they died (n=40). Nematodes were found in the middle intestine (n=50-80 in each larvae). These nematodes were isolated to study their reproduction. Experimental infections were made on the same host. The damage observed in the larvae, clearly evidences that this nematode species is responsible for the death of the host, when considerable in number (n>50), as they form dense packs causing intestinal obstruction and alterations in digestion that would impact in the metabolism, leading to death.

Index terms: Diloboderus abderus, nematodes, Leidynema sp., biocontrol.

Symposium and Poster Session

[2040] ANTICARSIA GEMMATALIS NUCLEOPOLYHEDROVIRUS INFECTIVITY IN SEVEN INSECT CELL LINES

M. E. B. Castro¹, Z. M. de A. Ribeiro¹, A. R. de M. Pontes & M. L. de Souza¹, ¹Embrapa Recursos Genéticos e Biotecnologia, P. O. Box 02372, Brasília, DF 70.849-970, Brazil. E-mail: elita@cenargen.embrapa.br.

The Anticarsia gemmatalis Nucleopolyhedrovirus (AgMNPV) has been applied, in Brazil, as a biopesticide to control the velvetbean caterpillar (Anticarsia gemmatalis). Although it is known that the virus is very specific to its natural host, cell culture has been required to select productive systems and to improve studies on gene regulation. The infectivity of Anticarsia gemmatalis Nucleopolyhedrovirus to different lepidopteran cell lines was investigated. The cytopathic effects induced by the virus and the production of viral particles were examined and compared in the following cell lines: Anticarsia gemmatalis (UFL-AG-286), Trichoplusia ni (TnSB1-4 and Tn368), Spodoptera frugiperda (IPLB-SF-21AE and SF9), Lymantria dispar (Ld652Y) and Bombyx mori (BM-5). Cells were propagated in TNM-FH medium supplemented with fetal bovine serum. They were seeded at 2,5x10° in 60mm² plates, inoculated with virus at a multiplicity of infection (MOI) of 10 pfu per cell and incubated at 27°C. At several times post infection (0, 12, 24, 48, 72 e 96 h p.i.) they were examined by phase-contrast microscopy. In general, cellular rounding and nuclear hypertrophy were shown already at 12 h p.i. Some cellular protusions were detected at 24 h p.i. and then disappeared at 72-96 h p.i. Polyhedral inclusion bodies (PIBs) were then observed by 48h p.i. and increased during the subsequent periods of the infection. However polyhedra were not visualized in Ld652Y and BM-5 infected cells. In addition BM-5 cells underwent extensive lysis after incubation with AgMNPV, being 70 % of them ulready lysed at 96 h p.i. Analysis by optical microscopy, at 96 h p.i., showed that the number of cells producing polyhedra reached 95% to 100 % in both Tn5B1-4 and UFL-AG-286 cells. It also reached 70%, 40% and 25% in SF21, Tn368 and SF9 cells, respectively. In parallel, measurement of viral titers (budded virus) by endpoint dilution method showed that Tn5B1-4, UFL-AG-286 and SF21 cells were highly productive. Their TCID₅₀ values, at 48 h p.i., were about 10

[2041] THE EXPERIMENTAL TRIALS WITH THE VIRAL PRODUCT "Inf-He" FOR DENSITY CONTROL OF PEST POPULATIONS OF HYPHANTRIA CUNEA

<u>M. Ciuhrii¹</u>, M. Iamandei¹, T. Manole¹, ¹Dept. of Entomology, Research Institute for Plant Protection-Bucharest, Bvd. Ion Ionescu de la Brad, 8, sector 1, 71592, Bucharest, Romania, Fax.: 004-01-231.33.61;Tel.: 004-01-222.30,36; E-mail: icpp@com.penet.ro; insectfarm@penet.ro; delta@canad.ro.

Hyphantria cunea (Lepidoptera: Arctiidae) is known like a pest species which attack more then 300 species of trees and shrubs. The fall webworm, H. cunea is native to North America and is a major pest of trees in Europe and Asia. In Asia the pest is spread by two directions. One of this has reach peninsula Korea to China and South India. The second one tends to reach the Volga River and the south of Caspic Sea. The pest insect could be a real danger if his spreading in the Middle Asian territory is accomplished. This species could be an important feeding competitor of *Bombyx mori* (the common silkworm). This fact could mean the failure of the silk industry based on the silkworm rearing. In this situation the only control method that could be applied is the use of viral products based on granulosis virus, which had a selective, specific action, focuses on the fall webworm target. Over a period of 20 year we had dedicated to the research for obtaining of a viral product able to stop his migration in the Middle Asia and to be a proper method of control of the pest. In Romania the fall webworm has been introduced in 1952 and since then every year the webworm feeds on a wide variety of deciduous trees and shrubs, often resulting in complete defoliation. The species usually cats leaves late in the season and the real damage is done to the mulberry, nut and maple plantations. Attacking the trees from the inside of the cities areas the pest is producing of discomfort by inhalation of the pilosity of caterpillars. The viral product "Inf-Hc" is described by the follows characteristics: Formulation nowder

[2042] LESSONS LEARNED DURING THE DESIGN OF AN ARTHROPOD AND PATHOGEN QUARANTINE FACILITY

R. De Clerck-Floate¹, P. Plue² & T. Lee³, ¹Agriculture and Agri-Food Canada, Lethbridge Research Centre, P.O. Box 3000, Lethbridge, Alberta, Canada, T1J 4B1, ²Agriculture and Agri-Food Canada, 930 Carling Ave., Ottawa, Ontario, Canada, KIA 0C5, ³Public Works and Government Services Canada, 1000 Canada Place, 9700 Jasper Ave., Edmonton, Alberta, Canada, T5J 4E2

The Lethbridge Research Centre of Agriculture and Agri-Food Canada has completed design for a 883 square metre (9500 square foot) quarantine facility for the containment of biocontrol arthropods and, insect and plant pathogens. During the design phase of the project, several quarantine facilities in the United States were toured and information was gathered from people involved with quarantine design and maintenance in North America and abroad. From these tours and interviews and, our own challenges in design, we have developed a list of architectural and mechanical engineering solutions to meet user and regulatory requirements and budget constraints on such a project. These include: 1) Using a clustered, modular design for small insectrearing rooms. The rooms have special ventilation to address wide temperature range capabilities, elevated relative humidity and, potential allergy problems related to the rearing of insects. 2) Lowered ceilings in insect rearing rooms and imported shipment room to give better control of escaped insects and ease in cleaning. 3) Establishment of quarantine barrier at the ceiling, above which is located all mechanical equipment in a large non-quarantine interstitial space. 4) Natural light in many areas within quarantine to enhance work with insects (e.g., for mating and rearing requirements, insect trapping, improved viewing of insects during identification and sorting). 5) Mechanical and ventilation separation of the arthropod from pathogen areas of quarantine. The pathogen suite has its own entrance with shower, controlled pressure differentials, separately-treated waste water, and HEPA filtered exhaust air. 6) Flexible, economical waste management system. This includes triple-tank septic and batch chlorine systems for treatment of liquid wastes from arthropod and pathogen parts of quarantine, respectively, and pass-through autoclave and hot-box for treatment of solid materials. 7) Individual fan coil units for cooling greenhouse compartments versus the use of dedicated air handlets.

Index terms: containment, engineering solutions, insect-rearing, mechanical systems

[2043] EFFECT OF BACILLUS THURINGIENSIS, SUBSP. AIZAWAI FOR THE CONTROL OF PLUTELLA XYLOSTELLA ON CAULIFLOWER, BRASSICA OLERACEA

S.A.M.P. Coelho¹, **M.H. Calafiori¹ & C.L. Da Silva²**, ¹Agronomic Engineering Course. CREUPI. Postal Box 05. 13990-000 - Espírito Santo do Pinhal – SP – Brazil. E-mail: cpagrpin@rantac.com.br. ²Hokko do Brasil. E-mail: issamu@hokko.com.br

Diamond back moth is an important pest of the Cruciferae, where it destroys leaves. Insecticides residues is a problem in those cultures. Thus, the use of biological control is recommendable. This experiment was carried out in Jarinu county - SP, with cauliflower, variety Chinomaru II, in October, 1999. The experimental design was complete randomized block with 4 replications in field conditions. The treatments were: 1- control; 2- Bacillus thuringiensis subsp. aizawai (Xentari - 50 g/100 \Box); 3- Bacillus thuringiensis subsp. aizawai (Xentari - 60 g/100 \Box); 4- Bacillus thuringiensis subsp. aizawai (Xentari - 80 g/100 \Box); 5- Bacillus thuringiensis subsp. Austaki (Dipel - 100 nl/100 \Box); 6- clorfluzuron (Atabron 50 CE - 75 ml/100 \Box); 7- lufenuron (Match - 80 ml/100 \Box). There was an application of imidacloptid in all treatments for the control of aphids. Plots were shaped by 10 plants. The products were applied 4 times, weekly. Evaluations were done during the harvest time. Larvae and pupae were observed in 6 plants/plot and number of holes was counted in 12 leaves/plot. The results allowed to conclude that all products controled *P. xylostella* with efficiency above 83% and there wasn't occurrence of phytotoxicity. Index terms: pathogen, insecticide, diamond back moth.

[2044] THE SPECIFICITY OF *BEAUVERIA BASSIANA* FOR THE CONTROL OF MITE PESTS OF PAPAYA

K. F. S. Collier, J. O. G. de Lima, M. C. Araújo & <u>R. I. Sanuels</u>, Department of Plant Protection, Universidade Estadual do Norte Fluminense, Campos dos Goitacazes, RJ 28015-620, Brazil, E-mail richard@uenf.br.

Phytophagous mites are responsible for huge losses in agricultural production worldwide and are capable of rapidly developing resistance to conventional pesticides. Alternative approaches to control are therefore urgently required. Natural pathogens of certain phytophagous mite species have been investigated and at least one microbial acaricide (Mycar® based on Hirsutella thompsonii) has been produced for the control of the citrus rust mite. However, this product was a commercial failure probably due to limited shelf-life. The possibility of using fungi which are not natural pathogens of phytophagous mites, has to date not been well investigated. Two such candidate species are Metarhizium anisopliae and Beauveria bassiana, which are currently being used in various insect biological control programs and are more resistant to environmental conditions than some of the natural mite pathogens. In this preliminary study we tested one isolate of Beauveria bassiana (CG 24; natural host Hemiptera: Pentatomidae) against two important mite pests of papaya, Tetranychus urticae (Acari: Tetranychidae) and Polyphagotarsonemus latus (Acari: Tarsonemidae). We also investigated the specificity of this pathogen against one species of predatory mite, Neoseiulus idaeus (Acari: Phytoseiidae), which has been shown to be important in the natural suppression of phytophagous mites. Conidial suspensions in water $(5.75 \times 10^6 \text{ conidia} \text{ ml}^{-1} \& 5.75 \times 10^8 \text{ conidia} \text{ ml}^{-1})$ were applied to papaya leaf discs. Female mites were then transferred to the then dry leaf discs, which were maintained at 25°C and ~70% RH. Mites were transferred to fresh leaf discs after 24 hours. Mortality was observed on a daily basis. For *T. urticae*, the values for TL_{50} were 6.27 days (5.75 x 10^{6} conidia ml⁻¹) and 4.13 days (5.75 x 10^{8} conidia ml⁻¹). TL_{50} for control treatments was 12.08 days. B. bassiana CG 24 was not found to be pathogenic to either P. latus or N. idaeus at the highest concentration of inoculum used here. The results show that isolates of B. bassiana should be considered as potential agents for the control of mites and can be specific, without causing mortality of beneficial predatory mites. We are currently testing a range of *B. bassiana* and *M. anisopliae* isolates for pathogenicity against both species of phytophagous mites and the predatory mite.

Index terms: Tetranychus urticae, Polyphagotarsonemus latus, Neoseiulus idaeus, entomopathogenic fungi, microbial control.

[2045] A NEW FUNGAL ISOLATE FOR THE CONTROL OF DIABROTICA SPECIOSA

V. F.Consolo.¹; G. Cabrera.²; G. L. Salerno.¹ & <u>C. Berón¹</u>, 1.-FIBA. Vieytes 3103. 7600. Mar del Plata. Argentina. E-mail: fibamdq@infovia.com.ar. 2.-SABCL-USDA. Bolívar 1559. 1686. Hurlingham. Argentina.

Many species of cucumber beetles ocurr in South America. Particularly, in Argentina the most important coleoptera pest is Diabrotica speciosa an important cucumber pest. Both larvae and adults cause serious damage in all plant organs (flowers, roots and tubers). Entomopathogenic fungi are key regulatory factors in insect populations and also are the pathogens of choice for Coleoptera. Thus the use of biological agents will be an alternative in the control of cucumber pest. The goal of this project was the search of new strains with potential toxicity for the control of D. speciosa. Sixteen fungal isolates were obtained from soil samples and dead insects (Maecolaspis bridarolii larvae and D. speciosa adults). In a screening assay the isolate FHD13, identified as Beauveria bassiana, caused 70% of mortality in the third instar of D. speciosa. The CL_{50} value calculated using six different concentrations was 3.5×10^{10} conidia/ml. Then, FHD 13 was selected for preparing biological formulations in different oils. The conidial viability in the formulates was estimated at different temperatures (4, 17 and 26°C) and periods of storage. The best formulate condition (99.5% viability) resulted in the preparation with corn oil stored at 4° C during 28 days. It was evaluated in preliminary assay the pathogenicity of conidial formulation in the third instar of D. speciosa reaching 65% of mortality. In addition protease activities were measured in the culture media of the isolates in the presence and absence of D. speciosa cuticles. Enzyme activity was several times higher in the presence than in the absence of cuticles in all the cases. However, it could not be stablished a correlation between proteolitic activity and mortality. The isolate FHD 13 may be a good candidate to be tested as bioinsecticide in large scale.

Index terms: Diabrotica speciosa, entomopathogenic fungi, Beauveria bassiana.

[2046] INFECTION OF *DIATRAEA SACCHARALIS* (LEP.; PYRALIDAE) WITH THE MICROSOPORIDIA *NOSEMA SP*

H. Conte¹, A.A. Zacaro², Cruz-Landim, C.², ¹Dept. de Biol. Celular e Genética, Univ. Est. de Maringá (UEM), Av. Colombo n. 5790, CEP 87020-900- Maringá/PR, Brasil. E-mail: licon@wnet.com.br.Brasil, ²Dept. de Biologia, Inst. Biociências, Cx. P. n. 199, Univ. Est. Paulista, UNESP, Rio Claro/SP, Brasil, CEP 13506-900.

In insects, microsporidia are the most important parasites and cause serious diseases in beneficial and pest insects. Ingestion is most common route through which microsporidia reach host tissues, but in certain lepidopteran hosts, they can reach tissues and/or haemocoele by the process of the wasp's oviposition. Specimens of D. saccharalis were reared using artificial diet and 4h instar larvae was submitted to oviposition by the braconid Cotesia flavipes (Hym.; Braconidae). After eight days, larvae parasitized were dissected and the tissues isolated, fixed, processed and analysed using transmission electron microscopy. In D. saccharalis larvae, visceral fat body is the tissue most frequently infected by microsporidia. In the initial phase of infection it was observed that adipocytes show endoplasmic reticulum around these intracellular parasites; it was also observed an increase in the number of mitochondria but in the latter phase, there is a reduction of endoplasmic reticulum contrasted with an increased vacuolization process in the cytoplasm; the ribosomes are depleted, mitochondria decrease in size and many electrondense oval and elongate structures were identified as spores of *Nosema* sp. The two tipes of spores may represent variation and need molecular biology for confirm identity of taxa. Each spore is formed by three concentric layers (an outer proteinaceous exospore, a middle chitinous endospore and an inner plasma membrane) arround a very condensed cytoplasm .We observe depletion of lipids and protein reserves resulting in fat body degeneration and may be associated with microsporidial infection. There is evidence that the destruction of fat body tissue would reduce the production of juvenile hormone, thus resulting in abnormal larval development. It was observed a reduction in the population size of adults of *C. flavipes* when its host was infected by this protozoan. In other hand, if hymenopteran parasitoids may be susceptible to the microsporidia of their lepidopteran hosts, probably this same mechanism would be affecting the decreased production in our laboratory strains of C. flavipes. It must be considered that this hymenopteran may play a major role in wide spreading microsporidia transmission mainly in laboratory conditions although the excact mode (transovarial and/or transovum) need more investigations. In this dual parasitism, both parasitoids and microsporidia compete for the lepidopteran host nutrients. Index terms: parasitism, sporozoa, lepidoptera, adipocytes.

[2047] THE SPECIFICITY OF METARHIZIUM ANISOPLIAE AND BEAUVERIA BASSIANA IN THE INFECTION OF EGGS OF THE BRAZILIAN CHINCH BUG, BLISSUS ANTILLUS

D.L.A. Coracini & R. L Samuels, Department of Plant Protection, Universidade Estadual do Norte Fluminense, Campos dos Goitacazes, RJ 28015-620, Brazil, E-mail richard@uenf.br.

An important advantage of entomopathogenic fungi in biological control, when compared with bacteria and viruses, is that fungi are capable of infecting all stages of the insects life cycle, including the egg phase. However, very few studies have been carried out on the control of pests by infection of eggs. In this study, candidate fungal isolates chosen for the control of the adult and nymph stages of pasture pest, Blissus antillus, were screened for pathogenicity against eggs. Blissus eggs were exposed to isolates of Metarhizium anisopliae and Beauveria bassiana by immersion in spore suspensions or by precision spray application using a Potter tower. The results were somewhat unexpected. All of the *Metarhizium* isolates tested were pathogenic and highly virulent, whereas most of the Beauveria isolates caused relatively low infection rates. A standard concentration of fungal inoculum (5 x 106 spores ml-1) caused 100% infection when eggs were immersed in suspensions of Metarhizium isolates for 10 min. or subjected to spraying at the same concentration. At this concentration Beauveria caused a maximum of 43% infection (isolate CG11) and a minimum of 2% infection (CG04). When the concentration was reduced to 1 x 10⁴ spores ml⁻⁴, the infection rate remained above 90% for all Metarhizium isolates. At this concentration, Beauveria treated eggs hatched normally. In order to investigate the difference in the process of infection of Metarhizium and Beauveria, the adhesion and germination of spores on the egg surface were examined using fluorescence microscopy. Calcofluor M2R (Sigma) was used to stain fungal structures at periods of 24 and 48 hours following exposure of eggs to fungal isolates. Major differences were observed between Metarhizium and Beauveria. Firstly, the number of spores on the egg surface was higher for Metarhizium. Secondly, germ tube development showed marked differences. In Metarhizium infected eggs, the germ tubes were short and rapidly formed appressoria, however, in Beauveria, the germ tubes were observed to be thin and elongated, without appressoria. These results indicate that the specificity of the two species is determined by differences in adhesion and penetration. Index terms: entomopathogenic fungi, biological control, specificity.

[2048] HOST-HANDLING BEHAVIORS OF BLACK SCALE PARASITOIDS: A CASE FOR ANT MEDIATED EVOLUTION

K. M. Duane & M. S. Barzman. Div. Insect Biology, Univ. of California, Berkeley, CA 94706, USA, daane@uckac.edu.

Oviposition behaviours play an important role in the effectiveness of insect parasitoids. Oviposition decisions are influenced by external (e.g. host abundance) and internal (e.g. parasitoid egg load) factors. Nevertheless, there has been little attention given to one external factor: predation or interference of adult parasitoids during oviposition. We suspect that differences among closely related black scale, Saissetia oleae, parasitoids (Metaphycus hageni Metaphycus anneckei, Metaphycus lounsburyi) resulted from disparate evolutionary pressure driven, in part, to reduce to host-handling times. M. anneckei oviposits through the scale's ventral integument. In contrast, M. hageni and M. lounsburyi oviposit through the harder dorsal integument. These differences resulted in different host-handling times, with host acceptance/rejection times significantly less for *M. anneckei* than for either *M. hageni* or *M. lounsburyi*. Similarly, host feeding, which required more time than oviposition, was absent in *M.* anneckei but present in *M. hageni* and *M. lounsburyi*. In laboratory studies, the faster host handling time of M. anneckei resulted in greater reproductive success in the presence of scale-tending Argentina ants, Linepithema humile. M. anneckei remained foraged significantly longer than M. hageni (when ants were present) and completed oviposition in every trial, while *M. hageni* never successfully oviposited. In a field test, scale-infested oleander plants were divided into ant-tended and ant-excluded treatments and placed near a stand of coyote brush, Baccharis pilularis, which was a source of parasitoids. Results over a 6 month period show significantly more S. oleae and lower percentage parasitism in the ant-tended than ant-excluded treatment. More interesting was the influence of ant-tending on parasitoid species relative abundance. Primary parasitoids reared from S. olene collected on coyote brush consisted of: Metaphycus helvolus, M. lounsburyi, M. anneckei, M. hageni, Coccophagus lycimnia, *C. scutellaris, C. ochraceus,* and the egg predator/parasitoid *Scutellista caerulea*. However, that these parasitoid species did not distribute evenly between the ant-tended and ant-excluded treatments. The relative proportion of *M. helvolus* and *M. barletti*, which have relatively slow host-handling times, was significantly higher in the ant-excluded treatment, while the faster ovipositing *M. anneckei* was significantly more common in the ant-tended treatment. Similar observation were made with the relative abundance of Coccophagus species. This work suggests that ant-tending may place selective pressure towards parasitoids with faster host-handling time and no host feeding requirements. With these data, we can imagine a scenario in which greater evolutionary pressure was placed on *M. anneckei* to develop faster host-handling times to improve reproductive success in regions with scale-tending ants. Index terms: Metaphycus, Coccophagus, Saissetia oleae, ant-tending, oviposition

[2049] BT COTTON: RELATIONSHIP BETWEEN BIOEFFICACY, GENE EXPRESSION AND PROTEIN

J. Daly¹, J. Finnegan², K. Olsen¹ & H. Holt¹, CSIRO Entomology, GPO Box 1700, Canberra, ACT, Australia, 2601, E-mail: J.Daly@ento.csiro.au.

Genetically engineered cotton plants expressing insecticidal proteins from *Bacillus thuringiensis* (Bt) were developed using constitutive promoters so that efficacy could be maintained throughout plant development. The initial pest management and resistance management strategies devised for Bt cotton were built around this model. The major targets of these Bt cottons are lepidopteran pests, including the Old World species, *Helicoverpa armigera* and *H. purctigera*. In Australia, commercial cultivars of cotton express the Cry1Ac protein from Bt. Mortality of the two species of *Helicoverpa* on Bt cotton declines during the season from near 100% before the plants start to square to below 40% when mature bolls are present. There are many possible causes for the decline. We have observed the relationship between the mRNA levels in leaves, the amount of Bt protein present and the bioefficacy of the leaves. Over the season increased survival of larvae on leaves is associated with a decline in Bt protein present. Down regulation of the Bt gene is likely as greatly reduced levels of mRNA from the Bt gene are present in older plants. The relationship, however, is not always evident and other factors must play a role in influencing bioefficacy of Bt cotton.

Index: Helicoverpa armigera, Bacillus thuringiensis

[2050] REMARKABLE PHYSIOLOGICAL VARIATION AMONG ISOLATES OF THE MITE PATHOGENIC FUNGUS *NEOZYGITES FLORIDANA*: NUTRITIONAL REQUIREMENTS AND CRYOPRESERVATION

I. Delalibera Jr.^{1,2}, A. E. Hajek¹, R. A. Humber³, ¹Dept. of Entomology, Cornell University, Ithaca NY 14853, USA, ²Fellow from CNPq-Brazil E-mail id24@cornell.edu; ³USDA/ARS US Plant, Soil & Nutrition Laboratory, Ithaca NY 14853, USA.

Neozygites floridana is a fungal pathogen that is currently being released in Africa for the control of the introduced cassava green mite (CGM). The inability to produce N. floridana in vitro is one factor that has hindered molecular studies to detect establishment of introduced isolates in regions where native ineffective isolates already exists. This study reports culture media and cryoprotection treatments for isolates specific to CGM. A CGM specific isolate (CNPMF 8) was compared to two other isolates with wider host ranges (ARSEF 662 and ARSEF 5376) with respect to growth in different culture media and potential for cryopreservation. The CGM isolate is more fastidious than the two other isolates and only grows in a limited number of media. IPL-41 insect cell culture medium supplemented with 5% fetal bovine serum (FBS), 0.3% lactalbumin hydrolyzate and 0.3% yeastolate afforded good growth across all isolates (> 10^7 hyphal bodies/m). FBS, the most expensive ingredient in this media, can be replaced by lipid concentrate and plurionic F-68. Cultures of ARSEF 662 and ARSEF 5376 can be cryopreserved using 5% glycerol or 7% polydextrose with standard procedures for ultra-low temperature cooling (decreasing at a rate of $1^{\circ}C/min$ to $-30^{\circ}C$ followed by rapid uncontrolled cooling to $-80^{\circ}C$ or $-196^{\circ}C$). Standard procedures are not effective for the CGM isolates and best results were obtained using rapid, uncontrolled cooling.

Index terms: Zygomycetes, Entomophthorales, culture media, Mononychellus tanajoa, cassava green mite

[2051] DESIGNING PROTEINASE INHIBITORS FOR THE CONTROL OF *HELICOVERPA* SPECIES

<u>K.M. Dunse</u>¹, M. Korsinczky², D.J. Craik² & M.A. Anderson¹, ¹Dept. of Biochemistry, La Trobe Uni, Bundoora Australia 3083, E-mail: kdunse@bioserve.latrobe.edu.au; ²Centre for Drug Design and Development, Uni. of Queensland, Brisbane Australia 4072.

Floral tissues and wounded leaves of the ornamental tobacco, Nicotiana alata, produce copious amounts of small (6kD) serine proteinase inhibitors (NaPIs) which inactivate the major digestive enzymes in several insect pests. These inhibitors are derived from a precursor protein which contains six contiguous PIs that are cleaved into two chymotrypsin inhibitors (C1+C2) and four trypsin inhibitors (T1-T4). We are investigating the effect of these inhibitors on the growth and development of H. punctigera and H. armigera larvae and their effect on chymotrypsin and trypsin enzymes in the gut. Most gut chymotrypsin and trypsin activity is inhibited by the NaPIs, but some activity is NaPI resistant. PI resistant enzymes are being isolated and characterised and are the target for the design of new inhibitors. New potent proteinase inhibitors will be selected using phage display. One of the chymotrypsins has been expressed as a fusion protein with the gene III protein of the filamentous phage M13. A library of chymotrypsin variants is being produced to select for PIs that have enhanced activity against proteases resistant to the current range of PIs. Four major families of chymotrypsins have been cloned. Using the sequence predicted from one of these clones, we have prepared a model of NaPI in complex with Helicoverpa chymotrypsin.

Index terms: Helicoverpa, phage display, Nicotiana alata, proteinase inbibito.

Symposium and Poster Session

[2052] STUDIES ON ENTOMOPATHOGENIC FUNGI AGAINST WHITE GRUB HOLOTRICHIA SERRATA (COLEOPTERA : SCARABAEIDAE) IN SUGARCANE

S. Easwaramoorthy, J. Srikanth, G. Santhalakshmi, N. Geetha, Sugarcane Breeding Institute, Coimbatore 641007, India.

Laboratory and field studies were conducted with three muscardine fungi, namely Beauveria bassiana, Beauveria brongniartii and Metarrhizium anisopliae against the white grub Holotrichia serrata (Coleoptera : Scarabaeidae) in sugarcane. The three fungi were cultured on molasses, a by-product of sugar industry, at 1.5-4.5% vis-à-vis standard media. Radial growth (cm) in culture plates at the lowest concentration of molasses was on par with that on standard media for all three fungi which did not differ between them. Biomass production (g) varied positively with concentration of molasses and at higher concentration it was on par with that on standard media; there were no differences between the three fungi. Spore production liter' of media did not vary between concentrations of molasses and standard media but it was the lowest for M. anisopliae. In the laboratory, eggs placed in plastic boxes (9 cm h x 7.5 cm d) containing soil (218.7 ± 16.5 g) treated with B. brongniartii at 5 x 10⁶ - 10⁹ spores / box suffered infection and mortality rates similar to that in control; in a second experiment with M. anisopliae, eggs dipped in a suspension of $10^4 - 10^9$ spores / ml Experiment with *an instruction*, eggs impress in a suspension of 10 - 10 spites 7 in showed higher rates of infection and mortality. In similar laboratory experiments with grubs, the three fungi at dosages of $10^4 \cdot 10^9$ spores 7 box produced higher levels of mortality in third instar (6.7-93.3%) than in second instar (20.0-60.0%); *M. anisopliae* produced the lowest levels in both instars. In other studies, *B. brongniartii* at $10^9 \cdot 10^{10}$ spores / box produced 64.0 - 72.0% mortality in the two instars. In a pot culture experiment with *B. brongniartii* at a dosage equivalent of 10^{13} - 10^{16} spores / ha, first instar grubs showed lower levels of mortality (0.0-10.7%). In different pot culture tests on third instar grubs at 10¹³ - 10¹⁸ spores / ha dosage equivalent, mortality rates were higher than those for first instar. In three field trials, *B. brongniartii* applied to soil in 7 mold crop at dosages of 10^{13} - 10^{15} spores / ha, dispensed with sorghum grains used for mass culturing, produced variable infection levels in second instar grubs collected 30 days after treatment. In the first trial, a high 48.0% infection level was obtained at 10^{14} spores / ha; in the remaining two trials, lower mortality levels (<5.0%) were noticed even at the highest dosage. Dosage, time of application, method of dispensation of the fungi need further standardization. A sequential application of M. anisopliae as an ovicide and B. brongniartii as a larvicide can be a useful biocontrol package against the soil inhabiting H. serrata. Mass culturing the fungi on molasses enables their large-scale production in laboratories set up in sugar factories. Index terms: Beauveria bassiana, Beauveria brongniartii and Metarrhizium anisopliae

[2053] ENTOMOPATHOGENIC NEMATODES AS BIOLOGICAL CONTROL AGENTS OF INSECT PESTS: A CLEARER UNDERSTANDING

P. Fairbairn, A. C. Fenton, R. A. Norman & P. J. Hudson, Inst. Biological Sciences, Univ. Stirling, STIRLING, FK9 4LA, UK.

Entomopathogenic nematodes are soil dwelling obligate parasites of insects and have been utilised as biological control agents of several crop pests. They have been successfully targeted against the Japanese beetle (Papillia japonica), black vine weevil (Ottiorhynchus sulcatus) and the mushroom fly (Sciarid spp.) to name but a few. However, the levels of success so far achieved on these insect pests have proved inconsistent between trials. In order to increase the levels of control and the degree of uniformity between scenarios, we have to form a better understanding of the biology of the system. In particular the dynamics of the infection process need to be more fully understood. Using a mathematical modelling approach we have investigated the entomopathogenic nematode infection processes and have gained a clearer understanding of the mechanisms, which are important in delivering 'successful' control. Here we present the results of experiments investigating infection in the Galleria mellonella - Steinernema feltiae system that allows us to investigate particular infection processes which are important for the development of the model. By experimentally modelling different control scenarios we demonstrate that the processes of infection are not simple linear ones, as assumed by the simple models. Infection is found to be dependent on the period of exposure and host:nematode ratio. These differences have obvious implications for the development of the model and are important for the applied biological control of insect pests. We discuss how our experimental findings lead to a clearer understanding of the situations in which entomopathogenic nematodes may be utilised to their full potential.

Index terms: Galleria mellonella, Steinernema feltiae, Modelling, Infection dynamics

[2054] MODELS OF ENTOMOPATHOGENIC NEMATODES FOR **BIOLOGICAL CONTROL**

A. C. Fenton, J. P. Fairbaire, R. A. Norman & P. J. Hudson, Inst. Biological Sciences, Univ. Stirling, STIRLING, FK9 4LA, UK.

Entomopathogenic nematodes (Nematoda: Rhabditida) are lethal obligate parasites of a wide range of insect species throughout the world, exhibiting many characteristics that make them ideal candidates as biological control agents of insect crop pests. However, to date, they are used in relatively few crop systems. As with many other biological control agents, the practical use of these nematodes at present is often based more on trial-and-error than on a firm, ecological understanding. Clearly, there is a need to build on existing biological information and develop a more comprehensive understanding of the nematode-host system to determine their optimal use as biological control agents. Here we discuss the development of a series of models of increasing complexity, designed to assess the optimal use of these nematodes under a wide range of biological control scenarios. To begin, we develop simple SI-type models to determine the broad dynamics of the system. We then add extra biological realism, such as host stage structure and evaluate control success under a range of short- and long-term biological control goals. We then develop cellular automata models to incorporate explicitly the effects of space (e.g., host refuges, dispersal rates etc) on control success. At all stages, our models are parameterised and validated by laboratory and field experiments. We begin by obtaining general parameter estimates for our simple models using the greater waxmoth, Galleria mellonella in laboratory experiments. Finally, we combine the models with field data to explore the optimal method to control the mushroom fly, Sciarid spp. (Diptera: Sciaridae) which is a major economic pest of mushroom houses in Europe and the US. We conclude that a combined approach, incorporating laboratory experiments and field data into a structured modelling framework is essential for predicting the effectiveness of nematodes as biological control agents.

Index Terms: Sciarid spp., Galleria mellonella, cellular automata, parameterisation.

OF [2055] EVALUATION THE EFFICIENCY OF RACILLUS THURINGIENSIS IN THE CONTROL OF URBANUS ACAWOIOS (LEPIDOPTERA: HESPERIDAE)

F.A. A. Ferrara^{1,2}, A. M. Lunz³, J. G. N. Wendt², J. M. Pinto² & A. G. Carvalho³, CTAIBB, Univ. Fed. Fluminense, Bom Jesus do Itabapoana, RJ, 28360-000, Brasil. E-mail: fernando@lutarc.com.br; ²Depto. de Fitotecnia, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ, 23851-970, Brasil; ³Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro.

In the last three years, annual outbreaks of Urbanus acawoios (Lepidoptera: Hesperiidae) have been observed in the northwest and north of the State of Rio de Janeiro and south of the Espírito Santo. This moth used to appear every 3 to 5 years causing a total defoliating of the "sombreiro" Clitoria fairchildiana (Leguminosae: Faboidae). This tree is very used as ornamental plants on the edge of streets, public squares, parking and highways of the southeast area of Brazil. The action of ecological factors, among them the biotics, such as food and natural enemies, together with the non-biotics influence the fluctuation of the insects, making it necessary to adopt control measures. However, control methods that cause smaller aggression to the environment should be searched. The work sought to test the viability of Bacillus thuringiensis on second and third instars of U. acawoios as well as to determine the most effective dosage for the control of the species. The eggs were maintained in Petri plates. After the eclosion the caterpillars were fed with leaves of C. fairchildiana. The experiment about the action of B. thuringiensis on the caterpillars of second and third instars was performed in laboratory (23,48 ± 2,82 °C, 71,67 ± 3,45% relative humidity and 12 hours of fotophase) with twenty replications. The dosages of *B. thuringiensis* (Dipel® PM formulation) were 0, 50, 100, 150, 200, 400 and 600 grams / 400 liters of water. The result of mortality rate varied according to the schedule (period of exposition): 24 hours (2 to 8% for second instar and 16 to 60% for third instar), 48 hours (33 to 60% and 68 to 95%), 72 hours (64 to 100% and 88 to 100%), 96 hours (70 to 100% and 90 to 100%) and 120 hours (71 to 100% and 91 to 100%). The results showed that in higher dosages the mortality rate was higher in the first hours. However, as time passed by, mortality rate was significantly the same in all dosages, except the control for the third instar. For the second instar, the dosages were significantly the same between 150 and 600 grams / 400 liters of water, at the level of 5% of probability for Tuckey's test. Considering the results of the action of B. thuringiensis, it offers possibilities for the control of Urbanus acawoios populations taking into account the high mortality rate.

Index terms: Biological control, Clitoria fairchildiana

[2056] CONIDIAL VIABILITY OF TWO ENTOMOPATHOGENOUS FUNGI KEPT ON AQUEOUS SUSPENSION UNDER DIFFERENTS STORAGE CONDITIONS AND PERIOD

J.M.S. Ferreira¹, <u>R.P.C. Araujo²</u> & F.B. Sarro³, ¹Lab. of Entomology, Embrapa/CPATC, P.O. Box 44, Aracaju, CEP 49025-040, Brazil E-mail joana@cpatc.embrapa.br; ² Dept. of Biotecnology, Unesp, Araraquara, P.O. Box 355, CEP 14801-970, Brazil; ³ Dept. of Plant Protection, Unesp, Botucatu, P.O. Box 237, CEP 18603-970, Brazil.

The present work was carried out at Embrapa Coastal Tableland Research Center (CPATC), Aracaju, Sergipe State, Brazil, aiming to determine the conidial viability of Beauveria bassiana BbBr032/CPATC strain, isolated from Rhynchophorus palmarum and of Hirsutella thompsonii HtBrI/CPATC strain isolated from Aceria guerreronis (both strains from Sergipe, Brazil), in different storage conditions and period kept under aqueous suspension. The suspensions of B.bassiana and H.thompsonii were diluted to 109 and 107 conidia/ml concentration, respectively, then homogenized and distributed in 50ml vials. The experimental design was completely randomized, in a factorial 4x5 and 4x6 (four temperatures and five/six storage period) with three replications. The main treatments were: T1 storage in room temperature; T2 in refrigerator (4°C); T3 in freezer (-10°C) constant; and T4 in freezer (-10°C) with successive defrost at each period of evaluation. The evaluations were done at 5, 10, 15, 30 and 45 days intervals (and until 60 days for B. bassiana). Adults mortality was registered for 20 days and fungus infection confirmed in a humid chamber. Viability rates of 60.46% and 60.02% were obtained for B.bassiana when storaged for 60 days in -10°C temperature with and without successive defrost, respectivelly. Similar rates were obtained for H.thompsonii when storaged at same conditions up to 10 days. Viability losses of 47.94% and 34.74% were obtained for B.bassiana and H.thompsonii conidium maintained at room temperature for 5 days.

[2057] EFFICIENCY OF THE ENTOMOPATHOGENOUS FUNGUS BEAUVERIA BASSIANA (BBBR057/CPATC) STRAIN ON BLACK COCONUT BUNCH WEEVIL HOMALINOTUS CORIACEUS (COLEOPTERA: CURCULIONIDAE)

J.M.S. Ferreira¹, <u>R.P.C. Arauio²</u> & F.B. Sarro³, ¹Lab. of Entomology, Embrapa/CPATC, P.O. Box 44, Aracaju, CEP 49025-040, Brazil;² Dept. of Biotecnology, Unesp. Araraquara, P.O. Box 355, CEP 14801-970, Brazil, E-mail coqueiral@mar.com.br; ³ Dept. of Plant Protection, Unesp. Botucatu, P.O. Box 237, CEP 18603-970, Brazil.

The black coconut bunch weevil Homalinotus coriaceus Gyli (Coleoptera:Curculionidae) is considered an important pest of coconut palm in Brazil. The adult feeds on female flowers and on young nuts causing abortion and premature nut falls. The larvae form feeds on the coconut bunch burrowing a external gallery down towards the leaf petiole causing the fall of the whole bunch and severe losses in coconut production. Agricultural pests can be controlled either by classical chemical methods or biological ones. The deuteromycete fungus Beauveria bassiana has been largely used in Brazil as a bioinseticide for many pests. The present work was carried out at the Laboratory of Entomology of Embrapa Coastal Tableland Research Center (CPATC) Aracaju, Sergipe State, Brazil, aiming to determine the efficiency of the BbBr057/CPATC strain of B.bassiana found infecting adults of the coconut black bunch weevil in Sergipe. The experimental design was enterely randomized with four treatments, comprising three concentrations $(10^9, 10^8 \text{ and } 10^7 \text{ comprising three})$ conidia/ml) and the control group, five replications and 20 adults per treatment, totalizing 400 adults. The inoculation technique used was adults immersion into the fungus suspension for approximatelly 5 seconds. After inoculation, the adults were placed into individualized plastic bottles containing small pieces of sugarcane as food source. The mortality was observed daily during 20 days period. Higher infection level was obtained at concentration 10º conidia/ml (87%), out of which 71% between the 5th and 11th days of the experimental time. The concentration 10^8 and 10^7 conidia/ml showed an infection levels of 14% and 4%, respectively. No fungus infection was obtained in the control group. The results showed that the BbBr057/CPATC strain requires a minimum concentration of 10° conidia/ml to cause significative infection levels on adults of H.coriaceus. Index terms: coconut, biological control, palm

[2058] EFFICIENCY OF THE ENTOMOPATHOGENOUS FUNGUS BEAUVERIA BASSIANA (BbB+057/CPATC) STRAIN ON THE AMERICAN PALM WEEVIL RHYNCHOPHORUS PALMARUM (COLEOPTERA:CURCULIONIDAE)

J.M.S. Ferreira¹, <u>R.P.C. Arauio²</u> & F.B. Sarro³, ¹Lab. of Entomology, Embrapa/CPATC, P.O. Box 44, Aracaju, CEP 49025-040, Brazil;² Dept. of Biotecnology, Unesp, Araraquara, P.O. Box 355, CEP 14801-970, Brazil; ³ Dept. of Plant Protection, Unesp, Botucatu, P.O. Box 237, CEP 18603-970, Brasil, E-mail fbsarro@unesp.br.

Adults of Rhynchophorus palmarum (Coleoptera : Curculionidae) are vectors of the nematode Bursaphelenchus cocophilus, causal agent of "red ring", a lethal disease of coconut and other palms. The larvae form can cause death of plants by feeding on the bud tissues. The deuteromycete fungus Beauveria bassiana has been largelly used in Brazil as a bioinseticide for control of many pests. The present work was carried out in the Laboratory of Entomology of Embrapa Coastal Tableland Research Center (CPATC) at Aracaju, Sergipe, Brazil, aiming to determine the efficiency of the BbBr057/CPATC strain of B. bassiana found infecting adults of Homalinotus coriaceus (Coleoptera : Curculionidae) in field. The experimental design was completely randomized with four treatments, comprising three concentrations (109, 108, 107 conidia/ml) and the control group, five replications with 20 adults per treatment, totalizing 400 adults. The inoculation technique used was adults immersion into the fungus suspension for approximatelly 5 seconds. After inoculation, the adults were placed into individualized plastic bottles containing small pieces of sugar cane as food source. The mortality was observed daily for 20 days. Higher infection level was obtained at concentration 10° conidia/ml (91,54%). The concentration 10° and 107 conidia/ml shows a infection level of 58,22% and 38,20%, respectively. The infection in the control group was 3,77%. The results shows that the BbBr057/CPATC strains requires a concentration of 10⁹ conidia/ml to cause a significative infection level on adults of R. palmarum.

Index terms: coconut, biological control, fungus, palm

[2059] OCCURRENCE OF CULICIDAE (DIPTERA) LARVAE IN WATER HELD IN AQUASCYPHA HYDROPHORA (FUNGUS:STEREACEAE) IN CENTRAL AMAZON, BRAZIL

R. L. M. Ferreira¹, A. F. Oliveira¹, E. S. Pereira^{1,2} & N. Hamada¹, ¹Dept. of Entomology - Instituto Nacional de Pesquisas da Amazônia – INPA, Caixa Postal 478 CEP 69.011-970 Manaus- AM. Brazil. E-mail: ruth@inpa.gov.br, ²PIBIC/CNPq/INPA

Although Culicidae (mosquitoes) is an insect family with many species of medical and veterinary importance in Central Amazonia, community structure and habitats of these insects are poorly studied. The immature stages can use a wide variety of habitats. Characterization of different habitats of mosquito larvae and knowledge of community structure are basic requirements for integrated control methods. The present study was done on the August-November 1999 period in the Adolpho Ducke Reserve (INPA), located 26 Km east of Manaus (02°55'S;59°59'W), Amazonas, Brazil. A survey was conducted of the entomofauna that uses as its breeding place the rain water that accumulates in the Aquascypha hydrophora (Stereaceae) fungus. Aquascypha hydrophora grow on dead tree trunks, either fallen or standing. The fungus forms structures similar to cups or receptacles (mean diameter of 9.2 cm and height of 16.3 cm) that hold water, providing habitat for a rich aquatic entomofauna. During the study period the entomofauna was composed of 95% Culicidae (Diptera), 3% Dytiscidae (Coleoptera), 1% Chironomidae (Diptera) and 1% Chaoboridae (Diptera). The fungus grows under shade in humid environments beside streams in upland forest. Two areas were sampled where 77 A. hydrophora receptacles were examined; 64 of these had water and 54 were used by insects. The mean number of insects per receptacle was 7.8 (total number of insects = 345; maximum per receptacle = 44). The distance from the fungus receptacle to the ground varied from 4.5 cm to 210 cm; the mean water volume per receptacle was 35 ml; mean water temperature was 27°C and mean pH was 4.4. The Culicidae fauna was composed of Limatus durhami, Limatus pseudomethysticus, Limatus flavisetosus, Culex (Carrollia) urichii, Culex (Melanoconion) sp., Toxorhynchites haemorrhoidalis and Anopheles eiseni. Knowledge of the habitat of mosquitoes, especially those in forested areas, is very important as a contribution to understanding the distribution and outbreaks of vectorborne diseases.

Index terms: aquatic insects, mosquitoes, community structure, phytotelmata.

[2060] NOCTUIDAE PARASITOID COMPLEX IN GREENHOUSE VEGETABLE CROPS IN OESTE REGION (PORTUGAL)

E. Figueiredo¹ & A. Mexia², ¹DPPF/SAPI, Inst. Sup. Agronomia, Tapada da Ajuda, 1349-017 Lisboa, Portugal, ²INIA/EAN, Quinta do Marquês, 2784-505 Oeiras, Portugal; E-mail elisalacerda@isa.utl.pt.

Noctuid larvae are key pests of several outdoor and protected crops. To develop IPM schemes it is necessary to know the natural enemies present in each particular agroecosystem and to quantify the activity of these biological control agents. The identification of the species of the noctuid parasitoid complex and natural control evaluation started on 1992 with studies on *Helicoverpa armigera*. In 1995, this studies were enlarged for the other noctuid species found attacking greenhouse crops (Chrysodeixis chalcites, Autographa gamma, Thysanoplusia orichalcea, Peridroma saucia, Mamestra brassicae, Tricoplusia ni, Lacanobia oleracea, Agrotis segetum, Discestra trifolii, Phlogophora meticulosa and Spodoptera exigua) by fortnigh periodic surveys in the most important vegetable protected crops (tomato, lettuce, sweet pepper, green beans and cucumber) and laboratory rearing until adult emergence of entomological material collected. Fourteen parasition species, mainly hymenopteran, were found: eight braconids (Aleiodes sp. (two different sp.), Cotesia sp. (gregarious), Cotesia kasak, Cotesia plutellae, Macrocentrus sp. near collaris, Meteorus pulchricornis, Microplitis mediator), two ichneumonids (Ctenochares bicolorus, Hyposoter didymator), one eulophid (Euplectrus flavipes), one trichogrammatid (Trichogramma sp.) and a scelionid (Telenomus laeviceps) and a tachinid species not yet identified. Although the parasitoid complex composition varied, in species and importance for natural control, with the adopted protection strategy, noctuid species, crops, season and also along the years, the most important parasitoids revealed to be the hymenopteran larval parasitoids H. didymator and the complex C. kasak/C. plutellae and, in some years, the egg parasitoids Trichogramma sp. and T. laeviceps. Often, the first two were responsible for about 80-90% of the total parasitism. The other species have marginal importance on natural control of these key pests. The biodiversity was higher in IPM and organic farming greenhouses. Parasitism rate was also higher in organic farming, and specially, in IPM greenhouses, varying from 0% to about 30% concerning all noctuid larvae captured along time in a crop and reaching 100% in some punctual occasions.

Index terms: Hyposoter didymator, Cotesia kasak, Cotesia plutellae, Telenomus laeviceps, Trichogramma sp

[2061] ANTIMICROBIAL PEPTIDES FROM THE CATTLE TICK BOOPHILUS MICROPLUS

A. C. Fogaca¹, M.T.M. Miranda², A. Miranda³ & S. Daffre¹, ¹Dep. Parasitologia, I.C.B., Univ. São Paulo, P.O.Box 66208, CEP 05389-970, São Paulo, SP, Brazil, ²Dep. Bioquímica, Univ. São Paulo, Av. Lineu Prestes, 748, São Paulo, SP, Brazil; ³Dep. Biofísica, UNIFESP, Rua 3 de Maio, 100, São Paulo, SP, Brazil. E-mail: sidaffre@icb.usp.br. Finantial support: FAPESP and CNPq.

Arthropods have an efficient immune system to defend themselves against infections. Proteins and peptides with antimicrobial activity constitute an important part of this system. We detected a constitutive activity against Gram-positive and fungi in the hemolymph (plasma and hemocytes) and gut contents from the cattle tick Boophilus microplus. A fragment (33-61) of the bovine DDhemoglobin with antibacterial activity was purified from the gut contents by RP-HPLC. This peptide was synthesized manually by t-Boc strategy on an MBHA-resin being active in micromolar concentrations against bacteria and fungi. The activity of the synthetic peptide was analyzed also against eucaryotic cells: bovine erythrocytes and a protozoan, Leishmania amazonensis. The peptide has a weak activity against those cells. Since we were not able to detect antibacterial activity in the bovine erythrocytes, as result of endogenous process, we supposed that the hemoglobin is being processed in the tick gut, generating the active fragment. A partially purified fraction of the gut contents with proteolytic activity against hemoglobin was obtained by a size-exclusion FPLC. The product generated after the incubation of the hemoglobin with this fraction showed antibacterial activity. We are investigating if this product corresponds to the 33-61 bovine []-hemoglobin. In addition, we are purifying the antimicrobial peptides in the tick hemolymph by RP-HPLC. We detected two fractions with activity against M luteus. One of them was purified to homogeneity and the peptide molecular mass was 10.198,7 Da, determined by MALDI-TOF-MS. Its partial N-terminal amino acid sequencing (85 residues), obtained by automated Edman degradation, did not show high similarity with any data bank sequences. The full characterization of this peptide is underway.

Index terms: antimicrobial, peptides, ticks, hemoglobin and immunity.

[2062] CONTROL OF PINE SHOOTS MOOTH IN MONTERREY PINE WITH ENTOMOPATHOGENIC FUNGI

<u>R. A. France</u>, M. E. Gerding & D. A. Quintana, Inst. Inv. Agropecuarias (INIA), CRI Quilamapu, P.O. Box 426, Chillán, Chile.

The pine shoot moth (Rhyacionia buoliana) is the most important pest in the Monterrey pine plantations (Pinus radiata) in Chile. The larva feed and makes galleries in terminal buds, producing severe deformations in the main shoot. The affected shoots loose their apical dominance and render uncommercial timber. If the pest is left without control 58% of the trees can be affected with a 20% of timber reduction. The pest is currently managed with biological and chemical control, the former by the use of the larval parasitoid Orgilus obscurator, which have been an effective biocontrol. However, in young plantations, sandy soils and coastal areas this parasite is unable to keep the pest under the economic threshold, being necessary the use of chemical pesticides. We are developing an alternative to chemicals by the use of entomopathogenic fungi as a biopesticides. In 1998, 96 isolates of Beauveria spp., selected from an indigenous entomopathogenic fungi collection and cryopreserved in the Biological Control laboratory at INIA Quilamapu, were screened by topical inoculation of a sporulating culture on five third-instar larvas of R. buoliana. Four isolates, identified as Beauveria bassiana, reached 100% mortality after four days and were selected for consecutive tests. The next experiment was immersion of ten larvae (five replications) in different doses of conidial suspension (10² to 10⁸ spores/ml) for one second. LT50 and LC50 were calculated from mortality data evaluated daily. Isolation B453 reached the best pathogenicity with a LC50 of 10⁴¹ spores/ml after 9 days and a LT50 of 8 days at the LC50 concentration. Isolates B305 and B453 were massive produced in sterile parboiled rice and the resulting spores formulated with vegetable oil as a protector. A plantation of 20 ha of three years old Monterrey pine, affected by the first instar larvae of R, buoliana, was sprayed during summer 1999 by airplane, with a dose 1012 spores/ha. Persistence of the inoculum on the treated foliage was measured through feeding of fresh larvae of R. buoliana and Galleria mellonella. Also, the effectiveness of B, bassiana biopesticide was evaluated by counting the number of dead larvae vs. the damaged buds on the treated area. Preliminaries results showed the potential of B. bassiana as biopesticide and the possibility to replace the chemical applications. However, the use of formulated spores and, synchronisation between spraying time and the most susceptible stage of the pest are required before to succeed the traditional insecticides by a biopesticide.

Index terms: Rhyacionia buoliana, Pinus radiata, entomopathogenic fungi, Beauveria bassiana.

(2063] EFFECTS IN VITRO AND IN VIVO OF SOYBEAN KUNITZ TRYPSIN INHIBITORS AGAINST THE BOOL WEEVIL ANTHONOMUS GRANDIS

O. L. Franco^{1,2}, S. C. Dias^{1,2}, F. R. Melo^{1,2}, O. B. Oliveira-Neto^{1,2}, C. Bloch Jr.^{1,3}, R. G. Monnerat¹ & <u>M. F. Grossi De Sá^{1*}</u>, ¹ Embrapa Recursos Genéticos e Biotecnologia, SAIN Parque Rural, Caixa Postal 02372. Brasília, D.F Brasil, E-mail fatimasa@cenargen.embrapa.br ²Depto. de Biologia Celular, UnB, Brasília, Brazil³ Instituto de Química, UnB, Brasília, Brazil

The boll weevil, Anthonomus grandis is a major pest of cotton in tropical and subtropical areas of the Americas. The control of this pest is unknown and plant proteinase inhibitors show great potential as tools to engineer resistance of crop plants against pests. None inhibitors available and characterized have been demonstrated effects towards this insect pest. In order to identify factors involved in the boll weevil resistance, the activity of soybean Kunitz trypsin inhibitor (SKII) was analyzed in vitro and in vivo assays against larvae and adult insects of A. grandis. The commercial inhibitors purchased from Sigma was fractionated with ammonium sulfate in a range of 0-100% and applied in a reversed phase HPLC originating a major peak which showed inhibitory activity against serine-proteinases from bovine pancreas (BPT) and boll weevil larvae and adult (AGT). When neonate larvae were fed in an artificial diet containing a rich fraction of SKTI at three different concentrations (10 □M, 100 □M and 500 □M), a reduction of larval weight of 30% at 100 □M SKTI and around 65% at 500 IM SKTI was observed. Another interesting fact observed was a high deformities in pupae and adult insects treated with SKTI. At 500 □M of SKTI we observed a ratio of pupae deformities around 50% and in adult insects, this ratio increased to 81% at same concentration. In larval stage, was observed a reduction of weight and length, while in pupae stage, SKTI caused a latter metamorphosis and in adult stage, was observed some deformations as wings and thorax absences. This was the first time that an inhibitor was active in vivo and in vitro against A. grandis. By this fact SKTI can be a possible tool on engineered plants resistant against this insect pest. This work was supported by CAPES, CNPq and FAPDF.

Index terms: cotton, control

[2064] SAFETY OF *GRATIANA BOLIVIANA* AS A BIOCONTROL AGENT OF TROPICAL SODA APPLE (*SOLANUM VIARUM*): IS EGGPLANT A SUITABLE HOST?

D. Gandolfo¹, J. Medal², F. Mc Kay¹, D. Ohashi³ & J. Cuda², ¹South American Biological Control Laboratory, USDA-ARS, Hurlingham, Argentina. ²Departament of Entomology and Nematology, Univ. of Florida, Gainesville, FL., U.S.A. ³Fac. Ciencias Exactas, Químicas y Naturales. Univ. Nac. de Misiones, Argentina.

Solanum viarum Dunal (TSA) is a prickly shrub native to Argentina, Brazil, and Paraguay. Accidentally introduced in Florida during 1980's, it has spread at a dramatic rate currently infesting 1.25 millon acres in southeastern U.S. The leaf feeder Gratiana boliviana Spaeth (Cassidinae) is being evaluated as a biocontrol agent for this weed. In larval survival non choice tests G. boliviana showed a narrow host range, limited to its known natural hosts, S. viarum and S. palinacanthum, and on the cultivated S. melongena (eggplant). However, mortality on eggplant was 10 times higher than on TSA. Here we present the results of laboratory studies and field surveys to asses the risk of G.boliviana using eggplant as an alternative host. Fecundity and longevity were compared by keeping 20 newly emerged couples on TSA and eggplant. Females kept on TSA laid 3521 eggs (185 □ 35.6 eggs/□) compared with those kept on eggplant that laid 96 eggs (5 □ 1.63 eggs/□). All females that fed on TSA laid eggs compared with 45% on eggplant. Longevity was significantly shorter on eggplant (31 3.9 days) than on TSA (74 9.0 days). Ovipositional and feeding preferences were tested in multiple choice tests carried out in 1m3 cages. Two plants of each species with similar sizes, were kept for one week with 8 couples of G. boliviana (12 replications). In total 1275 eggs were laid on TSA (106 □ 54.9 eggs/rep.), and 2 eggs were laid on eggptant. In all replications leaf consumption of TSA ranged 10-50%; on eggplant some slight feeding (less than 5%) was observed in 3 replications. At the end of the test, average number of adults on TSA and eggplant was 13.2 and 0.35 respectively. Eggplant fields inside the area of distribution of G.boliviana have been surveyed since 1997 in Argentina (7 sites), Brazil (3), Paraguay (1) and Uruguay (1). Special attention was placed on organically grown fields or fields where insecticides were used only on seedlings and insect activity was observed. G. boliviana was never found on eggplant, although it was often found on TSA plants growing intermixed with the eggplant plants or at a distance of less than 100 meters. Considering the results of larval survival and adult fecundity no choice tests, the predicted population growth rate of G.boliviana on eggplant is below one, even under conditions of no food limitation and extrinsic factors of mortality excluded. We concluded that eggplant would not be an alternative host for G. boliviana.

Index terms: biological control, host specificity

[2065] SCREENING FOR NEW INSECTICIDAL COMPOUNDS PRODUCED BY ENTOMOPATHOGENIC FUNGI

C.A.T. Gava, M. Erthal Jr. & R.I. Samuels, Department of Plant Protection. Universidade Estadual do Norte Fluminense, Campos dos Goitacazes, RJ. 28015-620, Brazil. E-mail cgava@uenf.br

It is well known that certain entomopathogenic fungi produce toxic compounds, many of which have been found to be insecticidal. Avermeetin is an example of an insecticide of microbial origin with a market value of millions of dollars per annum, indicating that more microorganisms should be screened for production of novel bioactive compounds. In this study, the little known fungus Hirsutella sausserei (Deuteromycota: Hyphomycetes), was investigated. This fungus was isolated from a hymenopteran host and a pure culture obtained in vitro. Following liquid culture in BDA+ yeast extract, the culture filtrates were concentrated by freeze drying and tested for biological activity. Initial tests showed that the extracts were insecticidal, causing death when injected into 5th instar Diatrea sacharalis (Lepidoptera). In order to purify and characterise the compounds present in the extracts, reverse-phase and gel filtration chromatography were used. Sep-Pak C18 cartridges were loaded with 500 µl of x10 CF. The elution profile showed that a toxic compound was eluted in the 30-50% acetonitrile fractions, which caused death approximately three days after treatment. It was noted that a number of treated insects developed deformations due to incomplete development. This Sep-Pak fraction was run on gel-filtration chromatography in order to estimate molecular mass. Fractions corresponding to the toxic activity eluted in the molecular mass range of 15-20 kDa. The peak fractions were further tested for heat stability. It was found that boiling the fractions for 10 minutes drastically reduced toxic activity, suggesting that this compound is a protein. Protein toxins have been rarely found in entemopathogenic fungi, however Ilirsutella thompsonii is known to produce two protein toxins which are also slow acting. These toxins have not been shown to effect insect development, therefore it is possible that the toxins from *H. sausserei* are different to those of *H. thompsonii*.

Index terms: Hirsutella sausserei, toxin, insect, Diatrea sacharalis.

[2066] FIELD TRIALS ON THE EFFICACY AND PERSISTENCE OF IMPROVED FORMULATIONS OF NUCLEAR POLYHEDROSIS VIRUS AGAINST HELICOVERPA ARMIGERA ON CHICKPEA

N. Geetha ¹ "&"R.J. Rabindra², 1.Section of Entomology, Sugarcane Breeding Institt., Coimbatore-641007, 2. Department of Entomology, Tamilnadu Agricultural Univ., Coimbatore-641003

The field performance of six preparations of Helicoverpa armigera Nuclear Polyhedrosis Virus (HaNPV) was evaluated in two chickpea trials in farmers' fields in TamilNadu against a standard chemical insecticide, endosulfan and a microbial insecticide, Bacillus thuringiensis kurstaki (Btk) and an untreated control. NPV treatments comprised a simple suspension of semi purified HaNPV, a microencapsulated formulation, a wettable powder, an oil in water emulsion, an oil based suspension and freeze-dried semipurified HaNPV. and were applied at 1.5 x 10¹²POB (Polyhedral Occlusion Bodies)/ha to 40 m² plots in a 4 x 9 randomized block design. Endosulfan and Btk were applied @350g a.i/ha and 1 Kg /ha (as formulated material)respectively. Six applications of the nine treatments were made at intervals of seven to 10 days. All the treatments were applied with a back pack hydraulic sprayer except the oil formulations which were applied with a controlled droplet applicator(CDA). All treatments were applied with CDA in the second trial . Persistence of the formulations was studied by collecting leaf samples from chickpea field in both the trials at 0, 1, 3, 5 and 7 days after treatments and assaying against II instar H. armigera by leaf feeding method. Mortality due to virus was observed till 10 days.Initial larval population ranged from 10.75 to 13.75 per 10 plants among the treatments. In general, all the virus formulations were as effective as the unformulated virus and better than control as shown by the data on larval populations on V th and VII th day after sprays. Data on pod damage showed the superiority of virus treatments over control and Endosulfan. In the second trial also pretreatment count did not show any significant differences in larval populations among different treatments. All the treatments effectively reduced the larval populations over control and pod damage was lower invirus-treated plots than endosulfan and control. Data on the persistence of the formulations indicated that there was drastic reduction in larval mortality even after one day of exposure of virus to atmosphere. By third day, the mortality due to most of the viral formulations was less than 10 per cent and by seventh day it was negligible. Similar trend was observed in the second trial also. The persistence of endosulfan or Bik were not better than the virus to cause larval mortality.

Key words:Nuclear polyhedrosis virus, formulations, field trial, chickpea, Helicoverpa armigera

[2067] FIELD EVALUATION OF IMPROVED FORMULATIONS OF NUCLEAR POLYHEDROSIS VIRUS AGAINST HELICOVERPA ARMIGERA ON COTTON

N. <u>Geetha¹</u> & R.J. Rabindra², ¹.Section of Entomology, Sugarcane Breeding Instr., Coimbatore-641007; ².Department of Entomology, Tamilnadu Agricultural Univ., Coimbatore-641003.

The field performance of five preparations of Helicoverpa armigera Nuclear Polyhedrosis Virus (HaNPV) was evaluated and compared in cotton trial in farmer's field in Tamil Nadu against a standard chemical insecticide, endosulfan and a microbial insecticide, Bacillus thuringiensis kurstaki (Btk) and an untreated control. NPV treatments comprised a simple suspension of semi purified NPV, a wettable powder, an oil in water emulsion, an oil based suspension and a combination of crude suspension and \Box dose of endosulfan. The treatments were applied at 3.0 x 10¹²POB (Polyhedral Occlusion Bodies)/ha to 40m² plots in a 3 x 8 randomized block design. Endosulfan and Bik were applied @350g a.i/ha and 1 Kg /ha (as formulated material)respectively Six applications of the eight treatments were made at intervals of seven to 10 days. All the treatments were applied using a spray fluid volume of 12.5 I/ha with a controlled droplet applicator.Initial larval population ranged from 7.33 to 8.33 per 10 plants among the treatments. All the treatments had similar population levels after 2 sprays. Later on, the population reduction was higher in oil based formulations as well as the treatment with both virus and D dose of endosulfan. Data on square damage showed the superiority of virus treatments over control, Endosulfan and Btk Boll damage was significantly reduced by all the treatments compared to control, with NPV preparations performing as well or better than endosulfan and Btk standard. Final seed cotton yields per treatment were not consistent among treatments although NPV-formulations gave comparable or better yields when compared to control and Btk.

Key words: Nuclear Polyhedrosis Virus, formulations, Helicoverpa armigera, Bacillus thuringiensis kurstaki, field trail, cotton

[2068] USE OF ENTOMOPATHOGENIC FUNGI FOR THE CONTROL OF Caliroa cerasi

<u>M. E. Gerding</u>, R. A. France, L. O. Devotto & C. M. Alvarez. Inst. Inv. Agropecuarias (INIA), CRI Quilamapu, P.O. Box 426, Chillán, Chile. E-mail: mgerding@quilamapu.inia.cl.

The pear slug, Caliroa cerasi (Hymenoptera: Tenthredinidae), is a primary pest of cherry tree (Prunus avium) in Chile and its control had been exclusively based in chemicals insecticides. The insect never affect the fruits, but is able to cause 80% of leaves damage during the summer, which affect the production and tree longevity. C. cerasi has two or three generations during spring and summer. The adult is a small wasp (4.0-6.0 mm) that lays single eggs under the leaf cuticle, from where small larvae cover with dark green mucus emerge and feed until they reach 11.0 mm length. The insect pupa is found under ground, even at 70.0 num depth. The total insect cycle takes between 43 to 60 days. We have been working in a new option for pear slug control, through the use of entomopathogenic fungi. They have showed to be effective against larvae and pupae, when these fungi were applied to the foliage or soil, respectively. To select the best fungi isolates, a preliminary screening was accomplished with an indigenous entomopathogenic fungi collection (over 500 isolates), which is kept under cryopreservation by the Biological Control laboratory at INIA Quilamapu. Lab and field experiments were performed, in order to determine the larvae and pupae mortality caused by Beauveria and Metarhizium isolates. Metarhizium anisopliae (strain M221) and Beauveria bassiana (strain B323) were the most pathogenic isolates against pear slug in the lab, reaching a 100% of mortality after 7 days of inoculation. Both fungi were also evaluated in the field, where they were able to kill larvae on the foliage and pupae in the ground. The best control on the foliage was obtained with M221 (90%), better than B323 (52%) and the check. M221 was also more effective (63%) in the ground, when the inoculum was incorporated into the soil or was cover with straw mulch. Key words: Beauveria, Metarhizium, Pear slug

[2070] THE VELVETBEAN CATERPILLAR CONTROL WITH BACULOVIRUS ANTICARSIA APPLIED ON SOYBEAN CROP THROUGH A CENTER PIVOT SPRINKLE WATER IRRIGATION

S. A. Gomez¹ & D. L. Gazzoni², ¹Embrapa- Centro de Pesquisa Agropecuária do Oeste (CPAO), Caixa Postal 661, CEP 79804-970, Dourados, MS. Email:sergio@epao.embrapa.br; ²Embrapa-Centro Nacional de Pesquisa de Soja (CNPS₀), Caixa Postal 231, CEP 86001-970, Londrina, PR. E-mail: gazzoni@enpso.embrapa.br.

In the 1986/87 soybean crop season, an experiment and a validation field of experimental results were carried out at the Agricola Itamarati S/A, Ponta Porã, MS, Brazil. Both actions dealt with the velvetbean caterpillar control with its nuclear polyhedrosis virus (NPV), Baculovirus anticarsia. In the experiment 50, 75 and 100 equivalent larvae -EL- (11.E=1,3x109 polyhedral inclusion bodies) of B. anticarsia were applied, through a center pivot sprinkle water irrigation (equipment deviced to irrigate 118ha) working at full speed. The NPV suspensions, obtained from macerated dead larvae, were injected into the irrigation water with the aid of a chemical products injector (dose calibrater). The experiment was designed as a randomized block, with three replications and each plot consisted of a circle section of ca 3 ha. The evaluations of the larvae population were done by the cloth sampling method, with 10 samplings for each plot. At the date of the virus application there were the average of 14 small (≤1,5cm) and of 8 large larvae (>1,5cm) per sampling. The Santa Rosa soybean variety was at the full bloom stage with about 5% of the whole leaf area damaged by the insect. At the seventh day after the application, the doses of 50, 70 and 100LE provided control of, respectively, 96, 94 and 86%, practically without damage increment on the leaves, while the control plot (without application) suffered 15% of defoliation. The experimental result relative to the 50 EL was validated in another central pivot, in the same farm, but the virus being applied in the whole 118ha embraced by the irrigation equipment. The IAS-5 soybean variety, in the moment of the application, was also in the full bloom stage, presenting an average of 25 small and 8 large larvae and 9% of loss of leaf area. The evaluation, carried out 8 days after the application, showed that the larvae population was practically killed off, and the leaf loss reached 18% only.

Index terms: Anticarsia gemmatalis, Lepidoptera, Noctuidae.

[2069] IMPROVEMENT OF INSECTICIDAL NEMATODES- A GENETIC APPROACH

<u>I. Glazer¹ & D. Segal²</u>, ¹Department of Nematology, Volcani Center, Bet Dagan 50250; ²Department of Molecular Microbiology & Biotechnology, Tel-Aviv University 69978.

Entomopathogenic nematodes (EPN), in association with symbiotic bacteria, live in the soil where they locate suitable insect hosts, penetrate into their haemocel and release the bacterial symbionts. The bacteria multiply and kill the insect within two days. The wide host range, lack of pathogenicity to humans and livestock, and the availability of procedures for mass culture, make EPN attractive environmentally friendly bio-insecticides. However, their sensitivity to the extremes of the environment prevents them from reaching their full biocontrol potential. Selection, screening for new natural isolates, and mutagenesis have been attempted in an effort to enhance EPN tolerance to environmental harshes. Manipulation of genes involved in heat and desiccation tolerance offers a powerful attractive alternative. Recently, the technology for generating transgenic nematodes has been successfully adapted from C. elegans to EPN, opening the way for generating transgenic EPN with enhanced tolerance to environmental extremes. Indeed, transgenic EPN carrying a heat shock gene from C. elegans were shown to have increased heat tolerance. Yet, in view of the growing concern regarding the use of genetically modified organisms, we reasoned that field release of transgenic EPN will meet less opposition if the engineered genes were their own rather than from a foreign species. As a first step towards this goal we have isolated and characterized two heat shock genes from the EPN *H. bacteriophora*, and a glycogen synthase gene, involved in the biosynthesis of trehalose, which confers desiccation tolerance, from the EPN S. feltiae. Our progress along these lines will be described.

[2071] A COMPARISON OF CARABID SPECIES IN FOUR VEGETATION TYPES

G. C. Hamilton¹, J. H. Lashomb¹ & J. Ingerson-Mahar¹, ¹Dept. of Entomology, Rutgers – The State Univ. of New Jersey, 93 Lipman Drive, New Brunswick, NJ, 08901, USA, E-mail hamilton@aesop.rutgers.edu.

Differences in the numbers and types of carabid species found in soybeans, corn, azaleas, and azaleas planted with flowers (shasta daisy and coriander) were investigated over a two-year period using pitfall traps. All pitfall traps were sampled on a weekly basis during the growing season. All carabid individuals recovered were identified and used to determine weekly abundance. The data were also used to determine species richness. Weekly means were subjected to analysis of variance and mean separation tests to determine differences between habitats. A cluster analysis using the species richness values calculated for each habit was also conducted. Index Terms: Carabidae, species richness, diversity

[2072] THE USE OF PROTEASES TO ENHANCE THE INSECTICIDAL POTENTIAL OF BACULOVIRUSES

R. L. Harrison¹ & <u>B. C. Bonning</u>¹, ¹Dept. Entomology, Iowa State Univ., 418 Science II, Ames, IA 50011, USA, E-mail bbonning@iastate.edu

The basement membrane is a physical barrier to systemic infection of lepidopteran larvae by baculoviruses. One approach to improve the insecticidal activity of baculoviruses is to perforate or eliminate the basement membranes of their hosts. Towards this end, we constructed six recombinant clones of Autographa californica nucleopolyhedrovirus (AcMNPV) that expressed three proteases (Sarcophaga peregrina cathepsin L, "ScathL"; rat stromelysin-1, "STR1"; and human 72 kDa type IV collagenase, "GEL") that digest basement membrane proteins. The recombinant viruses expressed these proteases from either the carly *ie-1* promoter (AcIEITV3.ScathL, AcIEITV3.STR1, and AcIEITV3.GEL) or the late *p6.9* promoter (AcMLF9.ScathL, AcMLF9.STR1, and AcIMLF9.GEL). Recombinant protease activities were detected in the culture medium of cells infected with recombinant viruses by either gelatin/casein zymography or azocoll assay. AcMLF9.STR1 and AcMLF9.ScathL caused premature cuticular melanization of 5th instar Heliothis virescens. Melanization of internal tissues was observed in larvae infected with AcMLF9.ScathL but not in larvae infected with AcMLF9.STR1. Lethal concentration bioassays revealed no significant differences in virulence between the protease-expressing recombinants and wild type AcMNPV. Survival time bioassays revealed that AcMLF9.ScathL killed H. virescens significantly faster than wild type AcMNPV, and also significantly faster than a virus expressing an insect-selective scorpion neurotoxin from the p6.9 promoter. Larvae infected with AcMLF9.ScathL caused significantly less feeding damage on lettuce compared to that caused by larvae infected with wild type AcMNPV.

Index terms: *Heliothis virescens, Autographa californica,* nucleopolyhedrovirus, basement membrane, recombinant baculovirus insecticide.

[2073] FACTOR ANALYSIS OF SYNERGISTIC EFFECTS BETWEEN ENTOMOPATHOGENIC FUNGUS, *METARIHIZIUM ANISOPLIAE* AND SYNTHETIC INSECTICIDES TO SCRAB GRUBS

II. Hiromori, M. Hatsukade, Department of Applied Entomology, Faculty of Agriculture, Shizuoka University, Ohya, Shizuoka 422-8529, Japan, E-mail ahhirom@ipc.shizuoka.ac.jp.

Entomopathogenic fungus, *Metarhizium anisopliae* has been studied as useful biological control agent to many insect pest including the soil inhabiting pests. However, entomopathogenic fungi are easily affected by environmental factors such as tempareture, moisture and sunlight. These environmental factors made the control effects unstability in the field. To improve the unstability of fungal effects, the combined application with synthetic insecticides were developed.

Combined application of *M. anisopliae* and synthetic insecticides showed synergistic effects and resulted high mortality compared with single application of each agent. However, the mechanism of synergistic effects had been indistinct. In this study, we researched the mechanism of synergistic effects over the immunity system of scarab grubs, M. anisopliae treated with insecticides resulted decrease in hemocytes in the hemolymph of Anomala cuprea (Coleoptera: Scarabacidae) larvae. Furthermore, phenoloxidase activity in the hemolymph inhibited from both application of M. anisopliae and insecticides. These results indicated the synergistic effects were caused inhibitation of cellular and humoral defense system of A. cuprea. The observation under scanning electron microscopy, the number of conidia that adhered to cuticle of A. cuprea were increased both application of M. anisopliae and insecticides. The food consumption of A. cuprea treated with both control agents were reduced. These results indicated that the synergistic effects were obtained by restraining the action of A. cuprea and conidia of M. anisopliae were difficult to remove from the cuticle. Then, more large number of conidia were possible to penetrate into hemocoel of A. cuprea. The synergistic effects between M. anisopliae and synthetic insecticides caused inhibitance to immunity system and action of A. cuprea.

Index terms: synergism, immunity system, hemocyte, adhesion, Anomala cuprea

[2074] PHENOTYPIC VARIATION BETWEEN GENOTYPIC VARIANTS OF A NUCLEOPOLYHEDROVIRUS INFECTING PINE BEAUTY MOTH, PANOLIS FLAMMEA

D.J. Hodgson¹, **R.S. Hails² & J.S. Cory³, ^{1,2,3}Inst.** Of Virology and Environmental Microbiology, Mansfield Rd., Oxford, OX1 3SR, United Kingdom.Email: dihod@ceh.ac.uk.

Natural populations of the pine beauty moth, *Panolis flammea*, nucleopolyhedrovirus (*Pf*NPV) have been shown to contain high levels of genotypic variability, with individual host larvae containing at least 24 distinct viral genotypes. Four of these genotypic variants have been compared in bioassay experiments to ascertain whether this variation in genotype translates into differences in key phenotypic traits. Variants differed in their infectivity, speed of kill and yield upon death of the host, all factors which have the potential to profoundly influence host-virus interaction in the field. Such phenotypic variation ought to promote selection for the 'fittest' viral genotype: this begs the question why so much variation is observed in the field in this and other baculovirus systems. Coexistence of virus genotypes may be promoted by tradeoffs between phenotypic traits. Bioassay results were used to examine such tradeoffs, using mean phenotypic traits for each variant. There was a negative relationship between speed of kill and virus yield, but no correlation between these variables and infectivity. We discuss further ecological features of the *P*. *flammea* - virus interaction which may promote genotypic variation in the pathogen population. Index terms: baculovirus, bioassay, virus fitness, tradeoffs

[2075] DIFFERENTIAL TRANSMISSION OF ZUCCHINI YELLOW MOSAIC VIRUS AND TURNIP MOSAIC MOSAIC VIRUS BY MYZUS PERISCAE AND BREVICORYNE BRASSICAE

II. Huet, E. Lendler, A. Dubrovsky and B. Raccah¹, ¹Dept. of Virology, The Volcani center, Bet Dagan 50-250, Israel. braccah@volcani.agri.gov.il

Potyviruses include the largest number of plant viruses. This group include some of the most economically important viruses in annuals and perennials. Aphids transmit potyviruses in a typical non-persistent manner. Most non-persistent viruses are considered to be of low specificity for aphid vectors. However, in a recent study, we have found that *Brevicoryne brassicae* fail to transmit zucchini yellow mosaic virus (ZYMV) a virus that is readily transmissible by *Myzus persicae*. On the other hand, turnip mosaic virus (TuMV) was transmitted both by *B. brassicae* and *M. persicae*. This same strain is transmit readily by *B. brassicae*. The present knowledge suggest that the helper component (HC) serves as a bridge between the aphid's stylets and virions. Therefore, the HC of ZYMV and TuMV were purified and used for acquisition with for virions from membranes. In order to understand the specificity for aphid species, homologous and heterologous combinations of HC and viruses were examined in transmission experiments. The significance of these transmissions finding in elucidating vector specificity will be discussed.

Index terms: Brevicoryme brassicae, Myzus persicae, ZYMV, TuMV, Helper component, specificity, vector.

[2076] MOLECULAR CHARACTERIZATION OF BOMBYX MORI CYTOPLASMIC POLYHEDROSIS VIRUS SEGMENT 4

K. Ikeda & H. Mori, Department of Applied Biology, Kyoto Institute of Technology, Kyoto 606-8585, Japan, E-mail a6660001@ipc.kit.ac.jp

The cytoplasmic polyhedrosis virus (CPV) group, one of the genus *Cypovirus* classified within the *Reoviridae* family is characterized by the production of large proteinaceous crystals, polyhedra, in the cytoplasm of infected cells. Other genera *Orthoreovirus, Rotavirus, Orbivirus, Phytoreovirus, Fijivirus, Oryzavirus, Coltivirus,* and *Aquareovirus belong* to the *Reoviridae* family. Polyhedra are consisted of a single protein, C-polyhedrin, within which many mature virions are embedded. The viral genomes are composed of ten-segmented double-stranded RNAs. Outer capsid proteins of *Bombyx mori* CPV particle are VP1 and VP3 which are encoded by segment 1 and segment 4, respectively. cDNA cloning of segment 4 was carried out and the complete nucleotide sequence was determined. BmCPV genome segment 4 comprised 3,259 nt and possessed an open reading frame that encoded a predicted protein of 1,058 residues. Data base analysis showed that BmCPV VP3 was highly homologous to rice ragged stunt virus (RRSV: a member of *Oryzavirus*) P2 protein. Furthermore, phylogenetic trees derived from multiple sequence alignments of the homologous proteins from RRSV, *Nilaparvata lugens* reovirus (a putative member of *Fijivirus*), Fiji disease fijivirus. Recombinant BmCPV VP3 is expressed in insect cells by use of a baculovirus vector and the characterization will be discussed.

Index terms: cytoplasmic polyhedrosis virus, Bombyx mori, silkworm, Reoviridae.

Symposium and Poster Session

[2078] NEW ISOLATE OF *ERIOGASTER LANESTRIS* NUCLEOPOLYHEDROVIRUS IN LATVIA.

L. Jankevica¹, M. Kropa¹ & E. Jankevics², ¹Dept. of Experimental Entomology, Inst. of Biology, Univ. of Latvia, Miera street 3, Salaspils, LV-2169, Latvia, E-mail: liga_jankevica@hotmail.com; ²LU Biomedical Research and Study Centre, Ratsupites Street 1, Riga, LV – 1067

Baculoviruses rather rarely cause epizootic in pest populations under Latvian climatic conditions therefore nucleopolyhedroviruses (NPVs) have been isolated from 11 insect species. They are considered to be a safe biological insecticide and have a great potential in pest control. The present aim was to search for new isolates of NPV in the leaf-bearing forest pest populations and to determine its biological and morphological characteristics. In recent years population density of *Eriogaster lanestris* was low. In 1997 the infected larvae of *E. lanestris* with nuclear polyhedrosis symptoms were observed. Nucleopolyhedrovirus from *E. lanestris* was isolated first time in Latvia. The dimension of polyhedra was 800 to 1600 nm. Polyhedra contained large number of rod-shaped virions. Cytological preparations made by fixing the larvae of *E. lanestris* with characteristic symptoms of illness were investigated. Polyhedra of new isolate were observed in nuclei of midgut epithelial and fat cells, hypodermys, trachea and muscular sheet. Biological activity of new El NPV isolate was characterised by a bioassay using infection with disc method. Host range of new isolate was tested. Virus cause $25.4\% \pm 4.1\%$ mortality of *Malcosoma neustria* 3rd instar larvac. The next step of investigations is a comparison of viral DNA isolated from new NPV isolate. No amplification were detected in tests with El NPV using primers designed to detect DNA of different *M. neustria* NPV isolates.

Index terms: Nucleopolyhedrovirus, Eriogaster lanestris, polyhedra formation.

[2077] A PAECILOMYCES FUMOSOROSEUS MUTANT OVERPRODUCING CHITINASE DISPLAYS HIGH VIRULENCE AGAINS'T BEMISIA TABACI.

M. Iracheta, C. Hernández, L. Galán-Wong, I. Hernández-Torres, C. Rodríguez-Padilla, C. Hernández-Luna, R. Tamez-Guerra & <u>B. Perevra-Alférez</u>, Depto. de Microbiología e Inmunología. Fac. Ciencias Biológics/UANL. México. Av. Dr. Pedro de Alba y Av. Manuel Barragán. Cd. Universitaria. San Nicolás de los Garza, N. L. CP. 66450.

In recent years, biopesticides formulated with Paecilomyces fumosoroseus have demonstrated high efficiency for the Bemissia tabaci (whitefly) control. The mode of action of this fungi depend, in part, of its capacity to break and penetrate the insect cuticle by mechanical force and enzymatic degradation. The cuticle is formed by chitin microfibrils where they might constitute around 30% of the cuticle. Concern with enzymatic cuticle-hydrolysis, chitinases may play an important role in degrading the chitin barrier and increase the fungal virulence. In this study, we report the isolation of P. fumosoroseus mutants overproducing chitinases. A P. fumosoroseus strain (Pfr612. USDA-ARS) spore suspension was mutagenized with UV and plated on colloidal chitin agar (CCA) at 1.0% w/v. Those colonies showing biggest hydrolysis-halo in comparison with parental one were chosen. Four colonies were selected. In order to supervise the stability, the strains were subcultured on YPD broth (yeast extract 0.3%; peptone 1.0%; glucose 2.0% w/v) and CCA. After that, we selected a strain displaying better stability and it named as M84. Mutant and parental strains were inoculated on YPD and YPD plus colloidal chitin (YPCC) and incubated at 26°C for 168h. Fermentation parameters such as glucose consumption and biomass and N-acetylglucosamine (NAG) production were measured. Chitinases induction was evaluated in minimal medium supplemented with colloidal chitin (MMC). Bioassays were conducted by triplicate using third instar withefly nymph. The fermentation parameters on YPD showed that mutant strain yielded similar biomass production and glucose consumption than parental one. Moreover, when both strains were grown on YPCC, the NAG production start after glucose consumption, demonstrating that chitin synthesis is repressed by glucose in both strains. However these ones were fermented in MMC, the mutant strain produced almost three times more NAG than parental one. The chitinases were purified from supernatants and subject to chitinase activity on polyacrylamide plus glycol-chifn at 0.01% (*w*/y) under denaturing and native conditions. The chifn activity was revealed with white calcofluor. This assays showed the presence of single activity band of ca. 26 kDa. In laboratory bioassays M84 strain was 1.84-fold more virulent than parental one against B. tabaci nymph. Paecilomyces fumosoroseus, Bemissia tabaci, Chitinase

[2079] DNA SEQUENCE DATA USED TO VALIDATE SPECIES TAXONOMY AND ORIGIN OF UK SUBTERRANEAN TERMITE (ISOPTERA: RHINOTERMITIDAE) INFESTATION

T.M. Jenkins¹, R.II.J. Verkerk² & B.T. Forschler³, ¹Dept. Entomology, Univ. Georgia, Research Station, Griffin, GA 30223-1797, USA, E-mail: tienkin@gacs.griffin.peachnet.edu; ²Dept. of Biology, Imperial College of Science, Technology & Medicine, Silwood Park, Ascot, Berkshire SL5 7PY, UK. ³Dept. of Entomology, Univ. of Georgia, Athens, GA 30602, USA.

The first case of an established infestation of subterranean termites in the United Kingdom (UK) was identified during 1998 in Devon, England. The termites, Reticulitermes lucifugus grassei, were probably introduced to this site more than 30 years ago. We hypothesized that the source of the infestation as well as validation of species taxonomy could be accomplished through phylogeny analyses of DNA sequence data. We decided to sequence three different regions of DNA: two haploid mitochondrial DNA (mtDNA) genes and a diploid nuclear DNA (nuDNA) intergenic sequence region (ITS2). We sequenced from individual termites 1495-bp of the mtDNA, which included part of the cytochrome oxidase I (COI) gene, the complete cytochrome oxidase II (COII) gene, and the entire 350-bp ribosomal intergenic sequence (ITS2) region. Sixteen blind samples were included in the study, which represented termites collected from the UK, France and the USA. The French and USA populations were used for comparisons. All termite population samples were initially identified to species using morphological keys. Eight of the UK samples were collected at the infestation site and were characterized as R. lucifugus. Cladistic and phenetic phylogeny analyses of the individual gene sequences from all populations demonstrated that R. santonensis from France formed a monophyletic clade with R. flavipes from the United States. Reticulitermes lucifugus populations from France and the UK formed a monophyletic clade. Furthermore, there was little sequence differentiation among R. lucifugus populations. Reticulitermes virginicus and R. hageni from the USA were distinctly different from the other three species. These data suggest two scenarios. First, the UK R. lucifugus infestation is probably European in origin because this species is widely distributed throughout southern Europe. Second, R. santonensis and R. flavipes may represent one species. The type specimen for R flavipes was recovered from a greenhouse in Vienna, Austria over one hundred years ago. We suggest that R. flavipes could have been introduced into Europe early in the 19th century with the maritime trade that was conducted at that time between southern France and the United States and eventually misidentified as R. santonensis.

Index Terms: Isoptera, mtDNA, nuDNA, DNA sequence

[2080] THE POTENTIAL IMPACT OF GROBAL WARMING ON DECIDUOUS OAK DIEBACK CAUSED BY AMBROSIA FUNGUS CARRIED BY AMBROSIA BEETLE IN JAPAN

N. Kamata¹, K. Esaki², & K. Kato¹, ¹Lab. of Ecology, Fac. of Sciences, Kanazawa Univ., Kakuma, Kanazawa, Ishikawa 920-1192, Japan, E-mail: kamatan@kenroku.kanazawa-u.ac.jp; ²Ishikawa Forestry Research Institute, Sannomiya, Tsurugi, Ishikawa 920-2114, Japan

Since the late 1980s, deciduous oak dieback has been prevalent in Japan. This phenomenon has been recorded since the 1930s, but up to 1980, the epidemics continued for only a few years. More recently, however, the epidemics have continued for more than 10 years, and the area of dieback has been spreading new places where no dieback had been recorded in the past. An unidentified ambrosia fungus belonging to the genus Raffaelea is involved in this dieback. A symbiotic ambrosia beetle, Platypus quercivorus (Col., Platypodidae), is a vector of this fungus. This is the first example that ambrosia fungus carried by ambrosia beetle kills vigorous trees. Ambrosia beetles usually attack weakened or dead trees with a few exceptions like Platypus cylindrus in S Europe, Trachyostus ghanaensis in Africa, and Dendroplatypus impar in SE Asia, which attack vigorous trees but do not kill the host. According to many outbreak records of *P. quercivorus* in the evergreen oak stands in Japan, few evergreen oak trees were killed by this insect outbreak although many pinholes were found on the trunk surface (occasionally > 1/sq. cm). It was speculated that the pathogenic fungus, Raffaelea sp., was exotic and had been accidentally introduced to Japan, and that P. quercivorus was free from this fungus in places where no tree mortality occurred. However, when the oak dieback was first found in mixed forest stands of evergreen and deciduous oaks in Ishikawa Prefecture in 1997, this hypothesis was rejected because tree mortality caused by this fungus/beetle was more Hyperball than 50% of the attacked trees for *Quercus crispula* but low for other concurrent Fagaceae species (<5%) although the number of initial attacks by the beetle was similar. Concurrent oaks other than Q. crispula proved to be resistant to Raffaelea sp. An opposite tendency was found in P. quercivorus preference to tree species. Therefore, Q. cripsula was preferred least by this insect, but was the most susceptible to the symbiotic ambrosia fungus. Amongst the deciduous oak, Q. cripsula is distributed in the coolest place. Platypodids are prosperous in tropical and subtropical regions. *Platypus quercivorus* is distributed in S to SE Asia. Taiwan, and Japanese Archipelago. Oak dieback occurs in northern/high margins of *P. quercivorus* distribution and southern/low margins of Q. crispula distribution. Oaks other than Q. cripsula are resistant to Raffaelea sp. probably because a stable relationship has been formed among the tree, fungus, and insect in a long evolutionary process. Quercus crispula was probably left out of the coevolution. We hypothesized that oak dieback in Japan was the result of the warm climate since the late 1980s, which made the fateful encounter of P. quercivorus with Q. cripsula by pushing the distribution of P. quercivorus to a more northern and higher place. Because P. quercivorus can realize a high reproduction rate on dead brood trees, this beetle can propagate more rapidly on O. crispula than on other resistant oaks. It is speculated that future global warming will accelerate overlapping P. quercivorus and Q. crispula distributions, and that the dieback of Q. crispula will be more prevalent.

Index terms: Platypus quercivorus, Raffaelea sp., Quercus crispula, distribution

[2081] ENTOMOPHAGS OF THE POPLAR LEAF BEETLE IN TURKMENISTAN

E. Kokanoya, National Institute of deserts, flora and fauna 59, Azady Str., 744000 Ashgabad, Turkmenistan.

The poplar leaf beetle Plagiodera versicolora (Coleoptera, Chrysomelidue) is the main defoliator of various species of the willow (Salix spp.) in natural bioccenoses of the Kopet-Dag Mauntains and the cultural landscapes of the foothills. P.versicolora develops in Turkmenistan in three generations year and reaches it's maximum population in the first one. Natural enemies diminish the population of the beetle in the larval and pupal stages. In Turkmenistan the set of parasites P.versicolora uncludes four species relating to the families Eulophidae, Preromalidae (Hymenoptera) and Tachinidae (Diptera). Pediobius routensis (Eulophidae) developed as a primary parasite from the larva of the leaf Beetle and it was also developed as a primary parasite from the caterpillars of the elaeagnus leaf roller Apotomis lutozana. Schizonotus latus (Pteromalidae) was developed as a primary parasite from the pupas of P.versicolora. The parasite larvae develop 8-10 days. Under the conditions of a closed environment, without water, the parasites live 3 or 4 days. When fed with sugar syrup their lifetime is 8-11 days. In ecologically pure surroundings the damage to the P.versicolora was high - up 44%. As a secondary parasite, the Sch. latus was developed from the pupas of the Anthomyiopsis plagioderae, which is a primary parasite of the P.versicolora. Schizonotus sieboldi (Pteromalidae) the primary-secondary external parasite was developed from the pupas of the poplar leaf beetle. It is encountered rarely. Anthomyjopsis plagioderae (Tachinidae) primary single internal parasite evolved from pupas of the P.versicolora. It is encountered rarely. The compiling a summary list of the parasites of Plagiodera varsicolora within the confined of it's holarctic areal showed almost everywhere, the larvae of the leaf beetle are infected by the Schizonotus sieboldi.

[2082] BASELINE SUSCEPTIBILITY OF BREVIPALPUS (ACARI: TENUIPALPIDAE) TO ORGANOTIN ACARICIDES IN BRAZILIAN CITRUS GROVES

R. H. Konno, C. R. Franco & C. Omoto, Depto. de Entomologia, Fitopatologia e Zoologia Agrícola, Escola Superior de Agricultura "Luiz de Queiroz", Univ. de São Paulo, Av. Pádua Dias, 11, 13418-900 Piracicaba, SP, Brasil, E-mail celomoto@carpa.ciagri.usp.br

The mite Brevipalpus phoenicis is one of the most important pests of Brazilian citrus because it vectors the citrus leprosis virus which affects the productivity and quality of the fruit. Control of B. phoenicis has been done mainly by the use of chemicals Approximately 44% of active ingredients used for controlling citrus mites in Brazil belongs to the organotin group. Because of intense use of organotin acaricides, the objective of this work was to evaluate the baseline susceptibility of B. phoenicis to the acaricides fenbutatin oxide and cyhexatin. B. phoenicis populations were collected from citrus groves which received different regimes of organotin acaricide applications in the past 4 years (no organotin acaricide use, use of organotin acaricide in alternate years, use of organotin acaricide once per year). The toxicological characterization of a susceptible reference population of B. phoenicis was performed with a residual leaf spray bioassay. Citrus leaf disks were sprayed with a Potter spray tower. Then, leaf Idisks were placed on a small petri dish containing an agar-water mixture at concentration of 2.5%. Then, 10 adult mites were transferred on each disk. Bioassay dishes were kept in a climatic chamber at temperatue of 25 ± 1 °C and photoperiod of 14:10 (L:D). The mortality was evaluated 24 hours after mite infestation. Mortality data were subjected to Probit analysis to estimate the LC50 and to define a diagnostic concentration for monitoring resistance. The estimated $LC_{50}s$ were 59.33 µg of lenbutatin oxide/mL and 9.48 µg of cyhexatin/mL of distilled water. The diagnostic concentrations of 180 μ g of fenbutatin oxide/mL and 56 μ g of cyhexatin/mL of distilled water were chosen for monitoring the susceptibility of *B. phoenicis* to these acaricides. No significant differences in susceptibility of *D. phoenicis* to organotin acaricides were observed in populations collected from citrus groves which received different regimes of organotin acaricide applications. The susceptibilities to fenbutatin oxide and cyhexatin of B. phoenicis populations collected from commercial citrus groves were similar to that of the susceptible reference population. No success was obtained in attempt to select an organotin-resistant strain under laboratory conditions. Index terms: citrus, fenbutatin oxide, cyhexatin.

[2083] COMBINED APPLICATION OF MATING DISRUPTION AND BACILLUS THURINGIENSIS FOR CONTROL OF THE BERRY MOTH IN GREEK ISLANDS, LIMNOS AND SAMOS

A.G. Koutroubas¹, E. I. Navrozidis², Z.D. Zartaloudis² & G.K. Salpigidis², ¹National Agriculture Research Foundation, Plant Protection Institute of Volos, 380 01 Volos, Greece.2. National Agriculture Research Foundation, Plant Protection Institute of Thessaloniki, 570 01 Thermi, Thessaloniki, Greece.

The berry moth (Lobesia botrana D+S Lepidoptera Tortricidae) is the most important pest of grapeving in South Europe. Its main host plant is the european grapevine. (Vitis vinifera L.). During the last three years an integrated control program against the berry moth was applied in the Greek islands of the Aegean Sea, Limnos and Samos. In a vineyard of 25 ha in Limnos and 30 ha in Samos, the method of mating disruption was applied against the first and second generation of the berry moth while Bacillus thuringiensis in the rest of vineyards of the islands an integrated control program with two sprays of Bacillus thuringiensis per generation was applied, against the moth. The results showed that the dry and warm climate of the islands was the main reason for the significantly and gradual reduction of stored pheromones in the dispensers during the mating disruption. Therefore, it was necessary to spray against the third generation with Bacillus thuringiensis. In both cases the results were satisfactory when compared with the usual chemical control in which many applications of wide spectrum insecticides were used. The number of beneficial arthropods were increased significantly in the vineyards where mating disruption method and Bacillus thuringiensis were applied.

Index terms: Vitis vinifera , Lobesia botrana, Integrated management
[2084] INDUCED DISEASE RESISTANCE IN NORWAY SPRUCE AND ITS IMPLICATIONS FOR BARK BEETLE POPULATION DYNAMICS

P. Krokene, E. Christiansen & H. Solheim, Norwegian For. Res. Inst., N-1432 Ås, Norway.

A series of experiments since 1995 have demonstrated that pretreatment inoculation of Norway spruce (Picea abies) stems with pathogenic fungi induce enhanced resistance to subsequent massive fungal infections or mass-attacks by bark beetles. This induced resistance response follows dose-response dynamics, is non-systemic and induces resistance only in the pretreated stem section, is non-specific with respect to the type of pretreatment, and enhances tree resistance for up to one year after pretreatment. (1) Dose-response dynamics: Norway spruce trees (~16 m high) from a single clone were pretreated with low, medium and high dosages of cork borer inoculations with sterile agar or the virulent blue-stain fungus *Ceratocystis polonica*. Three weeks later all trees were subjected to a massive C. polonica inoculation. Control trees that received no pretreatment were killed by the mass inoculation. The high and medium fungal pretreatments reduced fungal colonization by 76-97% relative to the control, whereas the low dosage reduced colonization by 20-40%. Pretreatment with fungus was always much more effective than pretreatment with sterile agar. (2) Non-systemic response: Protection was demonstrated to be local and not systemic in an experiment where trees were pretreated with a medium dosage of C. polonica on the lower bole and mass inoculated further up the stem. (3) Pathogen non-specificity: Protection is also pathogen non-specific, as pretreatment with different fungi (Nectria fuckeliana, Heterobasidion annosum, C. polonica) all induce enhanced resistance to mass inoculation with C. polonica. Pretreatment with sterile agar or an avirulent C. polonica isolate induce only weak resistance, and the effectiveness of induction seems to depend on the amount of host tissues that is killed by the pretreatment. (4) Long-term protection: The induced disease response increases tree resistance for at least 1 year after pretreatment. An experiment where trees were pretreated 1-52 weeks before mass inoculation demonstrated that a 1-week interval was insufficient to induce resistance, 3, 6 and 9 weeks were equally effective, and even 52 weeks gave increased tree resistance compared to the untreated control trees. Induced disease resistance in Norway spruce has important implications for the population dynamics of bark beetles. Sub-lethal beetle/fungus attacks will not weaken trees and render them more susceptible to later attacks. On the contrary, such attacks will enhance tree resistance and increase the tree's ability to defend itself against subsequent attacks. Thus, inducible disease resistance in Norway spruce and other conifers could hasten the collapse of bark beetle outbreaks once the beetle population starts to decline and fewer beetles can be summoned to mass-attack trees.

Index terms: blue-stain fungi, induced disease resistance, Ips typographus, Norway spruce, systemic acquired resistance (SAR)

[2085] BIOEFFICACY AND PERSISTENCE OF NPV AGAINST SPODOPTERA LITURA ON COTTON SPRAYED AT DIFFERENT TIMINGS OF THE DAY

Gururai G. Kulkarni¹, P.S. Ilugar² & P.D. Sharma³, ¹⁷³Department of Entomology, CCS HAU, Hisar-125 004, INDIA, ²UAS, Dharwad - 580 005 (Karnataka)

Studies on the persistence of Spodoptera litura Fab. NPV (SINPV) on cotton @ 300 LE/ha with and without sunlight protectant (Boric acid @ 0.1%) at different timings of the day have revealed that SINPV persisted longer when sprayed along with sunlight protectant as compared to when applied alone. Amongst all treatments, higher mortality of *S. litura* larvae was recorded in monorotophos compared to NPV treatments. Among the timings of NPV, application as evening spray (4-6 pm) recorded higher mortality than afternoon (1-3 pm) and morning (9-11 am) sprays in immediately after spray treatment (0 hrs). When the pest was exposed to treated cotton leaves monocrotophos recorded 76.63 and 75.66 per cent larval mortality in 1996 and 1997 seasons respectively, followed by NPV + BA application at 4-6 pm (75.81 and 75.09%), NPV alone at 4-6 pm (63.71 and 60.74%), NPV alone at 1-3 pm (58.46 and 55.22%) and NPV alone at 9-11 am (52.28 and 49.91%) and when sprayed in evening hours, in descending order during 1996 and 1997 respectively. Like wise performance of SINPV along with sunlight protectant at all timings of spray was better than NPV alone.

Key words : Persistence, SINPV, Spodoptera litura, cotton

[2086] DEVELOPMENT OF ENTOMOPATHOGENIC NEMATODES FOR CONTROL OF OVERWINTERING CODLING MOTH LARVAE

L.A. Lacey, T.R. Unruh, R. Chauvin, H. Headrick, and J. Upton, USDA-ARS-YARL, Wapato, WA 98951 USA

ntomonathogenic nematodes (EPNs) have potential as biological control agents of overwintering codling moths. The tree trunk habitat of prepupae and pupae offers a protected environment in which infective nematodes can better survive while searching for and infecting cocooned codling moth larvae. Fruit bins are also used by codling moth larvae as sites in which to spin cocoons. In orchards where codling moths have been controlled during the growing season, infested bins may provide a significant source of invading moths. Treatment of bins for control of codling moth larvae prior to placement in orchards is not currently done. Interventions that could be applied to bins that are safe for humans and that are environmentally friendly would be highly advantageous. Our research demonstrates that entomopathogenic nematodes can provide effective and affordable control of codling moth larvae in fruit bins. The most important factors that influence efficacy of EPNs for codling mot control include the species of EPN, temperature and critical exposure time. Steinernema feltine and S. carpocapsae are among the most active species against codling moth larvae. Larvae that had been treated with infective juveniles (IJs) of S. carpocapsae and incubated at 95+% RH and 25 C are controlled when moisture is maintained for 8 hours or longer. Temperature below 15 C reduces the larvicidal activity of S. carpocapsae, but S. *feltiae* remains active below 10 C. Orchard trials of *S. carpocapsae* were conducted under various moisture conditions in summer 1998. Application of 10⁶ IJs/tree using a hand-gun sprayer provided 95% mortality when trees were wetted before application of nematodes and at regular intervals for 6 hours after treatment. Field trials of S. carpocapsae and S. feltiae in summer 1999 compared airblast sprayer and hand-gun sprayer for application of 2 x 10⁶ IJs/tree. Good control was obtained using S. feltiae with both sprayers and fair to moderate control was obtained with S. carpocapsae when moisture was maintained. Trials in autumn 1999 using a back pack sprayer revealed good activity for both species when temperatures were above 18 C during the six hours following treatment. However, when temperature was lower than 15 C during the six hours following treatment, S. feltiae significantly out performed S. carpocapsae. Diapausing codling moth larvae in fruit bins were highly susceptible to IJs of both EPNs. Immersion of bins in suspensions of S. carpocapsae ranging from 5 to 100 infective juveniles/ml of water resulted in 68-100% mortality.

Index terms: Steinernema carpocapsae, Steinernema feltiae, Cydia pomonella

[2087] FIELD TESTS OF THE INFECTIVITIES OF BEAVERIA BASSIANA (DEUT: HYPHOMYCETES) ISOLATE IMI 335249 AGAINST PANTORIIYTES PLUTUS (COL: CURCULIONIDAE) IN A COCOA SYSTEM

S. Laup, Cocoa & coconut Research Institute, P.O.Box 1846, Rabaul, ENBP, Papua New Guinea

Weevils of the genus Pantorhytes are major pests of cocoa. There is a lack of sustainability in the present control measures against Pantorhytes. The application of Beuveria bassiana on cocoa pods indicated that P. plutus was susceptible to B. bassiana isolates IMI 335249. P. plutus picked up viable conidia applied to the cocoa tree at 1 x 10⁸ conidial concentration in oil formulation. Oil enhanced infection of P. plutus by Beauveria and lower infection incidence resulting from application of conidia in water formulation. Conidia stayed viable in the cocoa ecosystem for more that two months. There was a gradual mortality count couple with the number of insect infected from day 3 to day 30, after a session of fungal application into the cocoa ecosystem. Pickup of viable conidia and infection depends to a large extend on the density of individual insects plus the probability of pickup of conidia by healthy individuals. Symptoms of infection mostly on the intersegemental regions. An approach to the field application of fungal entomopathogen is presented and discussed within the framework of an integrated control management system of Pantorhytes in cocoa ecosystem.

Index terms: Beauveria, infection, Pantorhytes, pest, cocoa, integrated mangement

[2088] IMPACT OF XYLELLA FASTIDIOSA DISEASES IN SOUTH AMERICA

R.P. Leite Jr.¹, ¹Área de Proteção de Plantas, IAPAR, C.P. 481, Londrina, PR 86001-970, Brasil, E-mail ruileite@pr.gov.br. Fellow of CNPq.

Diseases caused by Xylella fastidiosa have been reported from South America as early as the 30's. Plum leaf scald disease (PLS) was first reported in the delta region of the Paraná River, Argentina, in 1935. The disease was later reported from Brazil and Paraguay. PLS was very severe on Japanese plum (Prunus salicina L.) and its hybrids. Contaminated propagative plant material played a major role in the spread of the disease to new areas. The presence of insect vectors is very important for the spread of the bacterium from tree to tree within plum orchards. Orchards of the widely planted Japanese plum Santa Rosa cultivar was vanished by PLS in the Brazilian States of Paraná, Santa Catarina and Rio Grande do Sul in the middle 70's and early 80's. Nowadays, PLS is present in almost all plum growing areas of Argentina and Brazil. Highly praised PLS resistant plum cultivars are not available for planting. Strategy for control of PLS involves basically the planting of disease free nursery trees in isolated areas. Citrus variegated chlorosis (CVC) caused by a strain of X. fastidiosa was first reported in the Northwest region of the State of São Paulo, Brazil, in 1987. A similar disease of citrus called "pecosita" had been reported in the region of Missiones, Argentina, since 1984. CVC is a very serious disease on sweet oranges (Citrus sinensis Osb.), affecting all commercial cultivars of oranges, such as Pera, Hamlin, Natal, Valencia and Folha Murcha. The disease has not been observed in other Citrus spp., as mandarins, lemons, acid limes, and grapefruit. Contaminated nursery trees was the most import way for the spread of CVC to new areas. Several sharpshooters of the Cicadellidae family have been identified as vectors of X. fastidiosa in citrus. The disease is already present in all major citrus growing areas of Brazil, and in the Northeast citrus growing area of Argentina. Disease control strategy involves the production of healthy nursery trees under screenhouse conditions, control of insect vectors, and pruning of affected sweet orange trees. More recently, X. fastidiosa has been associated with a leaf scoreh type of disease on coffee trees (Coffea arabica) in Brazil. Infected coffee trees show marginal necrosis of the leaves, short internodes, and dieback of branches. Association of X. fastidiosa with coffee trees is widely spread and has been found in all coffee growing regions of Brazil. However, no assessment of the damage caused to the coffee crop has been made yet.

Index terms: Citrus, Coffee, Plum, CVC, citrus variegated chlorosis, plum leaf scald

[2089] DOSAGE-RESPONSE VALUES OF B.t.i. AGAINST AEDES AEGYPTI IN VARIOUS CONTAINER IIABITATS

L. A. De Leon, Panama Canal Authority, ESMS, P.O. Box 025594, Miami, FL 33102 - 5594, E-mail : Ideleon@pancanal.com

Field bioassays to determine the effectiveness of *Bacillus thuringiensis* serovar. *israelensis* (*B.t.i.*), were essential steps in the adoption of a standard preparation of the biolarvicide (Acrobe@ 1,200 international toxic unit [ITU/mg) in an aqueous suspension, for routine mosquito control operations against the *Aedes aegypti*. Progeny of field caught larvae reared up to the adult stage were obtained for the tests. Four classes of artificial container habitats (e.g., plastic container, glass bottle, metal bucket and tire) were used comparable to most common situations found within the Panama Canal Commission's housing and operational areas. Exposure to normal environmental conditions was duplicated. Results showed a general susceptibility of the local population of *Aedes aegypti*, and compare larvicidal activity in the various larval habitats tested. The bacterial suspension showed insecticidal stability under a range of temperature and other environmental conditions. Dosages of *B.t.i* ranged from 3 to 20 milliliters per liter, and mortality ranged from 20 to 100 percent. But concentrations of 4ml/liter and 11.2 ml/liter were the adjusted values for the LD50 and LD90 respectively in the overall picture. Toxicity appeared more prevalent in plastic containers, followed by metal tanks, glass bottles and finally tires, however 100% mortality was attained at the concentration of 20 ml/liter in all the containers. A rounded off dosage of 1 pint of Acrobe® per 5 gallons of water was calculated for large working volumes. [2090] DOSAGE-RESPONSE VALUES OF Acrobe ® BIOLARVICIDE AGAINST Aedes aegypti LARVAE IN VARIOUS CONTAINER HABITATS

L.A. De Leon

Panama Canal Authority, ESMS, P.O. Box 025594, Miami, FL 33102 - 5594 E-mail: Ideleon@pancanal.com

Field bioassays were made to determine a practical dosage of Acrobe @ biolarvicide, Bacillus thuringiensis israelensis (B.t.i.), prior to the adoption of a standard operational preparation of this commercial formulation (1,200 international toxic units of B.t.i /mg) as an aqueous suspension for routine mosquito control against Aedes aegypti larvae. Progeny of adults reared from field caught larvae were used. Four classes of artificial containers (plastic ice cream tubs, glass bottles, metal buckets and used tires) represented some of the most common breeding habitats found within the Panama Canal Authority's housing and operational areas. Exposures were made under local environmental conditions. Results showed an overall susceptibility of the indigenous population of Aedes aegypti and discriminated larvicidal activity of B.t.i in the listed larval habitats. Bacterial suspensions showed insecticidal stability under a range of temperatures and existing environmental regimes. Dosages of Acrobe @ ranged from 3 to 20 milliliters per liter and mortality varied from 20 to 100 percent. Concentrations of 4ml/liter and 11.2 ml/liter provided adjusted values for the LD50 and LD90 mortality levels respectively. Toxicity was greatest in plastic containers, followed by metal buckets, glass bottles and finally used tires, however 100% mortality was attained at a concentration of 20 ml/liter in all types of containers. Based on this study, a rounded dosage of 0.5 liters (approx. 1 pint) of Acrobe@ per 19 liters (approx, 5 gallons) of water was recommended as a practical mix for field applications of Acrobe @, (also sold in international markets as BMP-144X).

[2091] GROWTH OF FUNGI CULTIVATED BY CUTTING ANTS ON MURASHIGE & SKOOG NUTRIENT SOLUTION IN DIFFERENT PH

A. E. Loeck¹, C. R. Pierobom¹, A. P. Afonso¹, C. Zanela¹ & S. Coimbra¹, ¹Dept. of Fitossanidade, Univ. Federal of Pelotas, C. P. 354, RS CEP: 96.010-900, Brasil, Email: alcienim@ufpel.tche.br

For Random Amplified Polymorfic DNA (RAPD) analyses there is the need of growing fungi in a mineral culture medium to avoid contamination with DNA organic components. A experiment was done with the fungi cultivated by Atta laevigata (F.Smith, 1858) and Acromyrmex laticeps (Emery, 1905) grown in Murashige & Skoog Basal Salt with pH 4, 5, 6 and 7. Petry dishes were incubated at 25 1°C, in the dark, for 63 days. Bigger colony diameter occurred at pH 4 and 5 for both fungi.

Symposium and Poster Session

[2092] EFFICIENCY OF DIFFERENT CULTURE MEDIA IN THE IN VITRO GROWTH OF FUNGI CULTIVATED BY DIFFERENT LEAF CUTTING ANT SPECIES

A. E. Loeck¹, C. R. Pierobom¹, A. P. Afonso¹ & C. Zanela¹, ¹Dept. of Fitossanidade, Univ. Federal of Pelotas, C. P. 354, RS CEP: 96.010-900, Brasil, E-mail: alcienim@ufpel.tche.br

Aiming to increase growth of fungi cultivated by leaf cutting ants the following culture media were compared: Pagnocca (glucose 10g, sodium chloride 5g, peptone 4g, malt extract 16g, agar 10g, water 1000 ml); MS (ammonium nitrate 1650 mg, boric acid 6,2 mg, calcium chloride (anhydrous) 332,2 mg, cobalt chloride. $6H_2O$ 0.025 mg, cupric sulfate. $5H_2O$ 37.26 mg, ferrous sulfate 180.7 mg, manganese sulfate 16.9 mg, mollybdic acid (sodium salt).2H₂O 0.25 mg, org. gobalt chloride 0.83 g, potassium nitrate 1900 mg, potassium phosfate monobasic 170 mg, zinc sulfate. 7 H₂O 8.6 mg, agar 18g) and celulose asparagine (ammonium sulfate 0.5 g, L-asparagine 0.5 g, potassium phosphate 1 g, potassium chloride 0.5 g, mgnesium sulphate 0.2 g, calcium chloride 0.1 g, yast extract 0.5 g, cellulose 10 g, agar 20 g, water 1000 ml).Fungi from colonies of Atta sexdens piriventris Santschi, 1918 and Acromyrmex heyer Forel 1899, were used. Incubation was in BOD at 25 1°C, in the dark. Fungi from Atta sexdens piriventris developed colonies with bigger diameter in Pagnocca medium and smaller in MS. Colonies of fungi from Acromyrmex heyeri were also better in Pagnocca but the smallest diameters were in V8, with growth in MS superior to fungi from Atta sexdens piriventris. The results show interaction among isolates and culture media and also the possibility of in vitro growing of fungi cultivated by leaf cutting ants in a mineral medium.

[2094] EFFECTS OF VETIVER OIL AND ITS CONSTITUENTS ON COPTOTERMES FORMOSANUS AND ITS SYMBIOTIC FAUNA

L. Maistrello¹ & G. Henderson¹, ¹Dept. of Entomology, Louisiana State University Agricultural Center, 402 Life Sciences Bldg., Baton Rouge, LA 70803, USA, E-mail: Imaistrello@agetr.lsu.edu

Vetiver grass (Vetiveria zizanioides) is an Indian native plant whose domesticated type is cultivated worldwide in tropical and subtropical regions for its effectiveness against soil erosion and for the commercial importance of its oil, extracted from the roots. Vetiver grass is known to be naturally resistant to arthropod pests and diseases and vetiver oil is reported to repel insects from skin and clothes and to have a potent topical irritant activity on flies and cockroaches. Vetiver oil is an extremely complex mixture of 300 compounds: among these nootkatone and α - and β -vetivone have been identified to show termite repellent properties. Lower termites, such as C. formosanus, rely on the protozoa living inside their gut for the digestion of their cellulose food. Therefore substances negatively acting on protozoa survivorship may indirectly affect termite survival. As part of our research on natural product efficacy against Formosan subterranean termites, experiments have been performed to test the response of C. formosanus to various substrates and food sources treated with vetiver oil, nootkatone and α - and β -vetivone. Evaluations of tunneling behavior, measurements of food consumption, variation in the number of different species of symbiont protozoa present over time, variation in individual termite weight and termite survivorship were recorded. The results showed that vetiver constituents, especially nootkatone, negatively effect termite physiology and behavior and may represent promising natural alternatives as termite repellents.

Index terms: Formosan subterranean termites, Vetiveria zizanioides, nootkatone, termite repellents, symbiotic protozoa

[2093] FIELD TRIAL WITH THE ENTOMOPATHOGENIC FUNGUS METARHIZIUM ANISOPLIAE VAR. ACRIDUM AGAINST BANDS OF THE GRASSHOPPER KHAMMATOCERUS SCHISTOCERCOIDES IN BRAZIL

B.P. Magalhães¹, M. Lecoq², M.R. de Faria¹, F.G.V. Schmidt¹, J.B.T. Silva¹ & W.D. Guerra³, ¹Embrapa Genetic Resources and Biotechnology, P.O. Box 2372, Brasília, DF, Brazil, CEP 70849-970; ²CIRAD (Prifas), B.P. 5035, 34032 Montpellier Cedex I, France; ³MA/DFA, Alameda Anfbal Molina s/n, Várzea Grande, MT, Brazil, CEP 78115-140.

The efficacy of a mycoinsecticide formulated in vegetable oil was tested in Brazil against the grasshopper *Rhammatocerus schistocercoides*. A set of experiments was conducted in the Chapada dos Parecis region (Mato Grosso state), a permanent zone of outbreaks for this pest. Experiments were performed in zones of natural vegetation, against grasshopper bands in the third nymphal instar. Three nymphal bands were treated with a the mycoinsecticide formulation based on conidia of the entomopathogenic fungus *Metarhizium anisopliae var. acridum* (= *M. Javoviride*), strain CG 423. Three non-treated bands were used as control. The application was made with the aid of a hand-held ULV sprayer adjusted to deliver 2 litres of the formulation/ha, each containing 1 x 10¹³ conidia. Treatments were limited to the surface of the grasshopper bands and their immediate borders (5-10 m). The efficacy of the mycoinsectise, density, behaviour and daily movement of the band), allowing the insects to move freely in their natural environment. Insects were regularly surveyed and maintained in the laboratory, allowing estimates of the product 10 days after treatment. At 14 days post-spraying, mortality caused by the mycoinsecticide in the field was approx. 88%.

Index terms: entomopathogenic fungus, Metarhizium anisopliae var. acridum, Metarhizium flavoviride, grasshopper, Rhammatocerus schistocercoides, oil formulation, field trial

[2095] LARGE SCALE BACILLUS SPHAERICUS PRODUCTION

L. M. de A. C. Maranhão¹, E. M. M. M. Rios², D. M. P. da Silva¹, F. J. Cavalcanti Neto¹, W. M. Ferreira¹ & A. C. da Silva¹, ¹Empresa Pernambucana de Pesquisa Agropecuária - IPA, C.P. 1022, Recife, PE, Brasil; ²Universidade Federal de Pernambuco - UFPE, Av. Prof. Morais Rego, s/n, CEP 50.670-901, Recife, PE, Brasil. Support: Departamento de Antibióticos/UFPE, FACEPE, FINEP.

Bacillus sphaericus production for Culex quinquefasciatus control is implanted in Empresa Pernambucana de Pesquisa Agropecuária - IPA, as a result of institutional interactions. The fermentative process employs culture medium based in skim milk, supplemented with mineral salts, producing, after 48 hours, at 30°C, a fermented broth containing about 10° viable spores per milliliter and LC₅₀ = 30µg/L. The innoculum, corresponding to 3% of the final volume of fermentation, is prepared in nutritive broth enriched with yeast extract, adopting a propagation schema which employs from agitated flasks to bottles containing 15 liters of the medium, with air injection. The control of the fermented broth includes the survey of microorganisms which could contaminate the process. Tests accomplished with the material kept under refrigeration, indicated toxic activity stable for six months. The field assays, accomplished in many cities in different regions of Pernambuco State, showed efficiencies of 80 to 100% and a persistence varying from 2 to 167 days, depending on conditions and peculiarities of the sites treated: lakes, waterways, cesspools, gutters, inspection boxes.

Index terms: Bacillus sphaericus, Culex quinquefasciants, entomopathogenic bacteria.

[2096] EFFECT OF SUNLIGHT ON THE RESIDUAL ACTIVITY OF A TABLET FORMULATION BASED ON BACILLUS THURINGIENSIS ISRAELENSIS AGAINST AEDES AEGYPTI LARVAE

M. A. V. Melo¹ & L. Regis², ¹ Mest. em Biologia Animal, Dept. de Zoologia, Univ. Fed. de Pernambuco, Av. Moraes Rego, CEP-50670-420, Recife, PE, Brazil. ²Dept. de Entomologia, Centro de Pesquisas Aggeu Magalhães/FIOCRUZ, Av. Moraes Rego, CEP-50670-420, Brazil, E-mail mavarjal@cpqam.fiocruz.br. Supported by FACEPE/CAPES (PNPPG) and CNPq.

A tablet formulation of *Bacillus thuringiensis israelensis* Vectobac® Abbott (5000 ITU/mg) showed an initial efficacy against *Aedes aegypti* larvae in previous laboratory tests. The aim of this study was to investigate the effect of sunlight on its residual activity. Experimental containers filled with 40 litres of tap water and treated with one tablet, were submitted to two different conditions: indoor and outdoor. Outdoor containers were kept either in shade or exposed to direct sunlight for 120 minutes daily. Seventy early fourth-instar larvae were then introduced every three days into each container, and the percentage mortality was determined 48 hours thereafter. The containers were removed when less than 70% mortality was recorded. The formulation showed good efficacy after application, killing 100% of the larvae under both conditions, but significant difference in residual activity were observed. Lower persistence was observed in the outdoor, sun-exposed experiment (5 days) when compared with the shade and indoor test where the product remained active for 23 and 44 days, respectively. These results suggest that the toxins are degraded by ultraviolet light (UV). We conclude that product shows good residual activity when used indoor, lasting for more than 40 days.

Index terms: Bacillus thuringiensis israelensis, Aedes aegypti, formulation, control persistence

Symposium and Poster Session

[2098] INTERACTION OF THE ENTOMOPATHOGENIC FUNGUS, PAECILOMYCES FUMOSOROSEUS (DEUTEROMYCOTINA: HYPHOMYCETES) WITH THE PARASITOID, APHELINUS ASYCHIS (HYMENOPTERA: APHELINIDAE) AND THEIR COMPETITION FOR AN APHID HOST

A. L. M. Mesquita¹ & L. A. Lacey², ¹Embrapa/CNPAT – Cx. Postal 3761 60511-110 Fortaleza-CE Brazil, E-mail: mesquita@cnpat.embrapa.br

European Biological Control Laboratory, USDA-ARS, Parc Scientifique Agropolis, 34397 Montpellier Cedex 5, France

The interaction between the hyphomycete, Paecilomyces fumosoroseus, the Russian wheat aphid, Diuraphis noxia, and its common parasitoid, Aphelinus asychis, was investigated under laboratory conditions to determine if fungal infection of the aphid host had some effect on oviposition and feeding behavior of the female parasitoid and on development of parasitoid progeny. Similarly, the effect of previous parasitization by the wasp on the ability of the fungus to produce subsequent infection and interfer with parasitoid development within host aphids was investigated. The aphids were first infected with 2 times the LD₉₅ of P. fumosoroseus for D. noxia 3rd instars (5.2 x 104conidia/cm2) and at various intervals afterward exposed to 4-5 d-old parasitoid females for 1 h. Various combination of treatments were examined: exposure to P. fumosoroseus and parasitization simultaneously; aphids being infected and then exposed to the parasitoid 24, 48, and 72 h afterwards; aphids being killed by the fungus and exposed to the parasitoid (maximum 24 h after death); parasitoid alone; and fungal infection alone. The fungus required 3-5 d to kill the host and the parasitoid took 6 d at 22-24 C, 80-87% RH. The average number of aphids stung by parasitoids was not influenced by host infection with *P. funnosoroseus* but duration of ovipositor insertion was influenced by the length of the time interval between exposure to P. fumosoroseus and subsequent exposure to parasitoid females. A. asychis females spent considerably less time with their ovipositor inserted in dead aphids and aphids that had been exposed to P. fumosoroseus 72 h prior to contact with the parasites. The number of dead aphids fed upon by parasitoids was significantly less than in the other treatment groups. These observations indicate that probing by A. asychis provides information concerning host suitability. The percentage of successfully parasitized D. noxia was significantly reduced as a function of the time between infection with P. fumosoroseus and parasitization.

Index terms: Russian wheat aphid, *Diuraphis noxia*, biological control, natural enemy interaction.

[2097] GENERA OF ENCYRTIDAE (HYMENOPTERA: CHALCIDOIDEA) PARASITOIDS OF MEALYBUGS (HEMIPTERA: PSEUDOCOCCIDAE) IN NEOTROPICAL REGION

A. O. Menezes Jr.¹, ¹Universidade Estadual de Londrina, Depto. de Agronomia, Cx. Postal 6001, Londrina, PR 86.051-970, BRAZIL, E-mail ayres@sercomtel.com.br

Many species of mealybugs are known to feed on a variety of agricultural crops. When in high numbers, they could damage the host-plant by sap-sucking, injecting toxins, transmitting viruses or excreting honeydew. Normally, mealybug populations are kept under acceptable levels by natural enemies as predators and parasitoids, particularly in their original regions. Almost all primary parasitoids of mealybugs belong to the chalcidoid family Encyrtidae, represented by species of more than 50 genera in New World. Certainly, these parasitoids play a major role in regulating the populations of mealybugs that, otherwise could arise to pest levels. Many species os encyrtids have been used in biological control programmes along the XX century against mealybugs pests such as Dysmicoccus brevipes on pinapple, Antonina graminis on pasture grasses, Saccharicoccus sacchari on sugarcane and others. The control of the cassava mealybug in Africa is a recent successful case where neotropical species were used as biocontrol agents. The specimens studied were obtained from field collecting (swep net and yellow pan trap), host emergence and museum loan. Fifty five genera of eight tribes belonging to the Encyrtinae and Tetracneminae subfamilies were treated, including mostly of the primary and secundary parasitoids associated to mealybugs in the Neotropical region. An identification key to generic level and a diagnoses were provided to each genera, complemented with information related to number of described species, known hosts and geographical distribution. As a result of field and host collecting in Brazil, five genera were registered for the first time to the country, viz. Aeptencyrtus De Santis, Clausenia Ishii, Cocidoxenoides Girault, Holcencyrtus Ashmead and Parapyrus Noyes. The following were also obtained from fieldwork: Accrophagus Smith, Metaphycus Mercet, Pseudaphycus Clausen, Cheiloneurus Westwood, Prochiloneurus Silvestri, Aenasius Walker, Blepyrus Howard, Zarhopalus Ashmead, Guhaniella Timberlake, Anagyrus Howard, Apoanagyrus Compere, Gyranusoidea Compere, Leptomastix Förster, Leptomastidea Mercet, Tetracnemoidea Howard and Tetracnemus Westwood. Species of Aenasius, Anagyrus and Apoanagyrus were the more often collected associated to mealybug-hosts during the survey

Index terms: Encyrtinae, Tetracneminae, Aenasini, Anagyrini.

[2099] GENETIC CHARACTERIZATION OF BACULOVIRUS SSMNPV, A PATHOGEN OF STILPNOTIA SALICIS (LYMANTRIDAE) ISOLATED IN POLAND

<u>J Michalik^{1,2}</u>, E.Szolajska¹, J.Ziemnicka³ & L.Strokovskaya⁴, Inst. Biochem. & Biophys ,PAS, Pawinskiego 5A, 02-106 Warsaw, Pl, Kielee,Pl Inst.Plant Protection Miczurina 10, 0 Poznan,Pl, Inst. Mol.Biol.,Zabolotnogo115, Kiev Uk.

Baculoviruses comprise a diverse group of pathogens infectious for arthopods particulary lepidopteran insects. Over 500 species of insects have been reported to be infected with baculoviruses, which include members of the occluded subgroups A (nuclear polyhedrosis viruses, NPVs), B (granulosis viruses) and the non-occluded subgroup C. Although all baculoviruses have a double-stranded, supercoiled DNA genome packed in rod-shaped enveloped nucleocapsid , the size of the genome differs considerably between baculovirus isolates. In addition baculoviruses demonstrate diversity in viral infectiwity spectrum for host insects with many baculoviruses demonstrating a very narrow host range (Crook, 1981). Despite the evident diversity of baculovirusers , little is known about genetic relationships existing between different members. A series of investigators have compared the relatedness of the genoms of the multicapsid NPV of Orgyia pseudotsugata (OpMNPV) and Autographa californica (AcMNPV). It was observed Baculovirus infecting satin moth (Stilpnotia salicis) larvae, living on poplar trees, was isolated from dead larvae of last instar and characterized by restriction analysis of the genome. SsMNPV is typical nucleopolyhedrovirus of the genome size established as 128-134 kb, based on Hind III and Sac I restriction analysis. The only permisive cell line found by us for virus propagation in laboratory was IPL-Ld-65Y, coming from Lymantria dispar larvae. Restriction analysis made with several typical enzymes revealed that the most useful for further analysis of the genome are: Hind III, Xho I, Sac I, Eco RI, Pvu II, Sal I and Pst I. Partial sequence analysis of SsMNPV genome revealed that there is a big homology of several gen sequences to Orgyia pseudotsugata. In pohyhedrin gen this similarity is as high as 99%. Also flanking sequence of polyhedrin gen: promotor region and ORF1629 show very high sequence similarity. Also the orientation of polyhedrin and ORF 1629 in baculovorus genome is characteristic to Orgyia pseudotsugata and opposite to Autographa californica This suggests that SsMNPV isolated in Poland is a variant of OpMNPV virus although a natural hosts for both viruses live on different continents: Europe and America.

[2100] RESPONSE OF COPTOTERMES FORMOSANUS SHIRAKI TO ISOLATES OF METARHIZIUM ANISOPLIAE IN THE UNITED STATES: VIRULENCE AND REPELLENCY

R. J. MILNER¹, <u>J. E. POWELL²</u>, & M. S. WRIGHT³, 1csiro Entomology, Gpo box 1700, act 2601, Australia; 2usda, Agricultural Research Service, P O Box 225, Stoneville, Ms 38776, Usa, e-Mail: jpowell@ars.usda.gov; 3usda, Agricultural Research Service, 1100 Robert E. Lee Boulevard, New Orleans, la 70124, Usa.

One of the challenges to controlling subterranean termites is their ability to avoid toxic materials. When using fungi, one goal is to get the workers to spread the pathogen throughout the nest. This can only take place if the fungus is not highly repellent. We found that Coptotermes formosanus responded differently to the four isolates of Metarhizium anisopliae var. anisopliae that we applied in a wide range of doses. Three isolates were isolated originally in Australia (FI-610, FI-1186, FI-1248) and one in the USA (FI-1218). Conidia were produced on moist, sterile rice. Ten-fold serial doses ranged down from 3x10⁸ conidia/ml. Workers were dosed by dipping in the fungal suspension, then 40 insects were used per isolate at each dose for each colony tested. Four replications were monitored. Infection was confirmed by allowing sporulation to occur on dead test insects. FI-610 was the most virulent isolate and caused 100% mortality down to dose 3 (actual dose 5×10^5 conidia/ml). FI-1186 was least virulent causing 97.3% mortality at dose 2 (5 x 106 conidia/ml). Overall, all four isolates were virulent for the Formosan subterranean termite. To clarify differences in virulence between isolates, another bioassay was established using a more restricted range of doses. The most virulent isolate here was FI-1248, with FI-1186 again exhibiting less activity against worker termites. Little difference existed between FI-610 and FI-1248, with FI-1218 being less virulent and FI-1186 being least virulent. Compared with similar bioassays undertaken in Canberra with Coptotermes lacteus workers, C. formosanus is less susceptible to the four isolates. Further experimentation confirmed pathogenicity of each of the isolates when spores were combined with a formulation. Even at the highest dilution, 1:100 spores/formulation, strains HI-610, HI-1218 and HI-1248 resulted in >90% mortality between 2 and 5 days. This dilution scheme probably best represents the self-dosing regime in which *Metarhizium* will be used to control the Formosan subterranean termite through field applications. Based on laboratory observations, repellency of the Formosan subterranean termite to spores in order of least to greatest was FI-1186, FI-1248, FI-610 and FI-1218.

Index terms: Formosan subterranean termite, biological control, behavior, entomopathogen, fungus

[2101] DETECTION OF WOLBACHIA FROM ORIUS SPP. IN JAPAN

K. Miura¹², Y. Tagami², I. Ohta¹ & T. Shimizu³, ¹ Chugoku Natl. Agri. Exp. Stat., Fukuyama 721-8514, JAPAN, E-mail miurak@cgk.affrc.go.jp;² Hiroshima Univ., Higashi Hiroshima 739-8528, JAPAN;³ Natl. Ins. Seri. Entomol. Sci., Tsukuba 305-8634, JAPAN.

Five species of Orius ,which are important natural enemies, were examined for Wolbachia infection. Amplifies bands were detected from all investigated species with Wolbachia-specific polymerase chain reaction primers. Bacterial 16SrDNA was amplified by PCR and then sequence them. Molecular phylogenetic analysis demonstrated that the sequence belongs to a monophyletic group of the genus Wolbachia in the a-Proteobacteria. In 15 geographic populations of Orius spp., all the individuals examined possessed the Wolbachia. This fact indicates that Wolbachia was universally distributed among natural populations of Orius spp. We generated DNA sequences from Gene Bank. Phylogenetic analyses indicated that all the Wolbachia symbionts in Orius spp. may be descendants of a single ancestral infection. Index terms: Orius spp., Wolbachia, symbiont.

[2102] A CULTURE COLLECTION OF BACILLUS THURINGIENSIS AND BACILLUS SPHAERICUS PATHOGENIC TO INSECTS

R. G. Monnerat, J. O. Silva-Werneck, S. F. Silva, K. Bonfim, R. P. Pessanha, M. S. Aguiar & S. D. N. Nobre, Embrapa Recursos Genéticos e Biotecnologia, Parque Estação Biológica PqEB Final W3 Norte, P.O Box 02372. Brasília, DF, E-mail rose@cenargen.embrapa.br

Since 1989, the Microbial Pest of Control Laboratory of Embrapa Genetic Resources and Biotechnology Biological has isolated (WHO, 1985), identified, characterized and storicd *Bacillus spp.* to control insects pests with the purpose of creating a culture collection. The isolates are stored in sterile filter paper strips in glass sealed anpoules. This way, the isolates genetic characteristics are preserved for a long term, without suffering contamination. At present the culture collections contains 277 isolates of *Bacillus sphaericus* and 439 *Bacillus thuringiensis*. Pathogenicity tests were done against Diptera (*Culex quinquefasciatus and Aedes aegypti*), Lepidoptera (*Anticarsia gemmatalis, Plutella xylostella* and *Spodoptera fragiperda*) and Coleoptera (*Anticarsia gemmatalis, Plutella xylostella* and *Spodoptera fragiperda*) and Coleoptera (*Tenebrio molitor*). From 277 isolates of *Bacillus sphaericus*, 85 have already been serotyped. The majority (78) serotype H5aH5b and 125 are efficient against the urban mosquito *Culex quinquefasciatus*. From 439 isolates of *Bacillus thuringiensis*, 107 are serotyped and 329 were evaluated against *Aedes aegypti* and 55 showed positive results. Also, 350 were tested against *Culex quinquefasciatus* 27 showed positive results. From 432 evaluated against *Culex quinquefasciatus* 27 showed positive *against Plutella xylostella*, 87 are pathogenic and from 202 evaluated against *Tenebrio molitor*, 16 can be considered pathogenic.

Index terms: Culex quinquefasciatus, Aedes aegypti, Anticarsia gemmatalis, Plutella xylostella, Spodoptera frugiperda, Tenebrio molitor.

[2103] PATHOGENICITY OF NEW ISOLATES OF BACILLUS THURINGIENSIS AGAINST LEPIDOPTERAN AND DIPTERAN PESTS

R.G. Monnerat¹, S.F. Silva¹, K. Bomfim¹, R.P. Pessanha¹, M.S. Aguiar¹, S.D. Nobre¹ & J.O. Silva-Werneck¹, ¹Embrapa Recursos Genéticos e Biotecnologia, P. O. Box 02372, 70849-970, Brasília, DF, Brazil. E-mail: rose@cenargen.embrapa.br

Bacillus thuringiensis is an aerobic bacterium that during sporulation synthesizes crystalline inclusions composed of δ-endotoxins. These toxins show specific activity against insects and other invertebrates. The use of this agent in insect biological control is a promising alternative in view of technical, economic and environmental considerations, since its action is restricted to the target insects, and is harmless to other organisms. Bioinsecticides based on B. thuring iensis have been successfully used against lepidopteran, dipteran, and coleopteran pests. B. thuring iensis is ubiquitous, isolated from soil, water and dead insects. Laboratories worldwide look for new strains of this bacterium aiming to find isolates with different activity spectra or greater efficient against certain insects than known isolates. The goal of this work was to evaluate the pathogenicity of new isolates of B. thuringiensis from soil samples of different Brazilian regions, deposited in the Bacillus Germplasm Bank of Embrapa Genetic Resources and Biotechnology, against the velvet caterpillar (Anticarsia gemmatalis), fall armyworm (Spodoptera frugiperda), and mosquito larvae (Aedes aegypti). Sixty nine isolates were tested by selective bioassays, using an artificial diet, under controlled conditions. Fifteen of the isolates caused mortality equal or greater than 40% in *A. gemmatalis* and 9 produced this mortality level in S. frugiperda.

Index terms: Anticarsia gemmatalis, Spodoptera frugiperda, Aedes aegypt, biological control.

[2104] ANOTHER CASE OF INSECT AND TARSONEMID MITE (ACARI: TARSONEMIDAE) ASSOCIATION

G. J. de Moraes^{1,2}, A. C. Lofego¹ & E. Berti Filho¹, ¹Depto. Entomol., Fitop. e Zool. Agrícola, ESALQ/ USP, 13418-900 Piracicaba-SP, Brazil, E-mail gimoraes@carpa.ciagri.usp.br; ²CNPq Researcher.

Mites of the family Tarsonemidae are considered to have the greatest diversity of feeding habits within the Acari. The genera in the subfamily Acarapinae are known to be parasitic on insects, and can be recognized by the long, nearly straight cheliceral stylets and the invariable absence of prodorsal trichobothria in all stages of both sexes. The subfamily is divided into two tribes, Acarapina (Acarapis) and Coreitarsonemia, Asiocortarsonemus and Coreitarsonemus), the former associated with Apis bees and the latter, with Coreidae bugs. The bette Homalinotus coriaceus, Curcutionidae, is a Neotropical borer of floral peduncles of different palm trees in Brazil, where it is widespread. All stages of a new tribe, genus and species of São Paulo, Brazil. Nothing is known about the possible effect of the mite on the host. This is the first report of an association of Acarapinae with an insect in the order Coleoptera.

Index terms: Curculionidae, Arecaceae, mite, Acarapinae, parasitism

[2105] DESTRUCTION OF BACTERIA IN THE DIGESTIVE TRACT OF THE MAGGOT OF THE GREEN BOTTLE FLY, *PHAENICIA SERICATA*

<u>K. Y. Mumcuoglu</u>,¹ J. Miller,¹ M. Mumcuoglu,¹ M. Friger² & M. Tarshis³, ¹Dept. of Parasitology, The Kuvin Center for the Study of Infectious and Tropical Diseases, ²The Interdepartmental Unit, The Hebrew University-Hadassah Medical School, Jerusalem, and ³Department of Epidemiology and Health Evaluation Services, Faculty of Health Sciences, Ben-Gurion University, Beer-Sheva, Israel

Maggots of the green bottle fly, Phaenicia sericata were first used for the treatment of suppurative skin infections by Baer in 1931. This method was used extensively in the 1930's and 1940's, and then abandoned with the introduction of antibiotics and the use of aggressive surgical debridement. Ten years ago maggot debridement therapy was reintroduced and thousands of patients have been treated by this technique in USA, Great Britain, Germany, Switzerland, Sweden and Israel. Baer observed that the maggots significantly reduced the number of bacteria in wounds and called them "viable antiseptics". He suggested that bacteria are killed as they pass through the maggot intestinal tract. In order to investigate the fate of bacteria in the alimentary tract, sterile maggots were incubated with a GFP-producing E. coli and the digestive tract was subsequently removed. The presence of bacteria in the different parts of the intestinal tract was studied using a Zeiss 410 laser scanning confocal microscope. A computer program was used to analyze the intensity of the fluorescence. The crop and the midgut were the most heavily infected areas of the intestine. A decrease in the amount of bacteria toward the end of the midgut was observed. The number of bacteria decreased even more significantly in the anterior part of the hindgut and practically no bacteria were seen in the posterior end, near the anus. The viability of bacteria in successive regions of the alimentary tract was studied on LB agar plates.

[2106] POTENTIAL IN AUSTRALIA FOR A HELICOVERPA BACULOVIRUS

D.A.II. Murray, R.J. Lloyd & J. Boddington, Department of Primary Industries Po Box 102 Toowoomba Q 4350 Australia.

Helicoverpa armigera is a scourge for producers of fibre, grain, fodder and food crops in Australia, costing an estimated A\$225M annually in chemical control and lost production. Reliance on conventional synthetic insecticides has turned a full circle. More than 20 years ago a Helicoverpa nucleopolyhedrovirus (NPV) made a foray into the Australian insecticide market. Eventhough it had many of the altributes of a successful biopesticide, it did not compete in the market place with the new synthetic pyrethroids and carbamates. Insecticide resistance to these insecticide groups has changed the outlook as control of H. armigera is unreliable using conventional chemistry. There are also increasing pressures to adopt sustainable insect pest management approaches that embrace a responsible attitude towards the environment and the community. In late 1998, a Helicoverpa NPV, under the trade name Gemstar®, was registered in Australia for Helicoverpa spp. control on grain sorghum and chickpea. Registration on cotton was approved in January 2000. The imported product costs about A\$60/L and is used at rates from 100 to 500 mL/ha. There has been an amazing uptake of Gemstar in the marketplace as pest managers recognise the potential contribution of this product. Limited use on a suite of other crops is allowed under permit. The adoption of Gemstar has been accompanied by a growing acceptance that total pest control is not achievable nor necessary in many of today's crops. Conservation of natural enemies is fundamental to this approach. Gemstar has delivered the goods, but it should not be used like any other insecticide. Education and understanding how Gemstar works are crucial, as are application and tinuing. Much of the current effort with Gemstar is to improve its performance and broaden the registration suite. The addition of milk powder has repeatedly improved field performance of Gemstar. Various other additives have been evaluated, but none of these were equivalent to milk powders. Increasing persistence of NPV through the use of UV protectants has not been delivered, and in some crops multiple low rates are viewed more favourably than a single high rate application. Ultra low volume application has demonstrated its potential for cost effective *Helicoverpa* management in grain sorghum. An *in vitro* NPV was equivalent to Gemstar in initial field trials. The future for Helicoverpa NPV in Australia is very promising. It has comented a niche in the marketplace, and this will invariably expand as users fully understand its capabilities. A locally produced in vitro product will also strengthen its share in a competitive insecticide market. An exciting time is dawning as finally some successful IPM programs are being developed. Just as before, the threat lies in new chemistry that provides a 'simple, quick fix' solution.

Index terms: Helicoverpa armigera, nucleopolyhedrovirus, NPV, in vitro

[2107] PHYLOGENETIC RELATIONSHIPS AMONG EUPTYCHIINE BUTTERFLY GENERA USING MORPHOLOGY AND MOLECULAR DATA

D. L. Murray, Dept. of Entomology, Louisiana State Univ., Baton Rouge, LA 70803, USA, E-mail dmurray@unix1.sncc.lsu.edu.

There are approximately 300 species and 43 genera of wood nymph butterflies in the diverse subtribe Euptychina (Nymphalidae: Satyrinae). Euptychines range from central United States to Argentina, with the greatest diversity in the Amazon, and are found in a wide variety of habitats. The natural history and evolutionary relationships of these butterflies are largely unknown even though the group contains some of the most abundant and widely distributed butterflies in the Americas. Little work has been attempted on the group since the 1960=s, and the present classification is one of the most confusing in butterfly systematics. Traditional adult morphological character systems have not been useful in resolving the generic classification of the group or even confirming monophyly of the euptychine clade. In this study phylogenetic relationships among genera are hypothesized from cladistic analysis of larval and molecular characters. In surveying larvae for informative characters, all available instars were used, and analysis includes serial homologies of setae through the instars. Molecular data used is from DNA sequencing of the motochondrial gene cytochrome oxidase I (COI). Congruence between morphological and molecular cladograms is discussed, and comparisons are made to life history traits.

Index terms: Lepidoptera, Satyrinae, Euptychiina, larval characters, cytochrome oxidase I

[2108] COMPARATIVE EFFICACY OF BACILLUS THURINGIENSIS FORMULATIONS FOR CONTROL OF RICE LEAF FOLDER AND THEIR EFFECTS ON BIODIVERSITY IN RICE ECOSYSTEM

N. Muthukrishnan, K. Chozhan, M.S. Venugopal & R. Janarthanan, Department of Agricultural Entomology, Tamil Nadu Agricultural University, Agricultural College and Research Institute, Madurai 625 104, Tamil Nadu, India. E-mail nmuthu64@hotmail.com

Rice leaf folder Cnaphalocrocis medinalis is a serious pest in Tamil Nadu, India. We aimed at evaluating susceptibility of C. medinalis to commercial formulations of Bacillus thuringiensis in laboratory and wetland cropping system. In vivo experiments were conducted to measure dose and time-mortality relationship between larvae and wide range of doses, and compared with monocrotophos. Leaf folder larvae exposed during 1st and 2nd instar were much more susceptible than older larvae. No significant differences in susceptibility were found among 4th and 5th instars at lower doses. At higher concentration, 4th and 5th instar larvae had significantly lower mortality than did 3rd instar. The LC₅₀, LC₅₀, LT₅₀ and LT₅₀ values for older larvae were many-fold higher than those of 1st and 2nd instar. Formulation-wise dose and time-mortality relationship of 2nd instar larvae indicated that Halt WP was lethal to 50% larvae at 2g/l and at 16h post treatment (PT), and to 90% larvae at 8.5g/l and at 39h PT. Delfin 2g/i and at 16n post treatment (F1), and 05 90% taivag at 6.3g/i and at 35n F1. Definition WG accounted 2.5g/i and 34h PT as LC_{50} and LT_{50} values, and 11g/i and 95h PT as LC_{90} and LT_{90} values respectively. Agree WP was toxic at 2.8g/i and at 46h PT (LC_{50} and LT_{50}), and 12.7g/i and at 108h PT (LC_{90} and LT_{90}). Biobit WP contributed 50% kill at 3.5g/i and at 73h PT, and 90% kill at 16.3g/i and at 166h PT. Thuricide WS was least effective as its lethal values were 5.2ml/l and 120h PT for 50% mortality, and 20ml/l and 220h PT for 90% kill. However, monocrotophos 36 WSC contributed 50% mortality within 6h PT and at 2ml/l, and 90% mortality at 2.8ml/l and at 14h PT. Based on these results, field evaluation was conducted using low and high rates of application. Monocrotophos at 1000ml/ha was effective in minimizing larval control and leaf damage, and also reduction in biodiversity of non-target fauna. Halt 1250g/ha, Delfin 1500/ha, Agree WP1500kg/ha and Biobit 1750g/ha provided fair to excellent larval control, minimum leaf damage and yielded higher, and enabled good survival in predatory Coleoptera and spiders, and parasitic Hymenoptera. The significance of these results for effective integrated pest management strategies is discussed.

Index terms: Cnaphalocrosis medinalis, B.t. formulations, Dose and time-mortality, held evaluation, natural fauna

[2109] EFFECT OF A FORMULATION OF BACILUS THURINGIENSIS VAR. KURSTAKI ON THE IMMATURE STAGES, LONGEVITY AND FEEDING PREFERENCE OF PODISUS NIGRISPINUS

<u>M. L. Nascimento¹</u>, G. J. de Moraes², D. F. Capalbo³ & A. H. N. Maia³, ¹Dept. Plant Production - FCA/UNESP - Campus of Botucatu P. O. Box 237, E-mail: malu@fca.unesp.br; ²Depto. Entom., Fitop. e Zool. Agricola, ESALQ/USP, 13418-900 Piracicaba, SP; ³EMBRAPA/CNPMA P. O. Box 69, Jaguariúna, SP, Brazil.

The Pentatomidae Podisus nigrispinus is frequently mentioned as a promising biocontrol agent of eucalyptus leaf feeding caterpillars. The pathogenic bacteria Bacilus thruingiensis var. kurstaki (Btk) has been widely used for the control of eucalyptus pests. This studies was conducted to evaluate the effect of a formulation of Btk on the immature stages and on the longevity of two consecutive generations of P. nigrispinus, and toverify the feeding preference of that predator when offered healthy and diseased caterpillars. One hundred eggs of P. nigrispinus were obtained from 5 females and and omly divided into 2 groups of 50 eggs, each maintained by itself in a rearing arena. One of those groups was permanently fed healthy Bombix mori caterpillars (t1), and the other, caterpillars of the same species infected by Btk (t2). For the feeding preference test, 10 recently emerged adults of each sex were used, putting each insect individually in a small Petri dish. The duration of the immature phase was about the same in both treatments and in both generations, ranging from ca. 18 to 21 days. Survivorship was higher for t1 (ca. 80 and 64% in the first and second generations) than for t2 (ca. 56 and 42%, respectively). Significant differences in longevity were observed for males (first and second generation) and females (second generation), been always higher in t2. Healthy and diseased caterpillars were equally accepted as food by P. nigrispinus.

[2110] SUSCEPTIBILITY OF IMMATURE STAGES OF *THYRINTEINA ARNOBIA* (LEPIDOPTERA: GEOMETRIDAE) TO A POSSIBLE PICORNAVIRUS

M.L. Nascimento¹, C.F. Wilcken¹, Q. Novaes², J.A.M. Rezende², E.W. Kitajima³, & C. Orlato¹, ¹Dept. Plant Production - FCA/UNESP - Campus of Botucatu - E-mail: malu@fca.unesp.br; ²Dept. of Entomology, Plant Pathology and Zoology; ESALQ/USP, 13418-900 Piracicaba, SP; ³NAP/MEPA, ESALQ/USP, 13418-900 Piracicaba, SP. Brazil

Thyrinteina arnobia (Stoll) (Lepidoptera: Geometridae) is one of the most destructive pest among defoliator insects in commercial forests of Eucalyptus in Brazil. Chemical control of this pest has not been used due to the extension of planted area and environmental contamination risks. Recent electron microscopy examination of thin sections of tissue from dead larvae of T. arnobia showed the presence of numerous isometric virus-like particles, morphologically similar to viruses belonging to the family Picornaviridae. Purified virus particles were obtained by differential centrifugation of extracts from contaminated larvae and used for antiserum production and to evaluate the susceptibility of different larvae instars to virus infection. The experiments were carried out under laboratory conditions. First to sixth larvae instars, reared on artificial diet, were individually placed in acrylic pots and fed with Eucalyptus grandis leaves previously sprayed with a suspension of unknown concentration of purified virus. The experimental design was randomized in a 2 x 6 factorial. All larvae instars were susceptible to virus infection and died after days feeding. Sixth larvae instar showed the lowest susceptibility to virus infection. Antiserum strongly reacting with purified virus and infected larvae was produced and will be used for further serological and molecular characterization of the putative picornavirus as well as to understand its epidemiology. This entomopathogenic virus species may open up a new perspective for biological control of this pest in Eucalyptus.

Index terms: virus, eucalyptus, biological control

[2111] EFFICACY OF SPINOSAD NATURALYTE INSECT CONTROL AGAINST LOBESIA BOTRANA (LEPIDOPTERA: TORTRICIDAE) ON GREEK VINEYARDS

E.I. Navrozidis¹, E. Pitarn², Z.D. Zartaloudis¹, G.K. Salpigidis¹, D.G. Stavridis³, & A.G. Anthomelidis¹, ¹. National Agriculture Research Foundation, Plant Protection Institute of Thessaloniki, 570 01 Thermi, Thessaloniki, Greece. ². National Agriculture Research Foundation, National Agriculture Research Foundation, National Agriculture Research Foundation, Sigialias 19 & Chalepa, 151 25 Marousi. ³. Technological Educational, Institution of Thessaloniki, School of Agricultural, Technology Department of Plant Production, Lab. of Plant Protection, P.O. Box 145 61, 54 101 Thessaloniki - Greece.

Lobesia botrana (Grape berry moth) is the most destructive pest in Greek vineyards. Broad spectrum insecticides, that are used on grapes may be toxic to beneficial organisms. Spinosad is a new product from Dow AgroSciences derived from the actynomycete bacterium Saccharopolyspora spinosa and is the first active ingredient in the Naturalyte class. In Greece, Grape berry moth has three generations per year. Field trials were conducted during the period 1996-1999 aimed at evaluating the efficacy of spinosad. The product was applied in two spray programs. One was targeted at the beginning of the adult flight and the other at the peak, using a range of rates from 4.8-9.6 g.a.i./hl. Flufenoxuron was used as a standard, at the beginning of the flight and labdacyhalothrin at the peak of the moth's flight. Spinosad's ovicidal activity was also evaluated in laboratory experiment. The product was applied on 1, 2 and 3 days old eggs and flufenoxuron and fenoxycarb were used as references. The results of the field trials showed that spinosad was very effective in controlling the grape berry moth using both spray programs. At the beginning of adults flight the rates of 4.8-7.2 g.a.i./hl provided 86-94 % control. The same sates recorded slightly lower efficacy when applied at the peak of grape berry moth flight. This shows that spinosad is very flexible in the timing of application. Flufenoxuron was numerically inferior to spinasad rates, beginning from 7,2 g.a.i./hl and labdaeyhalothrin was weak and inconsistent across the years. The results of the laboratory experiments indicated that spinosad ovicidal activity increased with the age of the eggs. The mortality of 1, 2 and 3 days old eggs was 42.15% and 40.7% and 71.0% respectively. None of reference products showed more than 42 % mortality. In addition, spinosad was very selective to the important predator Chrysopa carnea (Neuroptera: Chrysopidae). Because of its low toxicity to this non target insect, spinosad fits well to an Integrated Pest Management program.

[2112] COMPATIBILITY OF ENTOMOPATOGENIC FUNGI WITH NEONICOTINOIDS INSECTICIDES

P.1. Neves¹, E. Hirose², P. T. Tchujo³ & A. Moino Jr.⁴, ¹Univ. Est. de Londrina (UEL), C.P.6001,86051-970, Londrina/PR-Brazil. E-mail pmojneve@uel.br; ² Fellowship CAPES/Univ. Est. de Londrina (UEL), C.P.6001,86051-970, Londrina/PR-Brazil. Fellowship PIBIC/CNPq/UEL, C.P.6001, 86051-970, Londrina/PR Brazil; ³Univ. Fed. Lavras, C.P.37, 37200-000, Lavras/MG-Brazil. E-mail alcmoino@ufla.br.

The in vitro fungitoxic effect of the neonicotinoid insecticides acetamiprid (Saurus 200 SP), imidacloprid (Confidor 700 WDGr) and thiamethoxam (Actara 250 WG) in three SF), imidacioprid (Confidor 100 wDOr) and infamethoxam (Actara 250 wO) in three concentrations (AR= average field recommendation, 0.7AR and 1.3AR) to entomopathogenic fungi *Beauveria bassiana*, *Metarhizium anisopliae* and *Paecilomyces* sp. was studied. The effect of insecticides on conidia germination, vegetative growth and conidiogenesis was compared. Insecticides had no effect on conidia germination, except under the higher concentration (1.3AR) of acetamiprid (Saurus 200 SP), in which significant inhibition of M. anisopliae occurred. B. bassiana and *M. anisopliae* vegetative growth was significantly inhibited by the three concentrations of acetamiprid (Saurus 200 SP) treatment only. Thiamethoxam (Actara 250 WG) treatment, in the AR and 1.3AR concentrations, was significantly inferior, for *B. bassiana* vegetative growth. *Paecilomyces* sp. vegetative growth was higher than that of the control in the following treatments: 0.7AR and AR of acetamiprid (Saurus 200 SP), all concentrations of imidacloprid (Confidor 700 WDGr) and in the two smaller concentrations, 0.7AR and AR, of thiamethoxam (Actara 250 WG). Conidia production was significantly smaller for *Paecilomyces* sp. and *M. anisopliae*, in the higher concentration (1.3AR) of acetamiprid (Saurus 200 SP) treatment and, for Paecilomyces sp., in the higher concentration (1.3AR) of initiacloprid (Confidor 700 WDGr). Thiamethoxam (Actara 250 WG) inhibited *M. anisopliae* conidia production significantly, in the small concentration (0.7AR) only. Significant increase in the conidia production of Paecilomyces sp. fungus was observed in the following treatments: two small concentrations, (0.7AR) and AR of acetamiprid (Saurus 200 SP), and in the two higher concentrations, AR and (1.3AR), of thiamethoxam (Actara 250 WG) treatments. The use of insecticides, in the formulations and tested concentrations, in major cases, has no negative effect on the germination, vegetative growth and conidia production of *B. bassiana*, *M. anisopline* and *Paecilomyces* sp. So in an IPM program where this entomopathogens are important pest regulators this products in this formulations and concentrations may be used.

Index terms: selectivity, acetamiprid, imidacloprid, thiamethoxam.

[2113] GROOMING CAPACITY INHIBITION IN CORNITERMES CUMULANS INOCULATED WITH ENTOMOPATHOGENIC FUNGI WHEN TREATED WITH IMIDACLOPRID

P.J. Neves¹; S.B. Alves² ¹UEL, C.P.6001,86051-970, Londrina/PR-Brazil.E-mail pmojneve@uel.br; ²ESALQ/USP C.P.9, 13418-900,Piracicaba/SP-Brazil. E-mail sebalves@carpa.ciagri.usp.br;

This study was carried out to attest inhibition in C. cumulans grooming behavior when treated with entomopathogenic fungi and sublethal concentrations of imidacloprid insecticide. Observations were made under the Scanning Electronic Microscope (S. E. M.). The 100 and 10 ppm concentrations of imidacloprid were chosen once they provide a sharp reduction in activity soon after contamination and a lower death rate up to 24 hours. So, under these circumstances, the establishment of the pathogen should take place up to a level where it can compete and beat the antagonists present in the host. The grooming capacity in termites may be observed by comparing the quantity of B. bassiana and M. anisopliae conidia deposited on the worker cuticle soon after application and six hours after when no more conidia was observed on the insect. The termite workers showed an efficient grooming mechanism which allowed the removal of all conidia from the cuticle of soldiers and other workers, in the first hours after fungal application. Grooming is carried out by the workers, among themselves and on the soldiers, probably using structures similar to brushes found on the end of the mandibles. When in contact with the insecticide imidacloprid, in sublethal concentrations, there was a inhibition of grooming behavior that allowed conidia to germinate and penetrate the insect cuticle, causing infection. This grooming inhibition occurred because insect activity is considerably reduced with the use of a stressor (imidacloprid) at low concentrations. This association is important for the use of this two entomopatogenic fungi in C. cumulans mount termite field control.

Index termes: Beauveria bassiana, Metarhizium anisopliae, mount termite.

[2114] DEVELOPMENTAL CYCLES OF THE ENTOMOPATHOGENIC FUNGI BEAUVERIA BASSIANA AND METARHIZIUM ANISOPLIAE ON THE TERMITE CORNITERMES CUMULANS AS DETERMINED FROM SCANNING ELECTRON MICROSCOPE (SEM) STUDY

P.J. Neves¹; S.B. Alves² & R. M. Pereira³ ¹UEL, C.P.6001,86051-970, Londrina/PR-Brazil. E-mail pmojnevc@uel.br; ²ESALQ/USP C.P.9, 13418-900,Piracicaba/SP-Brazil. E-mail sebalves@carpa.ciagri.usp.br; ³Dept. Entomology and Plant Pathology, University of Tennessee, PO Box 1071, Knoxville, TN 37901-1071, USA. E-mail rpereira@utk.edu

Techniques for preparation of Beauveria bassiana and Metarhizium anisopliae-treated Cornitermes cumulans for scanning electron microscope (SEM) observation were compared for the external study of fungal development on the insect. Fixation of the insects in 4% glutaral dehyde for 6 hours, followed by immersion in 1% $\mathrm{OsO_4}$ for 1 hour, dehydration in acetone series, and critical-point drying under CO2 provided the best results. The external development of M. anisopliae and B. bassiana on the termite Cornitermes cumulans is study. The observations shows that M. anisopliae conidial germination occurred on several regions of the termite body mainly between 6 and 12 h and penetration mainly between 12 and 24 h after fungal application. Several penetration points were observed originating from the same germ tube. Colonization of the host by M. anisopliae occurred between 24 and 72 h, and most insects died between 72 and 96 h. Conidiogenesis initiated between 96 and 120 h reaching its peak between 144 and 166 h. Development of B, bassiana was similar with mainly conidial germination between 6 and 12 h, and penetration between 12 to the 24 h. Colonization occurred between the 24 and 72 h. Growth of B. bassiana mycelia out of the cadavers and the beginning of conidiogenesis occurred earlier than with M. anisopliae, between 72 and 96 h. Full sporulation of B. bassiana occurred between 120 and 144 h.

Index termes: mount termite, entomopathogens, fixation techniques.

[2115] PATHOLOGY AND SUSCEPTIBILITY STUDIES ON URBANUS ACAWOIOS (LEPIDOPTERA: HESPERIDAE) LARVAE INFECTED BY BACILLUS THURINGIENSIS VAR. KURSTAKI (H-3A:3B)

M. D. Nogueira¹ & <u>M. E. M. Habih²</u>, 1National Institute of Amazon Research (INPA).2Dept. Zoology, IB, University of Campinas (UNICAMP), SP, 13083-970. Email: mohamed@reitoria.unicamp.br

Due to the lack of informations concerning. Urbanus acawoios (Lepidoptera: Hesperiidae), and the severe damage caused by it in Clitoria racemosa trees in Manaus, AM, the present research was conducted. The study was undertaken under laboratory conditions, in order to investigate the possibility of its microbial control, utilizing a commercial formulation, Dipel, based on Bacillus thuringiensis var. kurstaki (H-3a:3b). The larval mid-gut contents of this insect species showed to be highly alkaline, with a pH varying between 8.4 and 9.2, with an average of 8.7, indicating initially, a possible susceptibility of the larval stage to such a pathogen. Such an indication, could be posteriorly confirmed by bioassays. During the preliminary tests, a dosage, equivalent to 110 g / ha $(17.40 \text{ IU/cm}^2 \text{ of leaf-covered} \text{ area})$ was utilized and resulted in median lethal times (LTs₅₀) of 42.28, 37.18, 28.00 and 51.87 hours for the 3^{nd} , 4^{th} , beginning of the 5^{th} and end of the 5^{th} instar active period, respectively. Giving more attention for the 3^{rd} instar larvae, three dosages were applied: 80 g/ha (13 IU/cm²), 150 (25 IU/cm²) and 280 g/ha (45 IU/cm²). In this case, the LTs₅₀ were calculated as 42.62, 30.77 and 30.06 hours, for each dose, respectively. External symptoms of the bacterial disease were studied among 5th instar infected larvae. Cessation of feeding and blockage of food uptake, regurgitation, general paralysis, darkening of tegument reaching black color, are the most important alteration before reaching death. The mid-gut histopathological changes caused by the δ-endotoxin of B. thuringiensis, included enlargement of the epithelial cells, cytoplasm vacuolization, chromatin condensation, dissociation and destruction of the epithelial cell boundaries, degeneration of the epithelial microvillous surface, cell bursting and scattering of their cytoplasmic contents in the lumen. The results obtained during the present work could indicate applications of B. thuringiensis, as a promising method for the microbial control of this urban pest.

[2116] ULTRASTRUCTURAL AND MOLECULAR IDENTIFICATION OF A WOLBACHIA ENDOSYMBIONT IN A SPIDER, NEPHILA CLAVATA

H. W. Oh, M. G. Kim, S. W. Shin & H.-Y. Park, Insect Resources Laboratory, Korea Research Institute of Bioscience and Biotechnology, 52 Eoun-dong, Yusong, Taejon, 305-600, Korea, E-mail hypark@mail.kribb.re.kr.

Wolbachia-like bacteria were observed in the egg cells of golden orb-weaving spider, Nephila clavata, by means of transmission electron microscopy. The bacteria exhibited the typical morphology of Wolbachia, including three enveloping membranes. Based on the amplification and sequencing of partial 16S rDNA and ftsZ gene, the bacteria were identified as Wolbachia, intracellular, transovarially inherited α proteobacteria in invertebrates. Phylogenetic analysis based on 16S rDNA and ftsZ gene sequences invariably indicated that the intracellular bacteria from N. clavata belonged to group A Wolbachia, which were found only from insects. Clustering of Wolbachia from N. clavata with group A Wolbachia indicates that the bacteria were probably transferred horizontally from insects to the spider via predator-prey relationship.

Index terms: intracellular bacteria, phylogenetic analysis, 16S rDNA, ftsZ gene

[2117] SELECTION OF CULEX QUINQUEFASCIATUS POPULATION RESISTANT TO BACILLUS SPHAERICUS STRAIN 2362

C. M. F. Oliveira¹, M. H. N. L. Silva-Filha¹, <u>M. A. V. Melo²</u> & L. Regia¹, ¹Dept. de Entomologia, Centro de Pesquisas Aggeu Magalhães/FIOCRUZ, Av. Moraes Rego, CEP-50670-420, Brazil, E-mail mavarjal@cpqam.fiocruz.br. ² Mest. em Biologia Animal, Dept. de Zoologia, Univ. Fed. de Pernambuco, Av. Moraes Rego, CEP-50670-420, Recife, PE, Brazil. Supported by FACEPE/FIOCRUZ and OMS.

Bacillus sphaericus (Bs) products have been successfully used in vector control programs in many countries. Recently, Bs resistance has been reported in Culex field populations from Brazil, India, France and China. The present study aimed to select a resistant population of C. quinquefasciatus to Bs 2362 strain and to investigate the resistant population of C. quinquefasciatus to BS 2502 strain and to investigate the resistance mechanism. The potential of Bs strain IAB59 as an alternative for controlling resistant larvae was also studied. C. quinquefasciatus population was selected in laboratory from eggs rafts collected from several breeding sites in a district of Recife city, Brazil. A selection pressure between 50 and 94% was imposed to close to 10,000 4th instar larvae at each generation, throughout 35 generation's (F35). This population showed at F18 a low level resistance: the resistance ratio (RR) reached 18fold. The continuous selection of this population leaded to a RR close to 2,500-fold at F35. Preliminary "in vitro" binding assays between the radiolabelled Bs toxin and brush border membranes fraction (BBMF) from larvae midgut suggested that resistance mechanism observed at F35 is correlated to a very low specific binding between the toxin and the BBMF. Investigation of cross-resistance to other Bs strains showed that larvae from F35, highly resistant to the strain 2362, are susceptible to the strain IAB 59 since It displayed a RR of 6-fold only. Those strains might show different modes of action and IAB59 is a promising agent to the management of Bs resistance in mosquito populations.

Index terms: Bacillus sphuericus, Culex quinquefasciatus, resistance, cross-resistance

[2118] VIRULENCE OF BEAUVERIA BASSIANA ISOLATES TO OLIGONYCHUS YOTHERSI (ACARI: TETRANICHIDAE)

<u>R.C. Oliveira</u>¹, L.F.A. Alves² & N.L. Gais², ¹UEL, Dept. de Agronomia, C.P. 6001, 86051-970, Londrina, PR, Brazil; ²UNIOESTE/CCBS, R. Universitária, 2069. Cascavel/PR, Brazil, CEP: 85814-110, E-mail: lasg@unimidia.com.br

Ilex paraguariensis ("erva mate") is the important culture in some region of Brazil, Argentine and Paraguay. Its foliage is used to prepare tea and "chimarrão". The monoculture plantation of erva mate favored the occurrence of phytophagous insects and mites, including Oligonychus yothersi. This mite has been commonly observed in the last years in Brazil. They cause the premature defoliation reducing the leaves production. Aiming minimize the use of chemical acaricides the studies were carried out at Laboratory of Zoology of UNIOESTE at Cascavel, State of Paraná, Brazil. It was evaluated the pathogenicity and virulence of 21 isolates from entomopathogenic ungus Beauveria bassiana to control of Oligonychus yothersi. The isolates were obtained from the collection of Biological Institute Experimental Center in Campinas, state of São Paulo, Brazil. The water suspensions with 1,0 X 108 conidia/mL were sprayed on the leaf discs with 20 adult females of mites. After the application, the leaf discs were transferred to B.O.D. chamber for incubation at 26 ± 1°C, 80 ± 10% of relative humidity and 14 hours of photophase. It was verified that all isolates were pathogenic to the mites causing 30 to 90% of corrected mortality and means values of LT_{50} ranging from 3 to 5 days. Six days after inoculation, CB82, CB84 and CB87 isolates were the most virulent killing 90% of mites. The reproduction of fungus on the cadaver was highest for CB31, CB64 and CB87 isolates and the last one was the most promising to control O. yothersi.

Index terms: Oligonychus yothersi, microbial control, mite, acari.

[2119] CHARACTERIZATION OF THE PROTEOLYTIC ACTIVITY OF ANTHONOMUS GRANDIS AND ISOLATION OF CDNAS ENCODING SERINE AND CYSTEINE PROTEASES

O. B. Oliveira-Neto^{1, 2}, J. A. N. Batista¹, R. R. Fragoso^{1, 2}, S. C. Dias^{1,2}, R. G. Monnerat¹ & <u>M. F. Grossi-De-Sá</u>¹, ¹ Embrapa Recursos Genéticos e Biotecnologia, SAIN Parque Rural, Caixa Postal 02372. Brasília, D.F. Brasil, e-mail fatimasa@cenargen.embrapa.br²Depto. de Biologia Celular, UnB, Brasília, Brasil

Anthonomus grandis (Coleoptera: Curculionidae), the boll weevil, has a widespread distribution in Brazil, and is an important pest of cotton (Gossipium hirsutum). Control by conventional means is especially difficult due the build up of resistance to pesticides within the population. The insect localization in the buds also provides protection against pesticides. We have investigated proteolytic activities in the guts of larval A. grandis and have shown it to be largely due to extracellular serine proteases and less abundant cysteine proteases in both larval and adult stages. Amplification by RT-PCR with primers for both protease classes, using total RNA from larval stage, has lead to the isolation of several incomplete cDNAs encoding six serine and two different cysteine protease classes. The sequences of the serine proteases show a high degree of divergence between themselves and little similarity with other serine proteases sequences present in the database which participate in many vital physiological process, from nutrition to morfogenetic regulation. Based on 5' and 3' RACE techniques, the complete cDNAs sequences were isolated. The availability of these protease genes will allow their in vitro expression and the selection of specific inhibitors through the screening of a library of mutant inhibitors by phage display. The regulation of these protease-encoding genes, and the nature of the response to dietary protease inhibitor, are relevant for the elucidation of the mechanism of induced insensitivity to protease inhibitors.

Supported by EMBRAPA, PADCT and CNPq. Index terms: cotton, physiological process

[2120] THE EFFECT OF CULTURE MEDIA ON VIRULENCE OF PAECILOMYCES AMOENEROSEUS ON SILVERLEAF WHITEFLY BEMISIA ARGENTIFOLII

G.Ottoni¹ & R.Creamer², ¹Universidade Federal de Goiás, Escola de Agronomia, Cx. P. 131, Goiânia, GO, Drazil, Cep: 74001-970, e-mail ottoni@agro.ufg.br; ² New Mexico State Univ., Dept of Entom., Plant Path. and Wood Sciences, Box 30003/MSC 3BE, Las Cruces NM, 88003, U.S.A.

In the Centro Oeste Region in Brazil, an entomopathogenic fungus had been isolated from Tibraca limbativentris (Hemiptera: Pentatomidae) in 1986. The fungus, identified as Paecilomyces amoeneroseus, was gently sent by Embrapa-Rice and Beans to the U.S.A., and it's potential as a biological control agent against Bemisia argentifolii has been reported. The future success of this fungus as a commercial insecticide depends upon developing effective and practical culturing techniques. By testing different media, we can determine which promotes faster growth or better sporulation of the pathogen, without compromising its virulence. Different culture media have been used for Paecilomyces spp. and other entomogenous fungi. The objective of this experiment, carried out at the University of California, Riverside, was to screen five different culture media for their ability to promote growth, sporulation, and virulence of *P. amoeneroseus*. Silverleaf whiteflies collected from agricultural areas in the Imperial Valley, CA, and CP211 was the fungal isolate. Colony growth was more rapid on modified Czapeck-Dox and PDA than on Yeast Extract or modified NRRL Cornsteep/Molasses media. Conidia production was greatest on the modified NRRL Cornsteep/Molasses medium, however this medium resulted on slow radial growth. A difference in virulence of isolates growing on these five culture media was not detected, although colony coloration varied. Other features such as conidia shape and size remained invariable. Synnemata production was not observed on any of the assayed media. When molasses was added to the NRRL Cornsteep medium, conidia production increased, which leads us to recommend it as a good medium for P. amoeneroseus. The experiment revealed that saprophytes produce conidiophores external to the insect cadaver, which could be mistaken for the sprayed entomopathogen, leading to inaccurate mortality assessment in biological control assays. It is necessary to re-identify fungi on dead whiteflies showing fungal sporulation and to verify that it is not a saprophyte. We suggest that these procedures become routine in biological control experiments.

Index terms: entomopathogen, virulence, culture media, sporulation, biological control

[2121] SUSCEPTIBILITY OF DIFFERENT LIFE STAGES OF *BEMISIA ARGENTIFOLII* TO THE ENTOMOPATHOGENIC FUNCUS *PAECILOMYCES AMOENEROSEUS*

<u>G. Ottoni</u>¹ & R. Creamer², ¹Universidade Federal de Goiás, Escola de Agronomia, Cx. P. 131, Goiânia, GO, Brazil, Cep: 74001-970, e-mail ottoni@agro.ufg.br; ² New Mexico State Univ., Dept of Entom., Plant Path. and Wood Sciences, Box 30003/MSC 3BE, Las Cruces NM, 88003, U.S.A.

A variety of entomopathogenic fungi have been reported to infect whiteflies Bemisia spp., offering potential for biological control. The age and the stage of an insect can affect the susceptibility to an entomopathogenic fungus. The objective of this study was to determine the influence of insect life stage on *B. argentifolii* Bellows and Perring susceptibility to *Paecilomyces amoeneroseus* (Hennings) Samson. Bioassays were carried out with P. amoeneroseus isolate CP211, obtained from Embrapa-Rice and Beans located in Goiânia, Brazil. Silverleaf whiteflies (B. argentifolii) were collected from agricultural areas in the Imperial Valley, California. Conidial suspension adjusted to 108 spores/ml was sprayed onto bean plants containing all life stages of the whitefly. After spraying, plants were kept in cages under controlled conditions. Mortality was evaluated 7 days after spraying and quantified as the percentage of infected eggs, nymphs and adult whiteflies per each two leaves, compared to the water-Tween-sprayed control. Insects were considered infected when mycelial growth could be observed external to the cadaver. Abbot's adjustment (Abbot, 1925) was used in the analysis because some mortality is caused by exposure to water spray and saprophytic fungi can grow on dead insects. The results of this experiment showed a significant difference in the susceptibility of adults, nymphs and eggs under laboratory conditions. The adult stage suffered the highest infection rates (67%). Nymphs were also susceptible, although levels were less than 9% infection. Efficacy of P. amoeneroseus against whitefly nymphs does not reach levels as high as other entomopathogens. However, this fungus causes a much faster infection under laboratory conditions, killing the insect in just 4 to 7 days. Eggs of whitefly species usually present low rates of infection or even no infection at all. Our results showed a frequency of 4.1% eggs infection.

Index terms: Bemisia argentifolii, Paecilomyces amoeneroseus, biological control

[2122] PIPERONYL DERIVATES BASED ON SESAMIN AND THEIR INHIBITION OF THE SYMBIOTIC FUNGUS OF LEAF-CUTTING ANTS

<u>F.C.Pagnocca¹</u>, S.R.Victor¹, O. C. Bueno¹, M.J.A. Hebling¹, M. Bacci Jr.¹, F.R.Crisósotomo² & J.B. Fernandes², ¹ Centro de Estudos de Insetos Sociais, Universidade Estadual Paulista,UNESP, Campus de Rio Claro, Caixa Postal 199, CEP 13506-900, Rio Claro,SP, Brazil, Email: pagnocca@rc.unesp.br; ² Departamento de Química, Universidade Federal de São Carlos, Caixa Postal 676, CEP 13565-905, São Carlos.SP, Brazil

Leaf-cutting ants are dominant herbivores and significant pests in agriculture and forestry in Brazil. They use plant material as substrate for culturing a symbiotic fungus. The ants exhibit preference for some plant species in a process related with chemical and physical properties of the plants. Virola sebifera Aubl. (Myristicaceae) is a native species of Brazil's cerrado which produces some lignaus sazonally. In a previous work we have described that some lignans are inhibitory for the development "in vitro" of the fungus Leucoagaricus gongylophorus and sesamin, a furofuranic lignan, was the most toxic of them. Six compounds were synthetized having the sesamin moiety as a model for evaluation of their activity towards the fungus. Thus, three of them were 3,4 methylenedioxybenzyl ethers and the others were 3,4 methylenedioxybenzyl (hydroxy) ethers. The assays of fungal inhibition were performed by addition of these compounds to the culture medium at concentration increasing from 10 µg/mL to 100µg/mL at 10 µg/mL intervals. A mycelial suspension containing 4.5 ± 0.5 mg dry weight/mL was inoculated in the tubes which were incubated at $25^{\circ}C$ / 30 days. The results were expressed in percentage of inhibition in relation to the control. For concentrations of 25µg/mL through 100µg/mL we found 80-90% of inhibition on fungal development In both groups of compounds the best inhibitory effect was observed with those compounds having eight carbons in the side chain. This inhibition was correlated with the size of the side carbon chain. Other compounds with similar basic structures are being developed in order to evaluate if the inhibitory effect can be enhanced with longer side chains. Index terms: Piperonyl compounds, antifungal activity, Atta sexdens, Leucoagaricus gongylophorus

[2123] FUNGI ASSOCIATED TO SCOLYTIDAE BEETLES IN PUERTO RICO

F. II. Pedreros¹ & J. D. Lodge², ¹Dept. of Biology, Univ. of Puerto Rico, P O Box 23360, San Juan 00931-3360 Puerto Rico, E-mail f.pedreros@eudora.com, is975999@upracd.upr.clu.edu; ²USDA-Forest Service, Palmer 00721, Puerto Rico.

Bark beetles (Coleoptera: Scolytidae) are well known by their ability to bore in both living and decaying woody tissues. Most of the species live symbiotically with fungi, which help the insects in establishing an appropriate brood chamber and, in some cases, constitute the only food source of the insects. In this work we sampled Scolytidae from some common plants in Puerto Rico (Caoba: *Swetenia mahogany* and *Plumeria alba*) and we study the structure and composition of the Scolytidae associated funga! community. We found four taxa of beetles: three morphospecies of *Xyleborus* and one *Hypotenomus*. Most common symbiont fungi were *Ophiostoma*, *Ceratocystis* and their anamorphs. An insect pathogen, *Metarrhizium* was also found. Additionaly, we found *Fusarium*, a potential plant pathogen. Other environmentally common fungal taxa, as *Penicillium*, *Trichoderma* and *Ciadosporium*, were found associated to Scolytidae too. There are enough data to suspect that Scolytidae are able to disperse plant pathogens, and this trait associated to their boring ability, places Scolytidae as an economically important taxon.

Index terms: Ophiostoma, Ceratocystis, beetles and fungi

HYPOTHENEMUS HAMPEI

<u>R.C. Pereira</u>, J. O. G. de Lima & R. I. Samuels, Department of Plant Protection, Universidade Estadual do Norte Fluminense, Campos dos Goitacazes, RJ 28015-620, Brazil, E-mail richard@uenf.br.

The coffee berry borer (CBB) is considered to be one of the most important pest species of coffee. CBB originated in Africa but has now spread to all major coffee growing regions of the world. This insects life cycle, spending prolonged periods within the coffee berry, means that conventional as well as biological control methods have failed to prevent serious crop losses. Entomopathogenic fungi appear to be good candidates for biological control as natural epizootics have been regularly reported, causing significant reductions in the pest population. However, applications of *Beauveria bassiana* under field conditions in Colombia, have been very disappointing. Therefore, the pathobiology of the interaction between CBB and entomopathogenic fungi such as B. bassiana and Metarhizium anisopliae, requires further investigation. In order to study virulence of fungal isolates utilising a non-intrusive method of infection, CBB were exposed to conidia which had been applied to filter paper, noninfested coffee grains and coffee grains recently infested by CBB. None of the fungi used here were isolated from CBB, however all 3 isolates tested were pathogenic to CBB. In the first tests, CBB were exposed to filter paper onto which had been applied 1×10^7 conidia⁻¹ of each isolate tested. The values for TL₅₀ were 4.12 days (LPP1: B. bassiana); 5.2 days (CG11; B. bassiana); 6.07 days (E-9; M. anisopliae). The most virulent isolate from the first tests, LPP1, was then applied to infested and non-infested coffee grains using 3 concentrations of inoculum (1 x 10⁷; 1.2 x 10⁶; 1 x 10⁵ conidia⁻¹). At the highest concentration used here, CBB mortality was 80% when insects were exposed to non-infested grains which had been treated with conidia. The same concentration of conidia applied to already infested grains caused 65% mortality. These results indicate that applications of fungi should be made before or shortly after CBB infestations. We are currently comparing the virulence of B. bassiana found naturally infecting CBB, with isolates from other host insects.

Index terms: Beauveria bassiana, Metarhizium anisopliae, biological control, entomopathogenic fungi.

[2125] GENETIC VARIABILITY AMONG BEAUVERIA BASSIANA AND PAECILOMYCES FUMOSOROSEUS.

<u>B. Pereyra-Alférez</u>, L. Galán-Wong, M. Iracheta, C. Rodríguez-Padilla, J. Contreras & R. Tamez-Guerra.

Depto. de Microbiología e Inmunología. Fac. Ciencias Biológics/UANL. México. Av. Dr. Pedro de Alba y Av. Manuel Barragán. Cd. Universitaria. San Nicolás de los Garza, N. L. CP. 66450.

Beauveria bassiana and Paecilomyces fumosoroseus represent two of most efficient biological tool for Bemissia tabaci (whitefly) control. In order to evaluate the genetic variability among B. bassiana and P. fumosoroseus strains, we performed a random amplified polymorphic DNA (RAPD) system. Our assays were carried out using 20 primer containing 60-70% GC. Both fungi strains were isolated in USA and México from whitefly (16), Trichoplusia ni (4), ant (2) and domestic fly (4). The strain were grown on YPD-broth for 4 days at 28°C and total DNA was purified. The RAPD's were made by duplicate and repeated twice using 2 independent DNA samples. RAPD products were loaded on polyacrylamide gels. Both fungus yielded consistent and reproducible DNA band profile, 2 to 17 DNA bands, ranging from 0.1 to 4.0 kbp, with 8 primers High variability was observed within B. bassiana strains was observed. The B. bassiana strains share only one band of 0.7 kbp. This band was constant in all isolates and it was independent either geographic origin or insect host. However, the P. fumosoroseus strains displayed very similar DNA pattern band. Results with OPA-13 primer showed a profile of 4 bands, 2 very conserved not only in size (0.1 and 1.1 kbp), but also in intensity, the exception was a mexican whitefly isolate, who did not yield minor band. The dv (dissimilarity value, 1-F) was calculated. The P. fumosoroseus strains showed a dv= 0.48 and B. bassiana a dv=0.55. These values reveled that B. bassiana had more divergence than P. fumosoroseus. This fact might be related with origin of the samples, because while main P. fumosoroseus strains were isolated from B. tabaci, B. bassiana ones were obtained from different host. In order to know the similarity and relationship within fungus, we done a cluster analysis for each genus. This analysis reveled high similarity between host or geographic origin in both genus.

Paecilomyces fumosoroseus, Beauveria bassiana, RAPD, Genetic variability

[2126] CODLING MOTH (CYDIA POMONELLA) AND THE USE OF GRANULOVIRUS IN ORGANIC AND INTEGRATED CONTROL

F. Polesney, BFL, Inst. of Phytoemd. Spargelfeldstr. 191, A-1220 Vienna, Austria

The CpGV product Carpovirusine was registered for control of codling moth in Austria some years ago. There are two nearly overlapping codling moth generations per annum in Austria. The egg laying period of the first generation lasts for about one and a half months. The egg laying period of the second generation lasts for more than a month. The use of CpGV against *Cydia pomonella* was evaluated in field trials. An effective treatment strategy using only CpGV requires a large number of applications during the whole period of larval hatching. Weekly applications are successful but applications at two week intervals results in an enormous decrease in efficaey. There are good opportunities to implement CpGV in integrated treatment strategies. There is no danger of cross resistance to other compounds used in Integrated Fruit Production. The combined use of CpGV with ovicidal insect growth gives good results and requires a reduced number of applications compared with traditional use of single compounds. The results of the different field trials are presented and discussed. Index terms: orchard, fruit, *Cydia pomonella*, baculovirus, granulovirus, biological control

[2127] CONTROL ASPECTS OF ORYZOPHAGUS ORYZAE WITH BEAUVERIA BASSIANA, METARHIZIUM ANISOPLIAE AND FIPRONIL IN WATER-SEEDED RICE

II. F. Prando¹, D. R. Sosa-Gómez² & G. H. Rosado Neto³, ¹EEI-Epagri, Cx. Postal 277, 88301-970, Itajaí, SC, Brazil. E-mail: hfprando@zaz.com.br; ²Embrapa Soja, Email: sosa@cnpso.embrapa.br; ³Zoologia/Entomologia UFPR E-mail: pgento@ufpr.br

The rice weevil Oryzophagus oryzae (Costa Lima) is associated with rice yield losses in Rio Grande do Sul and Santa Catarina states, Brazil. In Rio Grande do Sul, annual losses range from 13.5 million dollars to over 21.0 million dollars. In order to minimize this, rice growers use extremely toxic insecticides with irrigation water. The laboratory tests were concerned with the viability and susceptibility of the entomopathogenic fungi *Metarhizium anisopliae* (CNPSoMa12) and *Beauveria* bassiana (Ep01 and CB66) to sunlight and ultra-violet light. The effect of cuticle lipid extracts of O. oryzae and Cosmopolites sordidus Germar on these microorganisms, was investigated. O. oryzae and C. sordidus lipid extracts and hexane and three isolates of entomopathogenic fungi (Ep01, CB66 and Ma12) were used in a 3 x 3 factorial design. The field experiments were conducted in two consecutive years. A total of 13 treatments in four replications and in a completely randomized plots (3 m x 6 m) was used. Rice cultivar, Epagri 108, was water- seeded under 10 cm layer of water. All treatments were hand applied using a watering pot three days after seeding, except where seeds were treated. The viability rate of conidia isolates of M. anisopliae and of B. bassiana was 95%, 89% and 86% for isolates Mal2, Ep01 and CB66, respectively. The isolate CB66 was significantly affected by sunlight after a 4 hourexposition. The cuticle lipid extract of O. oryzae significantly stimulated germination compared to the cuticle lipid extract of C. sordidus. The isolate Ep01 showed greater germination and growth performance. Field experiments showed that biological and chemical treatments reduced significantly the amount of O. oryzae in treated plots as compared to control treatment. Fipronil treatments caused significantly reduction on the number of larvae, higher plants and lower water content of grains. The use of the entomopathogenic fungi *B. bassiana* and *M. anisopliae* to control *O. oryzae* is a feasible practice applied in combination with chemicals. Fipronil is efficient to control O. orygae and can be applied by hand (watering pot) after seeding or by seed treatment methods.

Index terms: biological control, microbial

[2128] POINT Contamination of gypsy moths population by LdNPV by means of pheromone traps

<u>O.Pultar</u>¹ & M.Švestka², ¹Biola laboratories, Agricultural Cooperative, Chelčice, Vodňany 38901, Czech Republic, biola@iol.cz; ²Výzkumný ústav lesního hospodářství a myslivosti, Dvo řákova 21, Znojmo 66902, Czech Republic.

The method of attractant aided dissemination of Lymantria dispar polyhedrovirus (LdNPV) was examined in the oak. The hypothesis of these experiments is: Males attracted into pheromone traps will be contaminated by virus, this one will be transferred to females during copulation and after by females on the eggs or/and on the place of oviposition. Virions should be able to infect the caterpillars during hatching or they can be contaminated by virions and then transfer them on their bodies into canopy of trees and to start infection during feeding by contaminated leaves. In 1998 density of pheromone traps was examined which is able to contaminate population of the gypsy moth without an efect of disruption. Number od 8 (plot A) or 16 (plot B) cylindrical traps with contaminating mixture (indifferent filling material, LdNPV and fluorescent paint for marking of males) were installed per hectar on the twoo plots 3 ha each. 3 monitoring pheromone traps and 2 traps with caged virgin females and sticky inserts for recapturing of males were installed on the same plots and on the check plot without contaminating traps (plot C). Recaptured males were examined under UV light. There 6.1; 10.3 and 8.7 males per one pheromone trap or 2.0; 6.8 and 11.0 per one female-containing trap were catched on the plot A, B and C, respectively. 31% and 34% of the males captured into pheromone traps and 25%, 11% and 21% of the males captured into female-containing traps were marked in the plot A, B and C, respectively. In 1999 different forms of pheromone traps (cylindrical and delta-shaped) were examined installing 4 cylindrical and 4 delta traps/ha on the area of 3 ha. Average contamination 40% of recaptured males was detected. 9% and 29%originates in the delta traps and cilindrical traps, respectively and 2% in the other experimental plot. These results are presented and diskused in the poster. Index terms: Lymantria dispar, fluorescent point, delta trap, cylindrical trap

[2130] ULTRASTRUCTURAL ASPECTS OF THE COLONIZATION PROCESS OF ECDYTOLOPHA AURANTIANA BY THE ENTOMOPATHOGENIC NEMATODE STEINERNEMA GLASERI

J. C. V. Rodrigues¹; M. M. Aguillera² & J. F. Garcia², ¹ Centro de Energia Nuclear na Agricultura, Univ. de São Paulo, C. Postal 96, 13400-970 Piracicaba, SP, Brazil. Email: jcvrodri@cena.usp.br. /Centro de Citricultura –Inst. Agron. de Campinas; ² Centro de Ciências Agrárias, Univ. Fed. de São Carlos, C. Postal 153, 13600-970 Araras, SP, Brazil. E-mail: marineide@dbv.cca.ufscar.br.

The lepidopteran Ecdytolopha aurantiana is an old Brazilian citrus pest, that in the larval phases attacks citrus fruits, mainly sweet-oranges. Recently, that species presented outbreaks, responsible for great economic losses, estimated in US\$ 50 million in 1999. Intensive search for efficient control methods that might contribute to the reduction of the pest population levels in orchards has been developed. The proposal of using entomopathogenic nematodes to control this pest is recent. This work reports ultrastructural observations of the larval colonization process in the last larval instar by the entomopathogenic nematode, Steinernema glaseri, isolated from Sta. Rosa de Viterbo, SP-Brazil. Larvae with characteristic signs of nematode infection (cadavers infected were flaccid and brown colored) were prepared for observation at the transmission (TEM) and scanning (SEM) electron microscopes. The specimens were fixed in glutaraldehyde - paraformaldehyde; post-fixed in osmic acid and dehydrated in acetone. For TEM analysis, specimens were embedded in epon resin and sections were stained with uranyl acetate, lead citrate and examined in a Zeiss EM 900 microscope. For SEM analysis, specimens were dryed by critical point (CO2 liquid) and sputter with gold. Control specimens without nematodes exposition were also prepared. Ultrathin sections of infected larvae indicated the nematode colonization and showed bacterial presence associated to the colonized places of the larval body, fact that is explained by this entomopathogenic nematode group feeding and acting in association to symbiontic bacteria. In the last incubation period (96 hours) the nematode number observed was high, occupying practically the whole larval body. This suggests a great rate of this nematode reproduction in E. aurantiana and also the high potential of this biological control agent for this pest. Index terms: Citrus, biological control, electron microscopy

[2129] WHITEFLIES AND THEIR PARASITOIDS' STATEMENTS IN HORTICULTURAL PROTECTED CROPS IN PORTUGAL

M.R. Queirós, C. Marques, <u>E. Figueiredo</u> & A. Mexia, DPPF-SAPI, Instituto Superior de Agronomia, Tapada da Ajuda, 1349-017 Lisboa, Portugal; E-mail elisalacerda@isa.utl.pt.

Whiteflies are a key pest in horticultural protected crops in Portugal. The Trialeurodes vaporariorum species is already reported all over the country and is the only species found in the region of the Ribatejo e Oeste, in a preliminary study carried through the period of 1996 the 1998 (Marques & Mexia, 1998). The Bemisia tabaci species, detected in 1992 in the Algarve region, is causing serious losses to the tomato growers, in the last years, because of the transmission of the TYLCV (Louro et al., 1996). A monitoring scheme for this species was set up in the Ribatejo e Oeste region in order to evaluate its presence related with the risk of TYLCV infection. Leaves/leaflets infested with "pupae" and nymphs of whitefly species were collected on tomato crops at 85 greenhouses from June to December 1999. Identification of the specimens was made based on the differential morphological characteristics of the emerged adults or, in case of doubt, by diafanization and microscopic observation of relevant characters. Although B. tabaci have been already found punctually in outdoor in the region, its presence was not observed in the studied greenhouses. Climatic factors like relative humidity and temperature conditions may not be favourable to the proliferation of the species (Queirós et al., 1999). However, it was detected, an increase of the populations of B. tabaci in relation to species T. vaporariorum in Algarve protected crops. In order to confirm the displacement of T. vaporariorum by B. tabaci, infested leaves/leaflets were collected in this region in 45 greenhouses, at two moments, June and October, periods of population peaks of species B. tabaci. The parasitoids species Encarsia formosa, Encarsia pergandiella, Encarsia tricolor and Amitus fuscipennis found in a preliminary study in the Oeste region at 1996-1998 (Marques & Mexia, 1999) were found in both Ribeteio e Oeste and Algarve region. However, other species were observed in the Algarve region waiting for identification.

Index terms: Bemisia tabaci, Trialeurodes vaporariorum, Encarsia sp., TYLCV

[2131] INSECTS AFFECTING SWEETPOTATO HARVEST

D. S. Ruberti¹ & M. M. Scandiani¹, ¹Laboratorio Agrícola Río Paraná. Ruiz Moreno 225, San Pedro, Buenos Aires, 2930, Argentina. E-mail: Erro! Indicador não definido.

The sweetpotato crop grows during spring and summer when the population insects are highest. The roots are attached since development beginning until harvest time. When insect attacks are very important, the sweetpotatoes commercial quality decreases considerably. During the 1998/1999 season, ten checks plots of 50 m length by 4 m with, placed in San Pedro area, were sampled at harvest time. There were not treated with insecticides. It was taken the 10% of the production from each check plot to analyze. As a result the following insect damage was determined: wireworms: 60 %, *Diabrotica sp.*: 55%, Other white grubs: 20%. These evaluations include since a few to a lot of damage. The lost threw away harvest was 54% due to the intensive damage caused by insect attack. These percentage are higher than those from the two last years, 21% (1996/97); 39% (1997/98). Index terms: wireworms, while grubs, damage

[2132] CARACTERIZATION OF NEW STRAINS OF BACILLUS THURINGIENSIS TOXIC AGAINST BOLL WEVILL, ANTHONOMUS GRANDIS

S. C. Dias, R. P. Pessanha, O B. Neto, M. F. Grossi De Sá & <u>R. G. Monnerat</u>, Embrapa Recursos Genéticos e Biotecnologia, SAIN Parque Rural, Caixa Postal 02372. Brasília, DF, e-mail: rose@cenargen.embrapa.br

The boll weevil, is a major pest of cotton in subtropical and tropical areas of the America continent. Most species of Anthonomus has preference for floral buds and fruits of its target plant. The infected tissues are used as food source and as development habitat, causing damage to cotton fibers. The control of this pest can be done by chemical methods and earliness cultivars. Presently, only broad spectrum insecticides are used to control this insect. If any efficacious biological agent became available which avoided the upsets in natural control typically associated with broad spectrum insecticides it could become an important component of cottton IPM programs througout the America. The complex spore-cristal of native strains of Bacillus thuringiensis was added to artificial diet. Neonate larvae, 48 hs after hatching, were puted in small orificie in artificial diet in Petri dishes. After four days the mortality of larvae was evaluated and the survivors were transfered to a new diet without Bacilus. After 15 days the final mortality was calculated. It analized 11 strains of Bacillus thuring iensis and % mortality range from 72,4 (S1342) 50,6 (S725). The % mortality in the control treatment was satisfactory. The positive control was Bacilus thuringiensis subesp. tenebriones which mortality range 50 a 70%. All the strains evaluated showed similar mortality to Btt, which is reference strain for mortality in Coleoptera.

Index terms: cotton, complex spore-cristal

[2133] POTENCY OF *BACILLUS THURINGIENSIS* AGAINST INSECTS OF STORED PRODUCTS

H.S. Salama & A. Abdel-Razek, National Research Centre, Dokki, Cairo, Egypt

Isolates of *Bacillus thuringiensis* (*B.t.*) were obatined from 56 samples of grains and flour mills in Egypt and Canada. Classification according to crystal morphology indicates dominance of the bipyramidal crystal type in isolates from grain samples while the bipyramidal and bipyramidal-rectangular types dominated other types in isolates from flour mills. Serological techniques were used to categorize *B.t.* isolates. Polymerase Chain Reaction (PCR) has been also used to allow rapid determination of the presence or absence of DNA sequence. A bioassay was made to determine the potency of the active isolates against the Indian meal moth *Plodia interpunctella* and the red flour beetle *Tribolium castaneum*. A high activity against *P. interpunctella* was recorded for the isolate coded E-AS16A (*B.t.* var. *indiana*) with LC₅₀ of 17.5 ug/g compared to 31.35 ug/g for the standard HD-1-S-1980. With *T. castaneum*, the highest activity was recorded for the isolate coded E-AS16B (*B.t.* var. *morrisoni*) and the LC₅₀ was 1921 ug/g. The susceptibility of different larval instars of both insect species to *B.t.* var. *morrisoni* has been investigated and showed a decrease with increasing age. Index terms: *Plodia interpunctella*, *Tribolium castaneum*, PCR, serology, *B.t.* isolates. [2134] DEVELOPMENTAL STAGES OF PHTHORIMAEA OPERCULELLA AS AFFECTED BY BACILLUS THURINGIENSIS

H.S. Salama & M. Sabbour, National Research Centre, Dokki, Cairo, Egypt

Bacillus thuringiensis var. galleriae HD-234 (B.t) affects the different larval instars of the potato tuber moth Phthorimaea operculella in varying degrees showing a gradual increase with the increase of the larval age. This endotoxin also showed an activity against other developmental stages. Prepupae and pupae sprayed with B.t. gave malformed moths with short longevity, low egg production and fertility. The effectiveness of B.t. has been also demonstrated against the moth and eggs. The moth longevity, egg production and fertility were affected when fed on sucrose diet with B.t. at certain concentrations; the effect progressively increased with the increase of concentration of the endotoxin. When egg masses were sprayed with B.t. the incubation period was prolonged. The survival of the hatched larvae was reduced when treatment was made shortly before egg hatching. On the basis of these findings, B.t. sprays may be recommended against various developmental stages with significant prospectives.

Potato tuber moth, pupae, eggs, B.t. var. galleriae

[2135] POTENTIATION OF *BACILLUS THURINGIENSIS* AGAINST LEPIDOPTEROUS INSECTS USING SAFE CHEMICAL ADDITIVES

II.S. Salama, National Research Centre, Dokki, Cairo, Egypt.

Biochemical appreaches have been developed to potentiate the activity of Bacillus thuringiensis (B.1.) varieties against various lepidopterous insects including Spodoptera littoralis, Agrotis ypsilon, Plodia interpunctella, Chilo agamennon and Pyrausta nubilalis. These approaches were based on the incorporation of some selected safe, non toxic and cheap chemicals with the endotoxin fed to the insect larvae. The tested chemicals include inorganic salts, protein and lipid solubilizing agents, amino acids and amides. Some of these chemicals significantly enhanced the endotoxin potency against the tested species but in varying degrees. Examples of the tested inorganic salts were CaCO₃, CaO, ZaSO₄ and K₂CO₃ (0.1 %) which increased the B.1. effectiveness by many folds against target insects. Large scale field experiments confirmed these results against lepidopterous insects on different field and vegetable crops. The mode of action of the tested compounds has been dicussed in the light of the results obtained.

Index terms: Inorganic salts, amino acids, protein solubilizing agents, Spodoptera littoralis

[2136] THE USE OF *BACILLUS THURINGIENSIS* TO CONTROL LEPIDOPTEROUS INSECTS ON POTATO CULTIVATIONS IN EGYPT

H.S. Salama, S.A. Salem, F.N. Zaki & A. Abdel-Razek, National Research Centre, Dokki, Cairo, Egypt.

The possible use of *Bacillus thuringiensis (B.t.)* preparation (Dipel 2X) as a substitute for chemical insecticides (Lannate and Hostathion) was evaluated against the two major insect pests of potato crop, *Agrotis ypsilon* and *Spodopera exigua*. Both the biopesticide and chemical insecticides were effective on the target insects. One spray or bait application of Dipel 2X at the rate of 750 gm/feddan provided a satisfactory protection of the potato crop against infestation with *A. ypsilon* or *S. exigua*. The average yield obtained from treated plots was 5.52 ± 0.33 tons/f compared to 5.9 + 0.4tons/f from plots treated with the chemical insecticide Lannate spray or Hostathion bait. The average yield in the control plots was significantly lower being 2.1 ± 0.32 tons/f. Incorporation of calcium oxide, significantly potentiated the effectiveness of *B.t.* against the target insects under field conditions. These results increase the promising prospectives and encourage the utilization of safe *B.t.* preparations as a substitute of hazardeous chemical insecticides against lepidoptera infesting potato cultivations.

Index terms: Agrotis ypsilon, spodoptera exigue, Lannate, Hostathion, Dipel 2X

[2138] ENTOMOPHTHORALEAN PATHOGENIC FUNGI (ZYGOMYCOTINA – ZYGOMYCETES) IN THE NATURAL CONTROL OF INSECTS – PROSPECTS IN SOUTHERN OF BAHIA, BRAZIL

S.E.M. Sánchez¹, A. L. Freitas², L. S. Lima³, G. B. Silva³, C. S. de Almeida³ & J. B. Lenl³, ¹ Prof. Dr. Researcher, Univ. Estadual de Santa Cruz – UESC, Dept. de Ciências Agrárias e Ambientais – DCAA. Rod. Ilhéus/Itabuna Km. 16 Bahia, Brazil. Fone: (073) 680 5261 Fax: (073) 630 5129 saul@jacaranda.uescba.com.br; ² Fellowship DCB – Program PIBIC/ CNPq; ³ Fellowship DCAA/ DCB – Program UESC

Research on entomophthoralean fungi in southern Bahia State, Brazil included enzootic and epizootic studies on the dynamics of entomophthoromycosis and on its interrelation with insect populations of various insect orders, geographical distribution and incidence on crops, natural grasses and other substrates. This work is being conducted in an orderly and sequencial manner, and the pathogens identified microscopically together with the biometric data of the structure of the fungi. The results are important for the region as they confirm the presence of *Erynia* on Calliphoridae and Sarcophagidae (Diptera) and on Formicidae *Paratrechina* sp. (Hymenoptera). *Entomophthora* was present on domestic muscid flies and *Entomophaga* on Acrididae and Gryllidae (Orthoptera). We also identified *Conidiobolus* on Coleoptera, Diptera and Homoptera, *Entomophaga* on Psychodidae *Telmatoscopus albipurciatus* (Diptera), and on Tipulidae (Diptera), and an unnidentified adult microlepidopteran. The biological material collected in the region demonstrates the effectiveness of these pathogens in the natural control of these insect populations. During the project (May 1998 to December 1999), the means monthly temperature and the relative humidity of the region varied from 20.5 to 25.0 °C and 82.0 to 88.8 % respectively; ideal conditions for the development of entomophthoromycosis.

Key words: Entomophthorales, Characterization, Identification, Geographical distribution, Incidence, Bahia-Brazil.

[2137] MICROBIAL CONTROL OF TICKS

<u>M. Samish¹, G. Gindin², E. Alekseev¹, I. Glazer², ¹Kintron Veterinary Inst., P.O.Box</u> 12, Bet Dagan 50250, Israel. E-mail: msami_vs@netvision.net.il; ²A.R.O., The Volcani Center, P.O.Box 6, Bet Dagan 50250, Israel.

Even though microbial control of plant pest is investigated and used for decades this aspect of tick control is as yet highly neglected. Indeed there exists as yet not even one commercial anti tick biocontrol agent. Ticks throughout their life cycle spent most of the time in hiding places in the upper layer of the ground i.e. under clods of earth, under leaf cover or even buried a few cm of soil. Such relatively moist places are suited for the development of entomopathogenic nematodes and fungi. Our trials showed that entomopathogenic nematodes (200 Us/dish) kill about half of the engorged Boophilus annulatus female ticks within 1.9 days and 90% in 5 days. Spraying nematodes on soil in buckets (50 IJs/cm²) killed 50 or 90% of the ticks on day 5 or 10 post contact respectively. Other tick species were found to be less susceptible to nematodes. The nematode strains most virulent in petri dish test were not the best in soil test. Dipping *Boophilus annulatus* engorged females in a spore suspension of the entomopathogenic fungus *Metarhizium anisopliea* $(1x10^7/ml)$ caused a mortality of some 50% within 6 d and 90% in 7 d. The surviving females laid 92% fewer eggs than the control. Only 2% of these eggs hatched and all larvae died within 6 d. Various stages of Hyalomma excavatum and Rhipicephalus sanguineus were found to be sensitive to the same fungi. The fungi strains differed markedly in their anti tick virulence. These results indicate that there exists quite a high potential for a microbial control of ticks. Further research is still required to hopefully transfer these findings into practical recommendations to farmers.

Index terms: Boophilus, Heterorhabditidae, Metarhizium, Rhipicephalus, Stainernematidae.

[2139] OBSERVATIONS ON THE VICE-LIKE STRUCTURES IN PUPAE OF PLUSIINAE (LEPIDOPTERA, NOCTUIDAE)

<u>L. Sannino¹</u>, B. Espinosa² & J. A. Tsitsipis³, ¹Ist. Sper. Tabacco, via P. Vitiello 66, 84018 Scafati (SA), Italia; ²Dipt. Ent. e Zool. Agraria, Univ. Napoli "Federico II", 80055 Portici, Italia; ³Laboratory of Entomology and Agricultural Zoology, Univ. of Thessaly, P.O. Rox 38334, Pedion Areos, Volos, Greece.

On the body dorsal surface of the Plusiinae pupae found on Mediterranean tobacco cultures are usually present particular structures, such as the vice-like and the semiannular structures, the shape of which is useful for species identification, as they are typical. In this paper the vice-like structures morphology of five species (Autographa gamma, Chrysodeixis chalcites, Diachrysia chrysitis, Macdunnoughia confusa, Trichoplusia ni) is comparatively described, highlighting the differences among them, until now little understood, and also trying to provide a functional explanation. Moscher (1916), listing the Plusiinae pupal features, mentions "prominent grooves" present on the posterior margin of metathorax and the first four abdominal segments, but does not indicate a possible function. Vice-like structures, usually three in number, are arranged between the adjacent margins of the first four abdominal segments. Each of them consists of two jowls, the caudal and the cephalic one. In gamma, the caudal jowl is regularly rounded and provided with uniformly distributed papilliform reliefs, while the cephalic one is prominent in the middle. In chalcites, the caudal jowl is very arched and thinly rounded, rugose on the contact surface only; the cephalic jowl is smooth and very arched. In chrysitis, the vice-like structures are very noticeable: the anterior jowl is swollen with transversal ridges, while the posterior consists of a noticeable squat prominent tubercle-shaped and rugose protuberance. In confusa, the caudal jowl is flattened on the contact surface and provided with irregular papilliform reliefs (concentrated mainly on the flat margin), while the cephalic one is straight in the middle. In ni, the caudal jowl is sinuous, sinuate in the middle and provided with very small reliefs on the extreme margin only; the cephalic jowl, instead, presents a transversal cavity, wave-like on the top and prominent. Plusiinae pupate on the foliage of the food plant in a flimsy silk cocoon. As a consequence, the pupa is easily exposed to predator attacks and wind shakes. The anchorage provided by cremaster, although enforced by the special spiral-shaped spines, is ineffective against transversal motions, which could be offset by a dorsal blocking device, instead. Vicelike structures enable pupa, in its normal lying position, to have a secure grip to the cocoon silk threads, which are squeezed as in a vice. The function of the aforesaid structures is hypothesised to be the tenacious blocking of the pupa to the cocoon silk. Index terms: Lepidoptera, pupae, dorsal structures

[2140] SELECTION OF ENTOMOPATHOGENIC FUNGI FOR USE IN COMBINATION WITH SUBLETHAL DOSES OF IMIDACLOPRID: PERSPECTIVES FOR THE CONTROL OF THE LEAF-CUTTING ANT ATTA SEXDENS (L.) (HYMENOPTERA: FORMICIDAE)

A.V. Santos, B.L. Oliveira & <u>R.I. Samuels</u>, Department of Plant Protection. Universidade Estadual do Norte Fluminense, Campos dos Goitacazes, RJ. 28015-620, Brazil. E-mail richard@uenf.br

The leaf-cutting ant Atta sexdens is a serious pest in tropical and sub-tropical regions. To date, no biological control strategy has been succesfully addressed for this insect. On the one hand, entomopathogenic fungi are promissing natural enemies of ants, since they are capable of overcoming the complex social organization of these insects. as reported by the incidence of natural epizootics. However, leaf-cutting ants posses many behavioral strategies which reduce the effectiveness of fungal infections. In the first part of this study four isolates of the fungus Beauveria bassiana (LPP1, LPP2, CG05 and CG24) and one isolate of Metarhizium anisopliae (E 9) were tested against adult foragers of A. sexdens. Ants were allowed to walk on filter paper discs, inside and holdes, previously impregnated with 1 ml of a conidia suspension $(1.2 \times 10^7 \text{ conidia/ml})$, maintained in a glass chamber (100% RH, 26° C) for 24 h and subsequently, transferred to sterile Petri dishes, maintained at 26° C, 70% RH, 24 h dark. The LT50 for LPP2, LPP1, E9, CG24 and CG05 was 3.41, 3.52, 3.91, 4.12 and 4.61 days, respectively. Experiments were carried out to test the toxicity of imidacloprid (IMI) to A. sexdens. Concentrations of 100, 10, 1 and 0.1 ppm IMI were dissolved in a saturated sucrose solution and ants were subsequently exposed to cotton wool balls soaked in the insecticide. Mortality was evaluated after 5 days exposure. Percent mortality was 90.49, 63.80, 27.63, 8.57 and 9.51 for 100, 10, 1, 0,1 ppn and the control group, respectively. Insects treated with 0.1 ppm were observed to have reduced locomotory activity, reduced aggressiveness and grooming behavior 24 h after exposure to IMI. A preliminary test was carried out to evaluate the combination of a sub-lethal dose of IMI (0,1 ppm) and infection by LPP2. Mortality due to fungal infection alone was 66.67%. Mortality of insects treated with IMI followed by exposure to the fungus was 83.33%. These results indicate that IMI increases the susceptibility of ants to infection.

Index terms: Beauveria bassiana, Metarhizium anisopliae, insecticide, biological control.

[2141] MASS PRODUCTION OF *BACULOVIRUS ANTICARSIA* TO CONTROL *ANTICARSIA GEMMATALIS* IN SOYBEANS: RESEARCH PROGRAM FROM THE AGRICULTURAL COOPERATIVES OF THE PARANÁ STATE

<u>B. Santos</u>¹, ¹Departamento de Patologia Básica, Universidade Federal do Paraná, Caixa Postal 19031, Curitiba, PR 81531-970, Brasil, E-mail santosb@garoupa.bio.ufpr.br

The mass production program of Baculovirus anticarsia aiming the production of biological insecticide for the control of the velvet bean caterpillar, Anticarsia gemmatalis in soybeans, accomplished by the Agricultural Cooperatives of the Paraná State started in 1987 in Cascavel City. The technology was developed by EMBRAPA/SOJA in Londrina, Paraná. The production of the virus is wholly accomplished in the field from December to January, using the natural occurrence of the caterpillar in the soybean crops in the Western Paraná. The virus is sprayed when samplings indicate larvae populations levels ranging 40 to 60 caterpillars per 2 m long. The collection of the dead caterpillars is accomplished by rural workers about 8 days after the spraying. About 188 workers are used (ranging from 20 to 496) a day for the collection, being obtained ca. 1.54 kg caterpillars/person/day. The mass production of dead larvae collected from the field offers as the main advantage a the great production, low cost, in a short period of time. However, this method presents great variation in the annual production, as its disadvantage. The annual average production along the past 13 years of program is 3.575 kg of infected caterpillars (from 295 to 12.347 kg), enough to 197.000 ha of soybean crops. This great variation in obtaining infected caterpillars is mainly due to several factors which act on the population of A. gemmatalis. The most important one is the weather. Companies that are interested in this agribusiness demand for a system of constant production of the caterpillars for obtaining of a balanced revenue. So, it is necessary to develop creation techniques of A. gemmatalis in laboratory with an industrial profile, seeking a constant and maintainable annual production along the time. In Brazil, it has been looked for to modernize the technique of formulation and some evolutions were obtained recently with mechanization of the extraction of the virus from caterpillars. Index terms: Lepidoptera, Noctuidae, biological control, baculovirus.

[2142] TRANSINFECTION OF *WOLBACHIA* ENDOSYMBIONTS AMONG THREE SPECIES OF LEPIDOPTERAN INSECTS

T. Sasaki¹, Y. Fujii¹, D. Kageyama², S. Hoshizaki² & H. Ishikawa¹, 1Dept. of Biological Sciences, Graduate School of Science, Univ. of Tokyo. Hongo, Tokyo 113-0033, Japan, Email sasaki@biol.s.u-tokyo.ac.jp; 2Dept. of Agricultural and Environmental Biology, Graduate School of Agricultural and Life Sciences, Univ. of Tokyo, Yayoi, Tokyo 113-8657, Japan.

The bacteria of the genus Wolbachia are intracellular endosymbionts harbored by many arthropod hosts. They are known to cause various reproductive alterations in their hosts such as thelytokous parthenogenesis, male killing, feminization and cytoplasmic incompatibility (CI). CI is a reproductive incompatibility that results in mortality of the embryos when uninfected females are mated to infected males or when female and male are infected with different Wolbachia strains. Phylogenetic analyses of Wolbachia carried by various arthropods have shown that they are divided into two major groups, A and B. It has also been shown that the effects of Wolbachia infections on the hosts are not congruent with the bacterial phylogeny. In an attempt to determine whether the difference in the mode of reproductive manipulation by Wolbachia depends on the difference in the bacteria or in the host, we performed transinfection experiments using three species of Lepidopteran insects, the Mediterranean flour moth Ephestia kuehniella, the Almond moth Ephestia cautella and the Adzuki bean borer Ostrinia scapulalis. E. kuehniella is infected with a A-group Wolbachia strain, and E. cautella is doubly infected with two strains of Wolbachia, one belongs to A group and the other to B group. Wolbachia infections in these moths are associated with the expression of CI. The B group Wolbachia harbored by O. scapulalis induces feminization of genetic males into functional females. Transferrs of the Wolbachia was Wolbachia of O. scapulalis was transferred into E. kuelmiella from which its natural infection had been removed by tetracycline treatment, the transinfected line showed the phenotype of male-killing. In the transinfection experiment from E. cautella to E. kuehniella, we obtained three lines different in the infection status, single infection with A-Wolbachia, single infection with B-Wolbachia and double infection with both A- and B-Wolbachia. The transinfected E. kuehniella carrying only B-Wolbachia originating in E. cautella expressed CI. On the other hand, the transinfected lines that had received A-Wolbachia from E. cautella expressed male-killing. These observations suggested that the phenotype induced by Wolbachia is determined by the interaction between the bacteria and hosts.

Index terms: Wolbachia, transinfection, feminization, cytoplasmic incompatibility, male-killing.

[2143] NEW HOST RECORD OF A GUT FUNGUS OF MYRIAPODA, ENTEROBRYUS OXIDI (TRICHOMYCETES; ECCRINALES)

II. Sato, Insect Pathology Laboratory, Forestry and Forest Products Research Institute, Kukizaki Ibaraki 305-8687, Japan, E-mail Hirokis@ffpri.affrc.go.jp.

Trichomycetes is a class of fungi belonging to Zygomycota. Species of this class are living in digestive tracts of insects, myriapoda, and other arthropods. Spores are produced in the gut and released to environment as fecal contaminants. By feeding the spores next infection begins. In the gut the spores germinate and produce appressorium to attach to the host's gut cuticle. Each species has special site to attach in the gut. Enterobyus is a genus which is living in the specifically hindgut of myriapoda. Hostspecificity of Trichomycetes, especially Eccrinales, hardly studied. Though this genus has been recorded from Japan, for the limited number of specimen there have been no identified species in this genus in Japan. In this study, a species of Enterobryus was derived from a species of myriapoda, Oxidus gracilis. From the morphological characteristics, this fungus was identified as Enterobryus oxidi. Subsequently, a species of Enterobryus was derived from other species of myriapoda, Niponia nodulosa. The fungus was thought morphologically also identical to Enterobyus oxidi. The two species of myriapoda are commonly sharing habitat and eat decayed leaves and soil. It is thought that the spores of E. oxidi had chances to be fed by those animals. All species of Enterobryus have been described from only one genus or one species of the host animal. Oxidus gracilis and Niponia nodulosa belong to the family, Paradoxosomatidae and Cryptodesmidae, respectively. Enterobryus oxidi had a wider host spectrum than genus.

Index terms: Oxidus gracilis, Paradoxosomatidae, Niponia nodulosa, Cryptodesmidae, Enterobryus oxidi

[2144] BACULOVIRUS-MEDIATED EXPRESSION AND ANTIFUNGAL ACTIVITY OF A DIAPAUSE-SPECIFIC PEPTIDE OF THE ADULT LEAF BEETLE

K. Sato¹, II. Tanaka² & K. Suzuki², ¹Dept. of Appl. Microbiol., Iwate Biotech. Res. Center, Kitakami 024-0003, Japan, E-mail: kensato@sv02.ibrc.pref.iwate.jp; ²Dept. of Biosci, and Technol., Fac. of Agric., Iwate Univ., Morioka 020-8550, Japan.

A diapause-specific peptide, diapausin, of the leaf beetle, Gastrophysa atrocyanea, exhibits antibiotic activity against some phytopathogenic fungi. However, it is difficult to yield high amounts of pure active diapausin required for precise assay of antifungal activity from small bodies (length: about 5 mm) of the adult leaf beetle. We have, therefore, expressed a diapausin cDNA cloned from the leaf beetle using Bombyx morifbaculovirus system. Recombinant diapausin secreted in the hemolymph was purified by a combination of acidic methanol-extraction and reversed-phase high performance liquid chromatography. Purity of recombinant diapausin was checked at each purification step by SDS-tricine PAGE and/or Western blotting using anti-diapausin antiserum. The final yield of purified recombinant diapausin was about 25% or equivalent to 50-µg/ml hemolymph. Western blotting analysis indicated that the size of recombinat diapausin (simply described below as diapausin) (4.5 kDa) was consistent with the size for natural diapausin. Diapausin exhibited a broad spectrum of antifungal activity against phytopathogenic fungi including Alternaria alternata, Botrytis cinerea, Fusarium oxysporum, F. solani and Verticillium dahliae. Concentrations of diapausin for 50% inhibition of fungal growth varied from 10 to 130 µg/ml. Diapausin did not overcome spore germination, but inhibited mycelial growth. The antifungal activity of diapausin against F. solani was affected by the presence of cations, e.g., Ca2+ and K+. On the other hand, diapausin was nontoxic for such entomopathogenic fungi as Metharhizium anisopliae and Paecilomyces farinosus. We are now attemting to express diapausin genes in tobacco plants, Nicotiana tabacum. Index terms: Gastrophysa atrocyanea, Bombyx mori, fungi, diapausin.

[2145] WOLBACHIA ARE DISTRIBUTED THROUGHOUT SOMATIC AND GENITAL ORGANS OF A MULBERRY LEAFHOPPER, HISHIMONOIDES SELLATIFORMIS

<u>M. Sato</u>, W. Mitsuhashi, T. Saiki, W. Wei, K. Watanabe & II. Kawakita, National Institute of Sericultural and Entomological Science, Tsukuba, Ibaraki 305-8634, Japan, E-mail: satomamo@nises.affrc.go.jp.

Wolbachia belong to the alpha subclass of the purple bacteria, and are known as intracellular symbionts to cause reproductive and sex-ratio disorders in many insects. They have been well described in the region of insect reproductive organs, but yet the presence within somatic organs has been poorly documented. By PCR assays and electron microscopy (EM), we examined the distribution of Wolbachia in both somatic and genital organs of *Hishimonoides sellatiformis*, which is an insect vector of mulberry dwarf-phytoplasma. Each insect's organ was carefully collected from leafhopper bodies in saline solution. For PCR assays, a template DNA was prepared from insect organs by using the CTAB method, and primers constructed by O'Neill et al. (1992) and our own were used to amplify 16S rDNA of Wolbachia. In all somatic organs such as brains, salivary glands, midguts, fat bodies, and thoracic ganglia, PCR products were obtained in a predicted size. The similar size of DNAs were amplified in several genital organs (ovaries, seminal receptacles, and testes), eggs, and newly hatched nymphs of the insect. The PCR product was identified as 16S rDNA of Wolbachia by its sequencing, which showed that our organisms belong to group A Wolbachia. In addition, rod-shaped bacteria (1 x 0.3 []m) were observed by EM in somatic organs, including mycetomes, brains, salivary glands, midguts, fat bodies and thoracic ganglia, and ovaries. The organisms closely resembled Wolbachia previously reported in shape, so that they were strongly suggested to be Wolbachia. Thus, we verified that Wolbachia are distributed throughout every somatic organ as well as others of genital type. The further studies will be required to verify the potential significance of Wolbachia infections in non-reproductive as well as reproductive organs.

Index terms: PCR detection, electron microscopy, symbiont

[2146] IDENTIFICATION OF ENDOPHYTIC BACTERIA IN CITRUS WITH BIOCONTROL ACTIVITY AGAINST *DIAPREPES ABBREVIATUS* (COLEOPTERA: CURCULIONIDAE)

R. G. Shatters, Jr., & A. Weathersbee, USDA, ARS, U. S. Horticultural Research Laboratory, 2001 South Rock Road, Fort Pierce, FL 34945, USA.

Research in the last few years has shown that diverse populations of bacterial species termed endophytes can live internal to plant tissues. Some of these organisms are obligate endophytic bacteria while others are more opportunistic. Although a few of these bacteria can be regarded as nathogenic, many induce no pathogenic symptoms on the host plant, and in fact, some endophytic bacteria improve the fitness of the host, and have been shown to be effective as biocontrol agents against pathogenic microorganisms. The effect of these endophytic bacteria on plant pest insects has not yet been studied, and was the basis of this report. We have isolated 72 endophytic bacteria from 14 different citrus varieties located in Fort Pierce, Florida, USA. The bacteria were isolated from new-growth stem tissue with three successive sterilizations steps using bleach, formaline, and ethanol. The surface sterilized stems were then imbedded on enriched nutrient agar plates (containing cyclohexamide to prevent fungal growth) and incubated at 30°C for 3-days. Stem pieces showing no bacterial growth were split open and placed on new nutrient agar plates. Bacterial growth observed within two days on the new plates was sampled for isolation by successive single colony transfer, and used for species identification. These isolates were identified by gas chromatographic profiling of the methyl esterase derivatives of isolated fatty acids. The fatty acid methyl esterase (FAME) profile was used to determine the genus and species using the Sherlock System software developed by MIDI, Inc. Isolates were shown to represent a diverse group of bacteria with members from 14 different genera. Using these bacterial isolates, a plate-screening assay was developed to test the effect of these bacteria on the larvae of a major citrus pest weevil; Diaprepes abbreviatus. Out of all isolated endophytes, 6 were toxic or pathogenic to D. abbreviatus. Bacteria that killed the D. abbreviatus larvae belonged to only three of the 14 genera isolated from citrus plants. These three genera included Bacillus, Pscudomonas, and Clavibacter. All three were active against D. abbreviatus larvae in petri-plate assays and in D. abbreviatus larvae growth medium. Results are presented with respect to the use of bacterial endophytes for the control of insect pests on crop plants.

Index terms: Diaprepes abbreviatus, endophyte, citrus, biocontrol

[2147] THE LONG-TERM EFFECT OF MICROSPORIDIA (NOSEMA SP., POLISH ISOLATE) ON THE GYPSY MOTH (LYMANTRIA DISPAR, LEPIDOPTERA: LYMANTRIIDAE) IN LABORATORY EXPERIMENTS

<u>A. Sierpinska</u>, Forest Research Inst., Bitwy Warszawskiej 1920 r. No. 3, 00-973 Warsaw, Poland, E-mail: A.Sierpinska@ibles.waw.pl

An isolate of Nosema sp. was found in gypsy moth larvae from Biebrza National Park in the north-east of Poland in 1997. Microsporidium infected 91 % of larvae. So high prevalence of the isolate in the gypsy moth population encouraged to the estimation of long-term influence of single infection on laboratory reared gypsy moth. In 1998 2nd instar gypsy moth larvae (New Jersey Standard Strain) were infected with spores of Polish microsporidian isolate. Larvae were feeding spores spread on the surface of an artificial diet. Five concentrations were used: 6.8 x 10⁰, 6.8 x 10¹, 6.8 x 10², 6.8 x 10³ and 6.8 x 104 spores / µl. Sixty larvae per concentration (and sixty control, not infected larvae) were reared in small groups: 2-10 larvae depending on the instar until pupation. For 1998 generation an influence of the infection on larval development, pupation, construction and the interface of an egg mass were observed for all concentrations. The above observations were done for 1999 and 2000 generations only for larvae infected with spores in the lowest and the highest concentrations. Except for observations mentioned above, also the amount of fertile and not fertile eggs in every egg mass were counted as well as numbers of hatching larvae. The larval development of 1998 generation infected with microsporidia was slightly delayed, but the mean pupal weight did not differ for infected and not infected larvae. The 1998 control females laid significantly longer egg masses than females infected as 2nd instar larvae with the highest concentration of spores. The mean amount of hatching 1999 larvae was 7-fold lower and the mean amount of not fertile eggs per egg mass was 2-fold higher for larvae infected in the previous generation with spores in the highest concentration, than for larvae infected with spores in the lowest concentration. Similar observations were noted for the next, 2000 generation of laboratory reared gypsy moth. The results showed that Polish microsporidian isolate is able to reduce gypsy moth population density in long-term laboratory experiment and suggested, that the isolate is probably transmitted transovarially.

[2148] EPIZOOTY OF *NOMURAEA RILEYI* IN SPODOPTERA FRUGIPERDA LARVAE IN THE CORN CROP, ZEA MAYS

R.C. Siloto¹, J. E. M. Almeida² & A. Raga¹, ¹ Lab. Entomologia Econômica, Centro Experimental do Inst. Biológico, P. O. Box 70, Campinas, SP, 13001-970, Brazil, Email: rcsiloto@carpa.ciagri.usp.br. ² Lab. Controle Biológico, Centro Experimental do Inst. Biológico, P. O. Box 70, Campinas, SP, 13001-970, Brazil.

In January 2000 Spodoptera frugiperda larvae, more than 2 cm of length, was observed naturally infected by (ungi Nomuraea rileyi in corn crop, in Casa Branca County (21°40'S; 47°10'W; 545 m), State São Paulo, Brazil. An evaluation in the field was realized in 100 plants of two lines, with approximately 90 days of age. 'Master' showed 62% of infested plants by S. frugiperda, 84% of infested plants with fall armyworm were infected with N. rileyi and 78% larva mortality. In Exceller', 40% of plants were infested with S. frugiperda, 77% of infested plants with S. frugiperda were infected with the fungus and 76% larva mortality. Up to fifteen days before the epizooty lhe local precipitation estimated in 421 mm. In the same period the medium temperature and relative humidity registered were 25 °C and 80%, respectively. It was observed that N. rileyi epizooties occurred at 26°C and 60 to 100% relative humidity. Therefore, after rainy periods and mild temperatures, followed by an dry period provide good conditions for the N. rileyi development, an important agent of natural biological control.

Index terms: Fall armyworm, entomopathogenic fungi, lines, biological control.

[2149] ENZYME PRODUCTION BY THE FUNGUS SYMBIOTIC WITH THE ANT MYCETAROTES PARALLELUS

<u>A. C. O. Silva</u>, ., M. Bacci, Jr, F. C. Pagnocca, , O. C. Bueno, M. J. A., Hebling Centro de Estudos de Insetos Sociais, Universidade Estadual Paulista, Ric Claro, SP. CEP.13506-900, Brazil – e-mail: acos@rc.unesp.br. Financial support: Fundação de Amparo a Pesquisa do Estado de São Paulo - FAPESP 95/4229-2 and 97/13383-0 and master degree fellowship FAPESP 97/04104-0.

Ant symbiotic fungi are thought to contribute to the insect nutrition through enzymatic degradation of organic matter. Among this matter, polysaccharides are known to be promptly metabolized by the fungus of the higher Attini ant Atta sexdens. However few is known on the metabolic ability of the fungi symbiotic with Lower Attini Ants. In the present investigation we have characterized the metabolism of polysaccharides and proteins by the fungus symbiotic with the Lower Attini ant Mycetarotes paralellus. This fungus was able to grow and degrade several polysaccharides as well as their hydrolysis products and proteins. Xylan was the most efficiently assimilated polysaccharide and thus it is likely the more important plant polysaccharide supporting fungal growth inside ants nests. Cellulose, the most abundant plant polyssacharide, was not efficiently metabolized by the fungus. Pectin was efficiently degraded but poorly assimilated, indicating that the high production of pectinase may be primarily used to macerate the plant tissue, removing the cement which keeps vegetation cells attached to each other, and thus access the other nutrients from plants. All proteins utilized as carbon sources have been promptly degraded by the fungus, but poorly assimilated. Thus it is likely that proteins, as well as pectin, are degraded by the fungus to expose other nutrient from plants. Finally, the fungus was also found to poorly degrade and assimilate chitin, which seems not to be an important carbon source inside ants' nest. The results obtained in the present investigation indicate that the symbiotic fungus of Mycetarotes paralellus is able to mediate the ants nutrition on several polysaccharides and proteins. If the fungal behavior in laboratory cultures typifies its role in nature, xylan and starch may be the most important carbon sources for fungal growth inside ants' nests. Since ants nutrition relies on the fungus, these polysaccharides may play an important part in ants nutrition as well.

[2150] BIOLOGIC CONTROL OF CULEX QUINQUEFASCIATUS IN CITIES FROM PERNAMBUCO STATE APPLYING BACILLUS SPHAERICUS

D. M. P. da Silva¹, L. M. de A. C. Maranhão¹, E. M. M. Rios², L. N. Regis³ & R. S. Cavalcanti¹, ¹Empresa Pernambucana de Pesquisa Agropecuária - IPA, C.P. 1022, Recife, PE, Brasil; ²Universidade Federal de Pernambuco - UFPE, Av. Prof. Morais Rego, s/n, CEP 50.670-901, Recife, PE, Brasil; ³Centro de Pesquisas Aggeu Magalhãe - CPqAM/FIOCRUZ, Av. Prof. Morais Rego, s/n, CEP 50.670-420, Recife, PE, Brasil.

In the state of Pernambuco, Brazil, *Culex quinquefasciatus* has considerable medicinal and social importance, in the transmission of Bancroft's filariasis and because of the discomfort caused by the process of hematophagism. The entomopathogenic bacterium *Bacillus sphaericus*, because of its action against mosquitoes, is considered the main control agent of this culicide. The Laboratory of Bioproducts Production in Empresa Pernambucana de Pesquisas Agropecuárias - IPA, has been producing, since 1997, together with Departamento de Antibióticos in Universidade Federal de Pernambuco and Instituto de Pesquisas Aggeu Magalhães/CpqAM - FIOCRUZ, *Bacillus sphaericus* 2362 in the scale of 1000 liters. The biolarvicide has been distributed, in the form of fermented broth, since 1997, to the Health Bureau from many cities in Pernambuco State: Altinho, Araripina, Bonito, Brejo da Madre de Deus, Caruaru, Floresta, Olinda, Recife, Petrolina, Salgueiro, Santa Cruz do Capibaribe, Santa Maria da Boa Vista, São Caetano, São João, São Joaquim do Monte, Serra Talhada, Toritama, e Trindade. The percentage of control was situated between 80 and 100%, 48 hours after application. For the experiments, IPA distributed about 6500 liters of fermented broth, 24.3% from this volume for the Program of Filariasis Control in the city of Recife; the rest was applied in the others cities, with the aim of reducing *C. quinquefasciatus* and the discomfort caused by this insect.

Index terms: Culex quinquefasciatus, Bacillus sphaericus, vector insects, entomopathogenic bacteria.

[2151] LARVAL PARASITOIDS AND PATHOGENS OF SPODOPTERA FRUGIPERDA (LEPIDOPTERA: NOCTUIDAE) IN FOUR CITIES IN PARAÍBA

M.T.C. Silva¹, <u>I.A. Mezzomo¹</u>, F.R. Guimarães¹ & M.G.A. Lima², ¹Laboratory of Biological Control, Dept. of Pharmacy and Biology, Paraíba State Univ., Félix Araújo Square, 13B, 58101-450, Campina Grande, PB, Brazil, E-mail jamezzo@zaz.com.br; ²Dept. of Biology, Ceará State Univ., P.O. Box 1531, 60740-020, Fortaleza, CE, Brazil, E-mail goretti@uece.br

Among the pests that attack corn, the Spodoptera frugiperda stands out, considered the principal pest of this culture in Brazil, being able to cause great damage also to other important cultures like sorghum, rice and sugarcane. The biological control is an important tectic within the integrated management of this pest, controled principally with insecticides. Searching to know the parasitoids and pathogens that attack this noctuid in the larval phase, larvae were collected in corn plantations within the city limits of Campina Grande, Lagoa Seca, Alagoa Nova and São José da Lagoa Tapada, from May 1997 to July 1999. In the laboratory, the larvae were individualized in Petri dishes and fed on an artificial diet. Of the 3324 larvae collected, 710 (21,4%) were parasited, being 478 (14,4%) by Chelonus insularis (Hymenoptera: Braconidae), 111 (3,3%) by Archytas incertus (Diptera: Tachinidae), 96 (2,9%) by Winthemia trinitatis (Diptera: Tachinidae), 12 (0,4%) by Campoletis flavicincta (Hymenoptera: Ichneumonidae) and 2 (0,06%) by Cotesia sp. (Hymenoptera: Braconidae). A nematode of the genus Hexamernis killed 112 larvae (3,4%), while a non-identified protozoa caused the death of 12 larvae (0,4%). The death rate caused by all the biotic agents was 34,2% in A. Nova, specially by C. insularis (33,3%); 30,9% in SJ.L. Tapada, predominating Hexamernis sp. (25,7%); 24,7% in L. Seca, specially by C. insularis (14,4%); and 9,2% in C. Grande, predominating C. insularis (10,5%). In the surveyed places, with the exception of S.J.L. Tapada, C. insularis was the most frequent natural enemy and with the highest rate of parasitism, being the most promising to be used in the biological control of S. frugiperda. The nematode Hexamernis sp. was efficient in sp.J.L. Tapada, reaching 72,0% of parasitism in on of the collections, although its performance limits itself to the rainy season.

Index terms: Insecta, biological control, fall armyworm.

[2152] CLONING AND HETEROLOGOUS EXPRESSION OF A BACILLUS THURINGIENSIS PROTEIN TOXIC AGAINST THE FALL ARMYWORM

LO. Silva-Werneck¹, P.W. Inglis¹, S.M. Melo¹, R.G. Monnerat¹ & M.F.G. Sa¹, ¹Embrapa Recursos Genéticos e Biotecnologia, P. O. Box 02372, 70849-970, Brasília, DF, Brazil. E-mail: joseilde@cenargen.embrapa.br

Bacillus thuringiensis is an aerobic bacterium that synthesizes crystalline inclusions, during sporulation, that are composed of one or more proteins, known as \delta-endotoxins or Cry proteins. These proteins are toxic to a wide variety of agronomic, forestry, healthrelated insect pests and other invertebrates. Because of their high specificity and environmental safety, bioinsecticides based on B. thuringiensis have been successfully used for more than 50 years. The goals to this work was to express a Cry toxin from a Brazilian B. thuringiensis strain toxic to the fall armyworm (Spodoptera frugiperda), in order to evaluate its isolated activity to the former and other insect species, to study toxinreceptor affinity, to produce anti-body and to develop a heterologous expression methodology (*Pichia pastoris*) for *B. thuringiensis* toxins. The coding sequence of the cry1Ab gene from the strain S93 of B. thuringiensis subsp. kurstaki was cloned in pUC18 and amplified by PCR using Bam HI primers. The PCR product was cloned in a shuttle expression vector for the yeast P. pastoris and amplified in Escherichia coli cells. P. pastoris GS115 cells were transformed by electroporation and analised by Western blot. A clone was selected and induced for expression. Samples collected at different hours post-induction were analised by SDS-PAGE and Western blot, showing a better expression level at 72 hours.

Index terms: Spodoptera frugiperda, biological control, Cry protein

[2154] INTEGRATED SYSTEM TO SIMULATE THE IMPACT OF THE FUNGUS NOMURAEA RILEYI ON BRAZILIAN ANTICARSIA GEMMATALIS POPULATIONS

E. R. Suiii¹, D. R. Sosa-Gomez², V. A. M. de Carvalho¹ & M. S. Tigano¹, ¹Embrapa Recursos Geneticos e Biotecnologia, PqEB Final W3 Norte, C. Postal 02372, 70849.970 Brasilia, DF, Brazil, E-mail sujii@cenargen.embrapa.br; ²Embrapa Soja, C. P. 231, 86001.970 Londrina, PR, Brazil.

The fungus Nomuraea rileyi is known as an important biological agent of Anticarsia gemmatalis (Lepidoptera: Noctuidae), a key soybean pest in Brazil. N. rileyi can prevent A. gemmatalis populations from reaching economic threshold levels in soybean, and consequently avoid the use of chemical insecticide applications against this pest. Little is known about the evolution of this disease on A. gemmatalis population dynamics. An integrated system of mathematical models has been developed, using the software "STELLA version 5.0 Research", to simulate the pest population dynamics and the progress of the disease caused by N. rileyi. The system integrates a model of N. rileyila, gemmatalis dynamics, the precision of the system has been improved by the introduction of data related to infection and conditions, host population and soybean variety is required for simulations. The system generates a curve of A. gemmatalis caterpillars population based on the estimation of N. rileyi condition rates. The generated data compared to the field data shows that the system developed can mimicry the N. rileyi'A.gemmatalis interactions. However, further studies on environmental factors affecting migration rates of the insect, N. rileyi condidingenesis dynamics and considial survivorship, are still needed to improve the precision of the model for the use on A. gemmatalis management. Index terms: Biological control, pest management, population dynamics

[2153] BIOLOGICAL ACTIVITY OF NUCLEAR POLYHEDROSIS VIRUS ISOLATED FROM CELERY LOOPER (ANAGRAPHA FALCIFERA KIRBY) AGAINST NUN MOTH (LYMANTRIA MONACHA L.)

I. Skrzecz, B. Glowacka, Forest Research Inst. Bitwy Warszawskiej 1920 r. nr 3, Warsaw, 00-973, Poland, E-mail: skrzeczi@ibles.waw.pl.

Diseases caused by entomopathogenic viruses may play an important role in reducing population numbers of forest insect pests. Special attention has been focused on nuclear polyhedrosis viruses and granulosis viruses from the family Baculoviridae due to their essential selectivity and the lack of induced resistance to these viruses in infected insects. Research on insecticidal efficiency of insect pathogenic viruses for control economically important defoliators (Lymantria monacha, Lymantria dispar, Panolis flammea and Dendrolimus pini) is currently being conducted by the Forest Research Institute, Poland. This study was carried out in order to evaluate the insecticidal efficiency of virus isolated from caterpillars of Anagrapha falcifera (AfMNPV) against nun moth (L. monacha) - the most harmful defoliator in Polish (finite of definite the laboratory conditions, caterpillars of nun moth fed on artificial diet infected with 5 different doses of AfMNPV $(2\pi10^5-2\pi10^9 \text{ PIB/ml})$. The mortality of observed caterpillars was evaluated every day. The intensity of nun moth feeding was determined by faeces dry mass produced by an average caterpillar over a 24 h period. The results of the experiments indicated that AfMNPV was infectious for nun moth. The mortality of caterpillars that fed on infected diet was higher (16-45%) than mortality of control caterpillars (10%). Microscopic observations indicated numerous polyhedral bodies in dead caterpillars and pupae from the groups treated with virus. The pathogen was not observed in dead control caterpillars or pupae. All caterpillars that survived the treatment with infected diet pupated, although a high mortality (47-100%) of obtained pupae was observed within a few days after pupation. The intensity of feeding decreased in infected caterpillars after 20 days of treatment.

[2155] SELECTION OF ENTOMOPATOGENIC FUNGI IN THE CONTROL OF LEPTOPHARSA HEVEAE

M.R.Tanzini^{1,2} & S.B.Alves¹, ¹Dept. of Entomology, Univ. of São Paulo, ESALQ, P.O. Box 9, Piracicaba, São Paulo 13418-900, Brasil, E-mail nutanzin@carpa.ciagri.usp.br; ²Scholarship from FAPESP.

The patogenicity of the one isolate of Aschersonia aleyrodis, 13 isolates of Beauveria spp., five of Hirsutella spp., 20 of Metarhizium anisopliae, two of Nomuraea rileyi, seven of Paecilomyces spp, seven of Sporothrix insectorum, one of Trichoderma sp. and four of Verticillium lecanii to nymphs of Leptopharsa heveae, a pest of rubber tree (Hevea brasiliensis, Euphorbiaceae) was evaluated under laboratory conditions. Conidial suspensions (1×10^8) of the isolates were applied with Potter tower to leaf disks of H. brasiliensis (0.2µl/cm²). Leaf disks were maintained under controlled conditions at 26±0.5°C; 80% RH and LD 12:12 for four days. H. thompsonii, A. aleyrodis and N. rileyi caused mortality between 23 and 50% and were considered of low virulence. For Beauveria spp., M. anisopliae, S. insectorum, Paecilomyces spp. and V. lecanii a great variation was observed in the patogenicity. The best isolates were Beauveria bassiana 1196 and 619 with 84 and 56% mortality after 3 days after inoculation, M. anisopliae 1144 and 1104 both with 90%, S. insectorum 1229 with 92%, V. lecanii 972 with 46% and P. fumosoroseus 1200 with 100% mortality. Trichoderma sp. a phytopathogenic fungus, caused 78% of mortality 4 days after inoculation. The high virulence of *M. anisopliae*, *S. insectorum* and *P. fumosoroseus* is an important and desirable characteristic for the development of a strategy of pest management in plantations of Heven with great potential for control of these insect. Index terms: Heteroptera, Tingidae, lace bug, Hevea brasiliensis, fungus, biological control

[2156] PHYLOGENY OF *PAECILOMYCES* SPECIES REVEALED BY ANALYSIS OF RIBOSOMAL RNA ITS SEQUENCES

<u>M. S. Tigano¹</u>, F. Driver², P. W. Inglis¹, J. W. H. Trueman³ & R. J. Milner², ¹Embrapa Recursos Genéticos e Biotecnologia (Cenargen), P. O. Box 02372, Brasília, DF 70770-900, Brazil, E-mail myrian@cenargen.embrapa.br; ²CSIRO Entomology, P. O. Box 1700, Canberra ACT 2601, Australia; ³Research School of Biological Sciences, Australian National University, Canberra ACT 2601, Australia.

The 5.8S rDNA and flanking internal transcribed spacers (ITS1 and ITS2) of the ribosomal RNA gene from Paecilomyces species were amplified using the polymerase chain reaction and sequenced. Sequences from P. amoeneroseus, P. carneus, P. farinosus, P. fumosoroseus, P. leycettanus, P. lilacinus, P. marquandii, P. penicillatus, P. tenuipes, P. variotti and P. viridis were compared to published sequences and phylogenetic trees were produced. The two observed major clusters agreed with the subdivision of *Paecilomyces* species, based on morphological criteria, into the sections *Paecilomyces* and *Isarioidea*. Section *Paecilomyces* included *P*. leycettanus and the type P. variotii and confirmed the relationship of these species to the teleomorph genera Talaromyces and Byssochlamys. Two clades were evident in this section, which also included Penicillium and Nomuraea anemonoides, which resemble *Paecilomyces* morphologically. These data agreed with other studies showing that the genus *Talaromyces* and *Penicillium* are not monophyletic. The relationship of *P. variotii* isolates with the two teleomorph genera indicate that it is probably a cryptic species. Section *Isarioidea* comprised three major clusters showing that this section too, is not monophyletic. One clade included *P. viridis*, *P. carneus* and isolates identified as *P. lilacinus* and *P. marguandii*, as well *N. rileyi*. Some other P. lilacinus and P. marquandii isolates were included in another clade along with Trichoderma. The clade containing the type for this section, P. farinosus, also included other entomogenous species, P. amoeneroseus, P. fumosoroseus and P. tenuipes. P. fumosoroseus was confirmed to contain a cryptic species, with one group of isolates closely related to P. tenuipes and another related to P. amoenoroseus. In this study, some prior mis-identifications were evident, proving that the ITS region can be useful to resolve the difficulties of classical taxonomy of these fungi. Our data suggest that Paecilomyces is a "form" genus only, and a major review is required, including the analysis of a more conserved gene region to clarify the phylogenetic relationships. Index terms: entomopathogenic fungi, rDNA, molecular taxonomy.

[2157] PHYLOGENY OF *PAECILOMYCES* SPECIES REVEALED BY ANALYSIS OF RIBOSOMAL RNA ITS SEQUENCES

M. S. Tigano¹, F. Driver², P. W. Inglis¹, J. W. H. Trueman³ & R. J. Milner², ¹Embrapa Recursos Genéticos e Bioteonologia (Cenargen), P. O. Symposium and Poster Session

[2158] EFFECT OF TREATMENT TIMING OF BACULOVIRUS SPODOPTERA AND BACILLUS THURINGIENSIS ON SPODOPTERA FRUGIPERDA

F. H. Valicente¹, L. L. Loguercio¹, F. T. França¹, E. Paiva¹ & M. R. Barrreto1, CNPMS/EMBRAPA. C.P.151, 35700, Sete Lagoas, MG, Brasil. Email: fernando_valicente@entm.purdue.edu

The objective of this experiment was to test the effect of treatment timing of pathogens Baculovirus spodoptera (B.s) and Bacillus thuringiensis (B.t) on Spodoptera frugiperda larvae, used together but at different timing intervals. S. frugiperda larvae were 2 and 6 days old, using 48 larvae per treatment with 4 replicates. Treatments, for each age included Baculovirus and Bacillus provided in the same solution and at the same time, Baculovirus provided 24, 48 and 72 pathogens before Baculovirus was provided to the same insects. After exposure to both pathogens, contaminated larvae were transferred to artificial diet. Results showed that there was no difference in the mortality among the treatments, except when B.t was offered alone to 6-day old larvae. Mortality was high (above 89,25%) for all treatments. No difference was detected for larval and pupal development period among the treatments for both ages. Abnormalities among pupae and adults were not detected in any treatment. Index terms: insect pathology, pathogen interaction

[2159] BIOPESTICIDE PRODUCTS FOR MIGRATORY PESTS IN AFRICA: REGIONAL EFFORTS TO HARMONIZE REGISTRATION PROCEDURES

L.J Vaughan, Office of International Research and Development, Virginia Tech. 1060 Litton Reaves Hall. Blacksburg, VA 24061-0334 USA. E-mail larryjv@vt.edu

Migratory pests in Africa, such as locusts and armyworms, present a potentially large, but irregular and geographically fragmented market for biopesticides. Migratory pest control campaigns in Africa result in widespread application of broad-spectrum synthetic insecticides. By their nature, biopesticides are typically narrow-spectrum products. This narrow spectrum could be an environmental advantage for control campaigns. However, narrow specificity inherently limits the range of insects against which a biopesticide may be used, thereby restricting the market size. Another constraint not faced by synthetic pesticides is that biocontrol agents may be subject to importation restrictions as "exotic" species. Defining the "exotic" or "indigenous" status of a biocontrol agent is important for determining the geographic extent of markets, and has important consequences for the ability to use biopesticides in transborder control programs in Africa. In addition to several efforts on the part of individual African countries, there are two regional efforts being undertaken to promote and harmonize the registration of biopesticides in Africa. The Inter-State Committee Against Drought in the Sahel (CILSS) already has regional guidelines in place for registration of synthetic pesticides among its nine member countries. Through USAID's Africa Bureau-funded biopesticide project, managed by Virginia Polytechnic Institute and State University, CILSS is developing guidelines for harmonized registration of biopesticides across West Africa. By contrast, there is no regional organization in Eastern Africa with an equivalent mandate and intergovernmental structure to that of CLLSS. Therefore, regional harmonization in Eastern Africa must be approached with a different model. The Virginia Tech project is working through the Desert Locust Control Organization for Eastern Africa (DLCO-EA) - an organization with a narrow mandate for assisting its eight member countries with migratory pest control operations - to develop a consensus on a core set of items which will be common to national biopesticide guidelines as they are developed. Index terms: regulation, biological control, locusts, armyworms

[2160] SCREENING FUNGAL PATHOGENS OF INSECTS FOR AMENABILITY TO LIQUID CULTURE SPORE PRODUCTION

F.E. Vega¹, G. Mercadier² & <u>M.A. Jackson³</u>, ¹USDA-ARS, Insect Biocontrol Lab, Bldg 011, BARC-West, Beltsville, MD, USA; USDA-ARS, ²European Biological Control Lab, Campus International de Baillarguet, Montferrier-sur-Lez, France; ³USDA-ARS, Nat. Ctr. for Agricultural Utilization Research, 1815 N. University St., Peoria, IL 61604, USA.

The potential to control insect pests with fungal pathogens has received considerable attention in recent years. Many fungal entomopathogens have been identified which actively infect and kill important insect pests. A major constraint to the commercial use of these biopesticides has been the lack of low-cost mass production methods that yield high concentrations of stable, infective propagules, ususally in the form of fungal spores. In order to assess the commercial potential of these pathogens, a screening protocol was developed to evaluate the amenability of these isolates to liquid culture spore production. Spore yields were measured for various fungal entomopathogens grown in six nutritionally different liquid media. Media with high and low carbon concentrations, 36 and 8 g/L, respectively, were tested at carbon-to-nitrogen (CN) ratios of 10:1, 30:1 and 50:1. In this study, six fungi were tested; two Beauveria bassiana strains, two Paecilomyces funosoroseus strains, one P. farinosus strain and one Metarhizium anisopliae strain. Spore yields were examined after 2, 4 or 7 days growth. In general, highest spore yields were obtained in media containing 36 g/L and a CN ratio of 10:1. After 4 days growth, highest spore yields were measured in the three *Paecilomyces* isolates $(8.3 - 22.9 \times 10^{4} \text{ spores/mL})$. Spore production by the *B*. bassiana isolates was variable with one isolate producing high spore yields (12.2 X 108 spores/mL) after 7 days growth. The *M. anisopliae* isolate produced low spore concentrations under all conditions tested. The ability of the *P. farinosus* strain (isolated from the coffee berry borer, Hypothenemus hamper) to rapidly produce high concentrations of spores (22.9 X 10^8 spores/mL in 4 days) prompted further testing to determine the desiccation tolerance of these spores. Liquid culture produced P. farinosus spores were mixed with diatomaceous earth, filtered to remove excess water and air-dried overnight at 23C with moist air (RH >60%). Germination assays showed that 80% of the spores survived the air-drying process. These results suggest that screening potential fungal biopesticides for amenability to liquid culture spore production can aid in the identification of commercially viable isolates. In this study, P. farinosus was shown to possess the production and stabilization attributes required for commercial development.

[2161] PROTOZOAN AND ENDOGENOUS CELLULASES FROM TERMITES OF THE GENUS COPTOTERMES

H. Watanabe¹, G. Tokuda², N. Lo³, M. Slaytor³ & H. Noda¹, ¹Nat. Inst. of Sericultural and Entomological Science, Tsukuba, Ibaraki, 305-8634, JAPAN, E-mail hinabe@affrc.go.jp; ²Bio-oriented Technology Research Advancement Institution, 1-40-2 Nisshin, Omiya, Saitama, 331-8537 JAPAN, ³Dept. of Biochemistry, The University of Sydney, NSW, 2000, AUSTRALIA.

Three discrete cellulase components were separated from extracts of the salivary glands (53.7kD), midgut (58.8kD) and hindgut protozoan fauna (64.3kD) of the Australian termite *Coptotermes lacteus*, on a Sephacryl S-200SF column (16/60; Pharmacia). The protozoan cellulase was further purified by SDS-PAGE, and its N-terminal amino acid sequence was determined. A set of degenerate primers was designed from this N-terminal sequence (ADHPKFTWQEVTG(C)GITNDN), and reverse transcription PCR was performed using the total mRNA of hindgut protozoans from the Japanese termite *C. formosanus*. Two distinct cDNAs showing similarity to the members of the glycoside hydrolase family (GHF) 7 cellulases were subsequently cloned from the individual protozoan species *Pseudotrychonympha grassii* and *Holomastidotoides hartmanni*. To clone endogenous cellulase cDNAs, a set of general primers for termite endogenous cellulases was designed from the sequence of the cellulase cDNAs from the salivary glands of the termite *Reticulitermes speratus* and from the nidgut to GHF9 members were cloned both from the salivary glands and the midgut tissue of *C. formosanus*.

Index terms: Coptotermes lacteus, Coptotermes formosanus, protist, glycosyl hydrolase family

[2162] NUCLEOPOLYHEDROVIRUS SPECIFIC TO FALL ARMYWORM

Symposium and Poster Session

M. A. Watanabe¹, A. de H. N. Maia¹, M. H. Romanini¹ & A. C. Barteli^{1 1}Laboratório de Entomologia, Embrapa Meio Ambiente, P. O. Box 69, 13820-000 Jaguariúna, SP, Brazil, E-mail watanabe@cnpma.embrapa.br.

Spodoptera frugiperda

The Spodoptera frugiperda nucleopolyhedrovirus (SFNPV) is an efficient pathogen for fall armyworm biological control. But its specificity is yet poorly known. Fall armyworm, velvetbean caterpillar and silkworm larvae in batches of 20 individuals of each species were fed on diets infected with 0,1 ml of a SfNPV suspension containing 1,0 x 10⁶ polyhedra/ml. The control group was formed by 20 insects of each species were treated with uninfected diet sprayed with distilled water. The fall armyworm and the velvetbean caterpillar were fed on artificial diets whereas the silkworm was fed on mulberry leaves. Daily evaluation of mortality was carried on until the larvae reached adult stage. 45% of the fall armyworm, 90% of velvetbean caterpillar and 55% of silkworm fed on infected diet reached adulthood. The survival rate of fall armyworm was significantly lower than that of velvetbean caterpillar ($\chi^2 = 6.27$, p = 0.0025) and than that of silkworm ($\chi^2 = 6.27$, p = 0.0123) indicating the specific action of SfNPV on the first species. No significant differences were observed between velvetbean caterpillar survival distribution and that of silkworm. After 7 days of treatment 25% of fall armyworm were dead; at 11.5 th day 50% were dead; the silkworm mortality reached 25% only after 20.5 days. The velvetbean caterpillar did not attain 25%, 90% of them reaching adult stage.

Index terms: Spodoptera frugiperda, Anticarsia gemmatalis, Bombix mori, Sf nucleopolyhedrovirus

[2163] BIOLOGICAL CONTROL OF SPRUCE CONE INSECTS USING BACILLUS THURINGIENSIS

I. Weslien¹ & C. Glynn¹, ¹The Forestry Research Inst. of Sweden (SkogForsk), SE-753 41 Uppsala, Sweden.

Experiments with *Bacillus thuringiensis* (Bt) were carried out on Norway spruce in seed orchards of Central Sweden. Spraying of young conclets was effective in reducing the damage by the spruce coneworn *Dioryctria abietella*.(Lep. Pyralidae). The treatment was most likely effective because larvae come in contact with Bt since oviposition in *D. abietella* occurs mainly on the surface of young spruce conelets. Biological control of cone-dwelling insects is, however, more difficult for those insect species that oviposit within strobil during flowering. Thus, Bt treatment of conelets had no effect on damage by *Cydia strobilella* (Lep. Torttricidae). Because larvae feed concealed within the cone the only occasion for introduction of Bt, for later contact with larvae, is during flowering before cone development. Therefore, we also tested the effect of Bt treatments of strobili during flowering. We assessed the treatment effects on insect mortality, seed yield and seed quality.

Symposium and Poster Session

[2164] COPING WITH CROWDS: THE EVOLUTION OF DENSITY-DEPENDENT RESISTANCE TO PATHOGENS

K. Wilson¹, A.F. Reeson², R.S. Hails², J.K. Pell³ & K.A.J. White⁴, ¹Institute of Biological Sciences, University of Stirling, Stirling FK9 4LA, UK, E-mail kw2@stir.ac.uk; ²Institute of Virology and Environmental Microbiology, Mansfield Road, Oxford OX1 3SR, UK; ³IACR - Rothamsted, Harpenden, Hertfordshire AL5 2JQ; ⁴Department of Mathematical Sciences, University of Bath, Bath BA2 7AY.

Many insects, most notably locusts, experience wide fluctuations in population density between successive generations. In low-density populations the risk of parasitism is usually iow, but as population density increases, so too does the rate of disease transmission. Life history theory predicts that if there is a cost to maintaining an effective inimune response, then this should be paid only when there is a significant risk of being parasitised. In other words, if the population density experienced early in development is a reliable predictor of the risk of parasitism then we would expect the allocation of resources to parasite resistance to increase in a positively densitydependent manner. We tested this prediction using caterpillars of the African armyworm moth, Spodoptera exempta and two pathogens (a nuclear polyhedrosis virus and an entomopathogenic fungus). As predicted, we found that pathogen resistance was substantially greater in insects reared in crowds than in isolation. This result was robust and replicated in both laboratory bioassays and field experiments, where twice as many solitary as crowded insects died. Our results suggest that the insect immune response is phenotypically plastic and that some species are capable of changing their allocation of resources to prophylactic resistance in accordance with the perceived threat of parasitism. We discuss the implications of these results for the population dynamics of the insects and their pathogens.

Index terms: Spodoptera exempta, SeNPV, baculovirus, phenotypic plasticity.

[2166] THE SPECIFICITY ANALYZE OF ENTOMOPATHOGENIC FUNGUS BEAUVERIA BRONGNIARTII

D. Yaginuma, II. Hiromori & M. Hatsukade, Department of Applied Entomology, Faculty of Agriculture, Shizuoka University, Ohya, Shizuoka 422-8529, Japan, E-mail t0930029@ipc.shizuoka.ac.jp.

The pathogenicity of entomopathogenic fungus, Beauveria brongniartii (Strain: PBbr-1) to Heptophylla picea larva indicates especially high. However the pathogenicity of PBbr-1 against other scrab grubs shows relatively low. We thought that the specificity of PBbr-1 derived from the interaction between immunity system of H. picea and PBbr-1. Insects are known to possess effective immunity system cuticle, celluluar and humoral defense against the penetration of fungi. The insect cuticle has the important role of physical barrier and chemical substances that inhibit the growth and adhesion to fungi. In case fungi penetrate the host cuticle, fungi undergo cellular and humoral defense response in the insect hemocoel. In this study, we investigated the immunity response of H. picea larva against B. brongniartii. Especially, we researched that hemocytes, phenoloxidase activity in hemolymph and adhesion of fungal conidia The total hemocytes of H. picea larva decreased after low on the cuticle. concentration PBbr-1 injection. Whereas the total hemocytes number of H. picea hemolymph was maintained control level after other conidial injection. The phenoloxidase activity of H. picea showed lower activity than control after injection of B. brongniarti and other fungus such as Metarhizium anisopliae. From these results, PBbr-1 was able to overcome the *H. picea* hemocytes, but other fungus was inhibited from hemocytes in the hemocoel. Furthermore, the adhesion and development of fungi were investigated under fluorescence and scanning electron microscopy. These microscope studies indicated that PBbr-1 conidia adhered the cuticle of H. picea larva compared with other fungus after treatment of same concentration. The difference of adhesive ability is another factor of specificity. In this study, we convinced that PBbr-1 efficiently adhered the cuticle and inhibited to the immunity system of H. picea larva. These abilities of PBbr-1 were the factor of pathogenicty specific to H. picea larva.

Index terms: Heptophylla picea, immunity system, hemocoel, hemocyte

[2165] MANIPULATION OF SPRAY PARAMETERS TO IMPROVE EFFICACY OF MYCOINSECTICIDES AGAINST INSECT PESTS OF FIELD CROPS

<u>S. P. Wraight¹</u>, M. E. Ramos¹ & C. A. Bradley², ¹USDA, ARS, U. S. Plant, Soil, and Nutrition Laboratory, Tower Road, Ithaca, NY 14853 USA, E-mail spw4@cornell.edu; ²Mycotech Corp., 2500 Continental Dr., Butte, MT 50702-4109, USA, E-mail cbradley@mycotech.com

Most entomopathogenic fungi establish infections by direct penetration of the host's exterior body wall. The infectious units must therefore be applied directly onto the target insect or onto substrata in the host habitat where inoculation can be effected indirectly during locomotion or feeding. This mode of dose acquisition puts these agents at a marked disadvantage compared to many synthetic chemical insecticides whose vapor activity or capacity for systemic or translaminar movement obviates the need for precisely targeted spray applications. This paper reviews and compares results of field studies designed to evaluate the effects of various spray application methods on the field efficacy of Beauveria basssiana against Bemisia argentifolii (silverleaf whitefly) infesting cucurbits and Leptinotarsa decemlineata (Colorado potato beetle) infesting potatoes. In whitefly trials, efficacy of B. bassiana applications from a hydraulic sprayer configured to spray straight downward from 20 cm above the crop canopy was significantly improved by lowering nozzles to within a few cm of the crop canopy, orienting them downward at a 45° angle, and increasing hydraulic spray pressure over the range of 3.5 to 28.1 kg/cm². Compared to overhead sprays, efficacy of applications against early-instar potato beetle larvae was increased by mounting nozzles on lateral drop tubes and directing them upward at a 45° angle. These configurations effectively targeted the abaxial leaf surfaces, where young insects were feeding in a microenvironment shielded from sporicidal solar radiation and with greater than ambient relative humidity. Unexpectedly, however, use of the drop-nozzle configuration to spray third-instar potato beetle larvae had little effect on efficacy. Parallel greenhouse studies suggested that secondary acquisition of conidia by potato beetle larvae feeding on contaminated foliage was limited and that direct inoculation of larvae with a high dose of conidia was necessary to achieve control. This work indicates considerable potential for improving efficacy of foliar applications of B. bussiana through manipulation of various spray parameters and underscores the importance of precise targeting of mycoinsecticide sprays. Index terms: Entomopathogenic fungi, Beauveria bassiana, Bemisia argentifolii, Leptinotarsa decemlineata, application technology, microbial control

[2167] MICRODIAL CONTROL OF APPLE INSECT PESTS WITH ENTOMOGENOUS FUNGI

K. Yaginuma, Apple Research Center, National Institute of Fruit Tree Science, Shimokuriyagawa, Morioka, Iwate, Japan, E-mail yaginuma@ringo.affrc.go.jp

The peach fruit moth, Carposina sasakii (=C. niponensis) and peach curculio, Rynchites heros directly feed on apple fruit. The former is a key pest of apple production and a serious pest of economic importance in Japan. Chemical insecticides have been used for control of insect pests because of low damage thresholds. However , mating disruption of lepidopterous pests has become recently accepted in insect pest management programs of apples and enhanced biological control of other pests. In pursuit of useful fungal pathogens for control of two insect pests, the pathogenicity to the pests were investigated in 97 strains of Beauveria bassiana, B. brongniartii, Metarhizium anisopliae, Paecilomyces amoeneroseus, P. cicadae, P. fumosoroseus and P. farinosus. Based on laboratory bioassays, P. fumosoroseus isolate FRP99 and M. anisopliae isolate FRM119 were chosen as agents for control of the moth and curculio larvae, respectively. Suspension of conidia were applied at 10¹¹ cfu/m² into soil of apple orchard because these pests pupate in soil and the survival in soil were monitored every 7 days for 4 months using two kinds of selective media. The isolates, FRP99 and FRM119 were detected in number of 4.5x106 and 8.3x106 cfu/1g of dried soil at 7days post-application, respectively. The number of FRP99 decreased sharply to one twentieth after 28 days. The number of FRM119 decreased gradually to one fourth at 42 days post application and lasted more than 106 for three months. The moth and curculio larvae were released to the soil samples collected from test plots and evaluated in the laboratory for morality. The average mortality of the moth larvae in soil samples treated with FRP99 was 83, 50 and 6% at 14, 28 and 49 days postapplication, respectively. With FRM119, the average mortality of the curculio larvae was more than 80% at two months post-application. The potential of entomogenous fungi for controlling two pests will be discussed in light of these result.

Index terms: Carposina sasakii, Rynchites heros, Paecilomyces fumosoroseus, Metarhizium anisopliae.

Session 11 – GENERAL AND APPLIED INSECT PATHOLOGY

[2168] MICROBIAL CONTROL OF IXODES SCAPULARIS

<u>E. Zhioua¹</u>, K. Heyer², H. S. Ginsberg³ & R. A. LeBrun², ¹Fisheries, Animal and Veterinary Science Dept., ²Dept. of Plant Science, ³USGS Patuxent Wildlife Research Center, Univ. of Rhode Island, 127 Woodward Hall, Kingston, RI 02881, USA, E-mail elzhioua@uri.edu.

Ixodes scapularis, is the principal vector of Borrelia burgdorferi, the etiologic agent of Lyme borreliosis, in the U.S. Steinernematid nematodes are pathogenic only to engorged female ticks, and thus have limited applicability. Recently, we have isolated entomopathogenic fungi from field-collected *l. scapularis*. Pathogenicity of these isolates is under study. We have shown that *Metarhizium anisopliae*, a commercially-available entomogenous fungus, is highly pathogenic to *l. scapularis* in the laboratory. We have also shown that *Bacillus thuringienis* is highly pathogenic to all stages of *l. scapularis*. Potential efficacy of a delivery system for entomopathogenic fungi and bacteria is currently being evaluated.

Index terms: Ixodes scapularis, Metarhizium anisopliae, Bacillus thuringiensis, pathogenicity

[2169] INSECT GUILDS GUIDE THE EVOLUTION OF MIMETISM

C. R. F. Brandão & R. Silvestre, Museu de Zoologia da Universidade de São Paulo, C.P. 42694, São Paulo, SP, 04299-970, Brazil, E-mails: crfbrand@usp.br; rogestre@usp.br.

In quantitative and qualitative surveys of the ant fauna, using different and complementary techniques in several cerrado (a tropical dry forest that once covered most of the Brazilian central plateau) localities (Silvestre et al. 1998), we recorded 331 ant species, selecting for the present analysis those taxa associated with field observation data. For this purposes the sample included 133 species, mostly recorded visiting sardine or honey baits. Gaps in our data were filled consulting the literature whenever the information is available. A cluster analysis with complete linkage revealed 13 well characterized functional groups (Bestelmeyer & Wiens, 1996, Andersen, 1997), involving species that share ecological characteristics as to foraging strategy combined with spatial utilization of the habitat (e.g. cryptic specialized predators). Some groups show a clear taxonomic identity (e.g. Cephalotini, Attini and Ecitonini). We have noticed that in different groups the ant species belonging to distant taxonomic positions share also the overall pattern in terms of external morphology, color and/or behavior, with one or a few in each group well equipped with efficient defense mechanisms and aposematic. For instance Pseudomyrmex termitarius (Pseudomyrmecinae) may have been the model for some Camponotus species of different subgenera (Formicinae) while Pseudomyrmex unicolor may have been the model for the mimetic Gigantiops destructor (also Formicinae). In both of these cases the pairs belong to the same functional group revealed by our analysis. Community structure are affected by the ecological relations and by the reciprocal evolutionary among its members.

Index terms: guilds, ant communities, cerrado.

[2170] GENETIC POLYMORPHISM IN PREY PREFERENCE AT A SMALL SPATIAL SCALE: A CASE STUDY OF SOIL PREDATORY MITES (HYPOASPIS ACULEIFER) AND TWO SPECIES OF ASTIGMATIC MITES AS PREY

I. Lesna & M. W. Sabelis, Section Population Biology, University of Amsterdam, Kruislaan 320, 1098 SM Amsterdam, The Netherlands, E-mail: sabelis@bio.uva.nl.

Arthropod predators usually feed on a variety of different prey types. At one extreme opulations consist of an ensemble of pure specialists for each prey type and at the other they are composed of generalists that indiscriminately seize any prey encountered. In between these extremes populations may be composed of generalist predators with learned or genetically fixed prey preferences. Whether mono- or polymorphism will evolve depends on various factors, such as the cost of flexibility for the generalist, the variability in supply of various prey species and the degree to which the population is homogeneously mixed with respect to mating. Population genetic models for well-mixed populations predict polymorphism in spatially and temporally heterogeneous environments, but only under a very restricted set of conditions, i.e. when heterozygote fitness is close to each of the homozygotes. To explore the robustness of these predictions these models need to be extended to include population dynamics and experimental tests are required. Here, we report on experimental evidence for genetic variation in a well mixed, local population. A sample of c. 150 individuals of the haplo-diploid predatory mite, Hypoaspis aculeifer, obtained from c. 0.25 m^2 sandy soil in a lily field (North-Holland), was collected and their offspring was subjected to two-way selection for prey choice, using two species of astigmatic mites as prey (Rhizoglyphus robini and Tyrophagus putrescentiae, further referred to as **R** and **T**). Individual female predators choosing exclusively **R** or exclusively T in three 10-minute dual-choice tests carried out at three-day intervals were set apart and reared (on T) as isofemale lines. Selection during four generations yielded three lines showing a high probability of choosing R and two lines choosing T. Cross-breeding in both directions resulted in hybrid females with intermediate preferences and the choices found in females from F1xParent backcrosses were best explained by assuming monogenic inheritance without dominance. Our selection and cross-breeding experiments demonstrate that polymorphism in prey preference can occur at a very small spatial scale within a local population. We discuss how such variability will alter the dynamics of otherwise monomorphic predator-prey models, and how the simple mode of inheritance of a preference trait can aid the evolution of ecotypes.

Index terms: Genetic polymorphism, hybrid advantage, genetic architecture, polyphagy, specialization, predators, prey preference

EVOLUTION INSECT-PLANT DIVERSITY AND OF [2171] INTERACTIONS

T. M. Lewinsohn, Lab. Interações Insetos-Plantas, Depto. Zoologia, Inst. Biologia, UNICAMP, C.P. 6109, CEP 13081-970, Campinas, SP, Brasil. E-mail: thomasl@unicamp.br

The diversity of phytophagous insect assemblages is set both by plant and insect attributes. Insect-plant evolution can accordingly be approached either from a phytocentric or from an entomocentric standpoint. Yet another alternative, which we pursue here, is to combine these two: that is, to study and analyze insect assemblages on plants ("plant faunas") and insect host ranges jointly. Questions that can be thus addressed include for instance: to what extent are processes that determine the size and composition of insect assemblages on particular hosts shared with, or reciprocate, those processes that set the insects' host ranges? do endemic plants tend to have exclusive assemblages of specialized endemic insects, or are their assemblages subsets of polyphagous insects on widespread plants? The joint analysis of variation of assemblages and realized host ranges on different spatial scales offer insights on the evolutionary inertia of host associations or, conversely, their ecological plasticity with local conditions. These questions are examined in an extensive data set of Asteraceae and their flowerhead-feeding insects sampled over a variety of localities, habitats and regions in southeastern and southern Brazil. Included hosts are mostly in the tribes Vernonicae and Eupatoricae, and main phytophagous groups are Tephritidae and Agromyzidae (Diptera) and Pterophoridae, Tortricidae and Pyralidae (Lepidoptera). The observed insect-plant associations are also contrasted with those from other continents, spanning scales from the local Funded by Fapesp (94/2837-2 and community to intercontinental contrasts. 98/05085-2) and CNPq (522251/96-0).

Index terms: Asteraceae; Tephritidae; community structure; biodiversity; interaction diversity.

[2172] SIMULATION OF THE TRI-TROPHIC SYSTEM COFFEE-BROCA-PARASITOIDS: POSSIBLE OUTCOMES FROM TWO DIFFERENT CLIMATIC REGIMES

J. R. Cure, Facultad de Ciencias. Departamento de Biologia Aplicada. Universidad Militar Nueva Granada.

As biologists we understand that life history traits affect the growth rates of populations. Numbers and size of the offspring, age distribution of reproduction and life span are all life history traits in which species differ (Futuyma, 1998). The problem has always been to have a consistent method that enables the practical use of this information, in terms of the useful application of laboratory data with field data and observations. When we talk about tri-trophic simulations we are referring to a very well structured system analysis for the simulation of ecological interactions and its outcomes. The system has been developed during the last 20 years, and although it has been extensively illustrated with biological control examples, it can also apply to basic ecology and applied biology in general (for a complete reference, see Gutierrez, 1996). Strengths of the system are: its ability to describe complex patterns using simple biological criteria as drivers of the models; the possibility of using available data to make initial assumptions; the capacity to incorporate new data as they are available; and its' modular approach, which permits the modification of functional relationships among variables as simulations suggest a new way for interpreting the data. In many countries of South America, coffee production is threatened by the introduced coffee berry borer, *Hypothenemus hampei* (Ferrari). There is a serious need to have a good method of control, which at the same time should be safe for the consumer. Several agencies in Latin America are currently looking for such a control and are introducing parasitoids and pathogens to deal with the problem (Hoyos and Aristizabal, 1996); however, there has not been a previous evaluation of the possible results of the introduced agents for the control of the borer. A tritrophic model was developed in order to have in advance, an estimate of the possible outcome of each parasitoid and their combination under different management strategies and climatic regimes (Gutierrez et al., 1998). Elements of behavior and life history of the borer and the parasitoids are incorporated into the model. The model is driven by climatic and management data (fertilization, pruning, etc.). What we are going to present is an example of the use of the approach to practical biological control. References:

[2175] SELF-ORGANIZED TOLERANCE TO STRESS IN TERMITES.

O. DeSouza¹ & O. Miramontes², ¹Depto. Biologia Animal, Univ. Fed. Viçosa, 36571-000 Viçosa MG, Brazil, Email: og.souza@mail.ufv.br, ²Depto. Sistemas Complejos, Instituto de Física, Univ. Nac. Autónoma de México, Apto. Postal 20-364, México, 01000 DF, México, Email: octavio@fenix.ifisicacu.unam.mx

Social insects present a notorious diversity of behaviours, ranging from very simple to extremely elaborated tasks. Contrary to general belief, many of these complex tasks are not a result of a blueprint "hardwired" into the nervous system of the insect. Rather, the concurrent action of simple individuals, performing simple local actions, may originate very complex group behaviour. Social behaviour thereby originated are not explicitly specified in the individuals' design or in their rules for interaction. Such an "spontaneous emergence of order" is generally called self-organization. Specifically for termites, most of the theoretical and practical studies on selforganization are devoted to the nest building process. It has been already shown that the complex architecture of a nest is self-organized, resulting from the action of termites that are guided by the work in progress, rather than by an internal map. We propose another class of self-organized behaviour in termites: tolerance to stress. Termites under serious stress, such as starvation or poisoning, are able to extend survival times, as long as they are confined in optimal group sizes. Apparently, the mechanism generating such an effect is the intensity and frequency of physical contact among group members, which seems to have no explicit relation to the survival of the individuals. This conclusion is supported by results from experiments performed with real termites as well as computer simulations.

(2174) ASSORTATIVE MATING, SEXUAL SELECTION, HAPLODIPLOIDY AND THE EVOLUTION OF SOCIAL BEHAVIOR IN INSECTS

<u>K. Jaffe</u>, Departamento de Biología de Organismos. Universidad Simón Bolívar, Apartado 89000, Caracas 1080A, Venezuela, kjaffe@usb.ve

Computer simulations of sexual reproduction among haploid, diploid and haplodiploid organisms showed that strategies in which females produce males asexually are evolutionary stable, displacing pure sexual organisms in interbreeding populations. Haplo-diploidy seems to drives evolution with a different dynamics than pure diploidy. Haplo-diploidy allows for a faster adaptation to a rough fitness landscape than pure diploidy. Haplo-diplod organisms showed higher probabilities for fixing alleles coding for altruistic behavior than diploid ones, and so did organisms reproducing with assortative mating. The results allow to predict that during phylogenetic evolution of sexual organisms, diploidy will be replaced by haplo-diploidy when the appropriate mutations occur, but that the reverse is unlikely. For the study of the evolution of social behavior, a theoretical game was developed. It was based on the eventual evolution of social behavior through development of altruistic cooperative care of the offspring or extended parental care. Alleles coding for five different strategies were simulated: 1- No care: A parent invested nothing in the offspring. 2- Communal care: A parent invested in any offspring irrespective of it was his own. 3- Open care: A parent invested half its acre-energy in its own offspring and half in any other offspring. 4- Opportunistic care: A parent invested only in its own offspring but its offspring could receive care from open or communal parents. 5-Closed care: A parent invested only in its own offspring and its offspring could not receive care from any other adult. The results suggest that social behavior without social synergy is very unlikely. Social behavior should emerge in evolution when cooperation improves synergistically the corresponding egoistic behavior and when alleles coding for altruistic or social behavior can be rapidly fixed in the population, by strategies such as haplo-diploidy, assortative mating, and probably others. The main conclusion thus is that social behavior has to be economically more efficient than the corresponding solitary behavior. Data are presented showing that this prediction is supported by laboratory and field observations in ants, termites and wasps.

[2176] BIO-ECONOMICS OF FITNESS: EXAMINING GOD'S UTILITY FUNCTION

A. P. Gutierrez, Ecosystem Science, 151 Hilgard Hall, Univ. California, Berkeley, CA 9472020

"DNA neither cares nor knows. DNA just is, and we dance to its music." (Dawkins 1995). A multi-trophic population dynamics model that attempts to unify ecological and economic theory of sustainable renewable resource utilization is proposed. Analogies between the energy acquisition and allocation strategies of organisms (plant or animal) in nature and modern humans are developed, and used to formulate a general objective function "maximizing" individual utility of consumption (cf. Dawkins 1995). The well-known economic concept of consumption is understood to be that part of profits that do not contribute to growth. We posit that fitness is analogous to profit and hence consumption in biology is the reproductive surplus that does not contribute directly to population growth. The currency of nature is energy and that of economics is a monetary unit, and both systems are driven by uncertainty. In economics, the discount rate reflects the level of uncertainty, while in biology uncertainty is reflected in the reproductive rate selected to counter expected mortality. In biology, consumption reflects the constraints of top-down and bottomup factors that limit population growth, while in economics the discount rates is often not related to the renewable resource being managed. Energy acquisition and allocation strategies in nature are genetically based and change on an evolutionary time scale, while in human economics the strategies are decision-rule based and may occur on a short time horizons in response to economic forces. The utility of consumption of all individuals in the population is maximized, and the objective function is subject to the constraints of the physiologically - based population dynamics model of the species in a food chain. The model applies to all trophic levels including human harvesting of resource species (see Regev et al. 1998). Humans are viewed as the top predator in the system. Sensitivity analyses of the model are used to examine how changes in the biological discount rate and physiological and behavioral parameters as well as environmental carrying capacity affect consumer and resource steady state levels. The analysis explains the role of the biological discount rate on biological consumption in r- and K-selected species. Index terms: economic and ecological theory, optimal control, population dynamics, natural selection, fitness, adaptedness, energy flow, r and K selected species

[2178] PHYLOGEOGRAPHY OF APIS MELLIFERA: SUBSPECIFIC DIVERSITY AND THE IMPLICATION FOR INTRODUCED POPULATIONS

W. S. Sheppard, Dept. of Entomology, Washington State University. 166 FSHN Bldg., Pullman WA 99164-6382, USA, E-mail shepp@mail.wsu.edu

The natural range of the honey bee includes Europe, western Asia and ali of Africa. A high degree of morphological and behavioral differentiation occurs within the species across this area of endemism. The visible nature of morphological differences led to an early appreciation of genetic diversity within the species and the development of a triany appreciation of generic diversity within the species and the development of a triangular dissification of subspecies. At present 26 subspecies are recognized and morphological and molecular data support the existence of 3 or 4 main "branches" within the species - corresponding roughly to African (A), northern European (M), southern European (C) and western Asian (O) distributions. Recent advances in molecular methodology provide data to readdress issues of subspecies origins, dispersal and subsequent gene flow. Estimates of the time since cladogenesis of the species range from about one million to nine million years. Moreover, radiation of the extant subspecies appears to coincide with the more recent estimate of cladogenesis, based on both morphology and the extent of nucleotide sequence divergence. The relatively rapid diversification of the numerous subspecies within Apis mellifera permit us to examine recent evolutionary processes. Imperfect barriers to gene flow among some subspecies and subspecies lineages provide examples of natural introgression useful to study ongoing hybridization, ecological genetics and the consequences of ancient hybridization. Honey bees spread widely throughout the world due to human activity, introducing various combinations of subspecies from both temperate and tropical regions into distinct new territories. As a consequence, we have new opportunities to examine the genetics of hybridization and the effects of selection acting on adapted and non-adapted genotypes across ecological zones. One highly visible example of this is the successful expansion of a sub-Sahara African honey bee subspecies into the Americas and its interaction with other introduced subspecies. Overall, the worldwide spread of Apis mellifera in historical time, both inside and outside the range of other Apis species, provides possibilities to investigate the genetic consequences of introduction, ecological displacement, and host shifts of parasites

[2179] CONTRIBUTIONS OF MITOCHONDRIAL DNA ANALYSES TO MELIPONINI BIOLOGY AND EVOLUTION

<u>M. C. Arias</u>, Depto de Biologia - IB, Universidade de São Paulo, São Paulo, Brazil 05508-900, E-mail mearias@ib.usp.br

The mitochondrial DNA (mtDNA) analysis has been widely used adding more informations about biology, genetics and evolution of different organisms. This molecular tool has been successfully employed to solve questions concerning phylogeography, phylogeny and population structure of honey bees. The mtDNA analysis of stingless bees is still very scarce. This group of hees comprises hundreds of species and exhibits a pantropical distribution. The origin of those bees is reported to be ancient than the genus Apis and South America has been indicated as their center of origin and dispersion, since presents the greatest species diversity. However some authors are still questioning about center of origin, routes of dispersion, phylogeny and phylogeography. Most of the Meliponini studies are based on morphology and behavior. In an attempt to start Meliponini mtDNA analyses, our group are studying five species of *Plebeia*, six species of *Melipona* and *Schwarziana* quadripunctata. The initial idea is to have a characterization of the mtDNA molecule and further apply this knowledge to population and evolutionary studies. The molecular approach was to characterize the mtDNA genomes using restriction enzymes and determine genetic variability among species and populations. Restriction maps were determined for all the studied species and the data set generated by RFLP were used to perform phylogenetic analyses. At population level we were already able to characterize two different populations of *Plebeia remota*, one from Paraná state and another from São Paulo state. These two populations have distinct morphological traits however they are considered as same species. Each population showed distinct haplotypes suggesting a possible geographic isolation that may lead to speciation. The whole mtDNA genome of Melipona bicolor is being sequenced. This species was chosen because it is endemic of Southern Brazil and it is getting rare due to the devastation of our forest. Approximately 65% of the genome are already cloned and sequenced. Preliminary results showed that Meliponini mIDNA is around 2 kb larger than the mtDNA genome of Apis mellifera (the only Apidae sequenced so far). Nonetheless the most striking finding is that the gene order is not conserved between Apini and Meliponini. This characteristic can be used as a marker for further studies focusing evolution an biogeography of stingless bees. The mtDNA data have shown a great genetic variability among Meliponini species, higher than found among Apis species. Our results are encouraging us to continue using this kind of analysis to understand biology and evolution of stingless bees. Index terms: Melipona, Plebeia, mtDNA, RFLP, evolution

[2180] HYMENOPTERA DNA TELLS ALL, WELL, ALMOST ALL

D. L. J. Quicke¹ & N. M. Laurenne², ¹Center for Population Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, UK; Unit of Parasitoid Systematics, CABI Bioscience UK Centre (Ascot), Dept of Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, & Dept. of Entomology, The Natural History Museum, London SW7 5BD, UK, E-mail d.quicke@ic.ac.uk; ²Finnish Museum of Natural History, Zoological Museum, Entomological Division, P.O. Box 17, FIN-00014 Univ. Helsinki, Finland

The Hymenoptera are one of the largest groups of insects and most of that diversity exists among the parasitoid taxa. Not surpringly, given the diversity of the group and also to an extent, the fact that few amateurs have historically been willing or able to get into their study, there has been no shortage of problems that traditional techniques have failed to solve satisfactorily so far. Sequence and other molecular data are now being used to tackle evolutionary questions at all levels in the order, from higher level relationships of superfamilies to analysing species level questions such as determining the origins of asexual lineages, the nature of virulence genes and the recognition of cryptic species. Molecular phylogenies are actively being constructed in most major groups and being used to test hypotheses about a range of questions such as the origins of endoparasitism, of host location strategies and directions in the evolution of other life history strategies. Examples of these sorts of study will be used to illustrate the enormous potential of molecular techniques in this order. Finally, I will suggest that in the next few years, DNA sequencing will become the primary means of identifying species in many sorts of study, such as in determining the host associations of the vast number of parasitoids for which rearing has so far produced no data.

Index terms: Systematics, taxonomy, cryptic species, DNA.

[2181] APPLICATION OF MOLECULAR GENETIC TECHNIQUES FOR A BETTER UNDERSTANDING OF EVOLUTION IN THE SOCIAL INSECTS

R.N. Johnson¹, & R.H. Crozier¹, 1: Department of Tropical Biology, James Cook University, Townsville Qld, 4811, Australia: E-mail: rjohnson@bio.usyd.edu.au.

The social insects have long fascinated biologists with their extremely complex lifestyles and social organisation with many hypotheses put forth to qualify such altruistic' behaviours (eg. Darwin, 1859; Hamilton, 1963). With the advent of increasingly complex and informative molecular genetic techniques, sociabilologists have been able to answer questions that could only previously be speculated upon. Two broad areas have emerged; 1) detailed population genetic studies of individual species, and 2) the reconstruction of phylogenetic relationships that can be as specific as intra-genus or so broad as to encompass an entire order. Our research group has undertaken many projects that fall within these two categories and have made significant contuibutions towards a broader understanding of the area in general. Index terms: evolutionary genetics, social insects, molecular techniques

[2183] GENOMICS AND LARVAL DEVELOPMENT IN HONEY BEES

J. D. Evans, Bee Research Lab, USDA-ARS BARC-E, Bldg. 476 Beltsville, MD 20705 USA. Email: jevans@asrr.arsusda.gov ph: 301-504-5143 FAX: 301-504-8736.

Along with their importance as beneficial insects, honey bees (Apis mellifera) have played a central role in studies of insect development. This study focused on the isolation and description of genes expressed by larval honey bees. Through the use of subtractive libraries and gene-expression analyses using genetic arrays and Northern blois, numerous genes were characterized whose expression patterns vary with age, sex, and caste of developing honey bees. Overall expression patterns at 168 loci were most similar between members of the same caste, although some genes were expressed in an age-biased manner regardless of caste. Queens showed a strong down-regulation of many genes that were expressed in embryos and first-instar latvae, including several hexameric storage proteins, a putative heat-shock protein (70 kDa), and an ortholog to a Drosophila cytochrome p450 gene. These genes were strongly expressed by workers throughout larval development. Queens showed higher expression of two putative binding proteins and an ortholog to the mammalian sex-linked smc locus. Genes implicated in nutrient transfer and storage in developing larvae often showed changes in expression between castes and ages. disproportionate fraction of ribosomal proteins arose from the subtractive libraries. Assuming these proteins help modulate ribosome activity, they may be indicators of the developmental tempo of larvae, and could be useful for assessing the initiation of various developmental programs. Efforts are ongoing to more directly ascribe function to these differentially expressed genes, and to identify genes that can be used across other social insects as indicators of larval developmental stages, timing of caste determination, and larval health.

Index terms: Apis mellifera, gene expression, caste, eusocial insect

[2182] THE EVOLUTION OF ADAPTIVE POLYPHENISMS

H. F. Niihout¹ & D.E. Wheeler², ¹Department of Biology, Duke University, Durham, NC 27708, USA, e-mail hfn@duke.edu, ²Dept. of Entomology, Univ. of Arizona, Tucson, AZ 85721, USA.

Polyphenisms are discrete alternative phenotypes that develop in response to specific environmental cues such as temperature, photoperiod, pheromones, or nutrition. Often the alternative phenotypes are adaptations that allows an insect to escape from a deteriorating environment, or allow it to better utilize the resources of a changing environment. It is generally believed that environments that change gradually, or environments that contain much fine grained spatial variation, favor the evolution of continuous phenotypic plasticity (adaptive reaction norms), whereas environments that change rapidly, or that are coarse-grained in some other way, favor the evolution of discrete alternative phenotypes (adaptive polyphenism). A central problem in understanding the evolution of polyphenisms is that the environmental cues that regulate the developmental switch to an alternative phenotype are almost always token stimuli (such a photoperiod), and not the actual environmental variables to which the alternative phenotype is an adaptation. If we assume that a polyphenism evolves from an initially non-adaptive reaction norm, then it is not obvious how the switch to a token stimulus could be accomplished by gradualistic changes development. Alternative adult phenotypes must arise through developmental changes that accompany metamorphosis. We have developed a model, based on the known developmental physiology of metamorphosis, that demonstrates how discontinuous developmental variation can easily evolve gradualistically from continuous reaction norms. This models also suggests the steps by which the sensitivity of a reaction norm (and by extension a polyphenism) to an environmental stimulus can be transferred to a token stimulus. We apply this model to understanding the development and evolution of seasonal polyphenisms, caste polyphenisms, and diapause.

[2184] GENE EXPRESSION AND CASTE POLYMORPHISM IN TERMITES

T. Miura, Dept. of Life Sciences, College of Arts and Sciences, Univ. of Tokyo, 3-8-1 Komaba, Tokyo 153-8902, Japan, E-mail cmiu@mail.ecc.u-tokyo.ac.jp

Although "polymorphic castes" in social insects are well-known as one of the most important phenomena of polyphenism, few studies of caste-specific gene expressions have been performed in social insects. To identify genes specifically expressed in the soldier caste of the Japanese damp-wood termite *Hodolermopsis japonica*, we first employed the differential display method using oligo-dT and arbitrary primers. comparing mRNA from the heads of mature soldier and pseudergates (worker caste). and identified a clone (PCR product) of 329 bp in length, termed SOLI. Northern blotting analysis showed that the SOLI mRNA is about 1.0 kb in length and is expressed specifically in mature soldiers, but not in pseudergates, even in the presoldier induction by juvenile hormone analogue (JHA), suggesting that the product is specific for terminally differentiated soldiers. By the method of 5'- and 3'-RACE (rapid amplification of cDNA ends), we isolated the full-length of SOLI cDNA, which contained an ORF with a putative signal peptide at the N-terminus. The sequence showed no significant homology with any other known protein sequences, suggesting that the gene encodes a novel protein. In situ hybridization analysis showed that this gene is expressed specifically in the mandibular glands. These results strongly suggest that the SOLI gene encodes a secretory protein specifically synthesized in the mandibular glands of the soldiers. Histological observations revealed that the gland actually develops during the differentiation into the soldier caste.

Index terms: termites, soldier caste, gene expression, mandibular glands.

Symposium and Poster Session

[2185] DEVELOPMENT AND THE EVOLUTION OF CASTES IN SOCIAL WASPS

J. H. Hunt, Dept. of Biology, Univ. of Missouri-St. Louis, St. Louis, MO 63121. Email jimhunt@umsl.edu.

Queen/worker difference in "highly social" insects such as honeybees, vespine wasps, and most ants incorporates morphological difference that can only reflect different developmental pathways as larvae. In "primitively social" insects such as paper wasps and some sweat bees, queens and workers do not differ in morphology. In these taxa, queen/worker differentiation is believed to occur among reproductively equi-potent adults. Data will be presented to test the validity of this supposition. Phylogenetic mapping of traits that are integral to sociality reveals that at the threshold of sociality in the wasp family Vespidae, key traits involve unequal distribution of nourishment among nestmates and the absence of mating opportunities for emerged females. Unequal distribution of nourishment is a plausible mechanism that can underlie developmental difference in caste. Morphometric studies of Polistine wasps reveal subtle but significant queen/worker dimorphism in at least some genera of Epiponini and Ropalidiini, which suggests that larval caste determination may occur closer to the sociality threshold than has previously been believed. Indeed, studies of storage proteins in various wasps reveals patterns of difference that coincide with the proposition that caste is determined during larval development. That is, Polistes paper wasp females that emerge early in a nesting cycle retain no storage protein following metamorphosis, whereas some of the females that emerge during the time when gynes are normally produced do retain storage protein following metamorphosis. This pattern reflects an underlying pattern of difference as a correlate of overall size in the solitary vespid Monobia quadridens. The pattern does not occur, however, in the yellowjacket Vespa maculifrons. Current research on storage proteins will be presented. Also to be presented are results to date on investigations intended to isolate genes differentially expressed during larval development by the yellowjacket Vespula maculifrons. Index terms: Polisies metricus, Monobia quadridens, Vespula maculifrons, storage

protein, gene expression

[2186] HORMONAL LINKS BETWEEN GENES AND PHENOTYPES IN SOCIAL WASPS

T. Giray¹ & M. J. West-Eberhard², ¹Dept. of Biology, Univ. of Vermont, Burlington, VT 05405, USA, E-mail tgiray@zoo.uvm.edu; ²Smithsonian Tropical Research Inst., c/o Escuela de Biologia, Universidad de Costa Rica, COSTA RICA.

Understanding the physiological mechanisms that link genes and phenotypes is a necessary complement to adaptive explanations for hypotheses regarding evolutionary transitions. Social insect colonies provide an extreme example of how the same genotype may lead to very different phenotypes, such as that of the reproductive queen and the more or less sterile workers. In addition, workers may also differ in their phenotypes due to changes in the social and other environmental conditions. The link between genes and phenotype in a particular environment is physiology; environmental conditions are sensed and particular sets of genes turned on or off, leading to different patterns of development. Hormonal mechanisms regulating queen reproduction and worker behavioral development have been identified in primitively and advanced cusocial insects, respectively. In three studies with the primitively cusocial wasp Polistes canadensis, we investigated how hormonal mechanisms regulating worker and queen phenotypes may have evolved. P. canadensis workers exhibit both age-related and age-independent division of labor. Aspects of worker division of labor are under juvenile hormone (JH) regulation. Queen reproduction is also associated with high JH hemolymph titers. In post-emergence nests, containing a queen and her worker progeny, the high-risk task of guarding was performed by older workers (>7 days of age), as in other social insects. Some workers foraged as young as 2 days of age, while others never foraged. Workers treated with a JH analog, methoprene, initiated guarding at significantly younger ages and in greater numbers than did control workers. There were no differences for ovary development of workers in the treatment and the control groups. There was a significantly higher JH titer in the guards in comparison to other workers. Reproductively active queens had the highest JH titers and ovary development. These results suggest the dual function of JH may have evolved from JH regulation of both reproduction and associated behaviors in a solitary ancestor. Index terms: Polistes canadensis, juvenile hormone, division of labor, polyphenism

[2187] DIFFERENTIAL DISPLAY PCR REVEALS ECDYSTEROID-RESPONSIVE GENES IN THE OVARY OF HONEY BEE WORKER LARVAE

C. Hepperle² & K. Hartfelder¹, ¹Zoologisches Institut, Universität Tübingen, D-72076 Tübingen, Germany; ²Depto. Biologia, FFCLRP, Universidade de São Paulo, Av. Differential Display Reverse Transcription PCR (DDRT PCR) is a sensitive highresolution PCR strategy to detect differentially expressed genes under a variety of natural and experimental conditions. We employed this technique to investigate the responses of ovaries of last-instar honey bee workers to makisterone A. The competence of larval ovaries to respond to ecdysteroids in vitro has previously been demonstrated, mimicking the response to differences in endogenous ecdysteroid titers in queen and worker larvae. Differentially expressed gene products were detected in native sequencing gels, reamplified, cloned, and sequenced. The derived amino acid sequence of each cDNA fragment was compared to known sequences of the SwissProt databank using BLAST algorithms. As a general rule, the ecdysteroid response in the larval ovaries consisted of a down regulation in gene expression. The differentially expressed gene products could classified into (1) prospective regulatory genes, (2) genes coding for proteins involved in cell-cell interaction, and (3) genes coding for household proteins, mainly of the oxidative metabolism. The cDNA fragment D5/U14 490 exhibits sequence homology to the transcription factor FTZ-F1, a factor known to modulate the ecdysone response of many genes in last-instar Drosophila larvae. The cDNA fragment D3/U4 220 shows homology to CUT proteins, transcription factors known to stabilize states of tissue differentiation in vertebrates and invertebrates. The cDNA fragment D5/U10 217 appears to belong to the superfamily of immunoglobulin cell adhesion molecules with similarity to the Kekkon proteins of Drosophila. Four cDNA fragments exibit sequence homologies to proteins of the oxidative metabolism, being cytochrom b, NADH oxidoreductase, a short chain dehydrogenase, and a catalase. In summary, the results of this DDRT-PCR approach to investigate the mode of action of morphogenetic hormones in honey bee caste differentiation demonstrate the considerable complexity of the ecdysone response in a specific tissue. Using this powerful method it became clear to us that we are yet only scratching the surface of hormone-modulated gene expression patterns that will eventually generate the morphologically distinct castes observed in highly cusocial insects. Future studies will, thus, have to take into account stage- and caste-specific responses of different tissues to the different morphogenetic hormones. Index terms: Apis mellifera, ecdysone, gene expression, ovary, metamorphosis

[2188] CHANGES IN BRAIN EXPRESSION OF CGMP-DEPENDENT PROTEIN KINASE GENE AND DIVISION OF LABOR IN COLONIES OF THE HONEY BEE APIS MELLIFERA

V. Ben-Shahar^{1,2}, M. B. Sokolowski² & G. E. Robinson¹, ¹Dept. of Entomology, Univ. of Illinois, 320 Morrill Hall, 505 S. Goodwin Ave., Urbana, IL 61801, USA, E-mail yehudab@life.uiuc.edu; ² Biology Group, Erindale Campus, Univ. of Toronto, 3359 Mississauga Rd., Missisauga, ON L5L1C6, Canada.

Modulation of behavioral and neural response thresholds to task-related stimuli is thought to play a prominent role in the regulation of division of labor among workers in insect societies. This modulation is considered to be a dynamic process, sensitive to both changes in internal state and environmental conditions. As part of our interest in identifying neural and molecular mechanisms that regulate response threshold plasticity in the honey bee, Apis mellifera, we studied brain expression of the gene encoding cGMP-dependent protein kinase (PKG) during division of labor. cGMP/PKG signal transduction pathway has been implicated in the modulation of olfactory responses in both invertebrates and vertebrates, and many task-related stimuli in the beehive are olfactory. In addition, expression of the PKG gene in Drosophila melanogaster (dg2, aka foraging) is regulated in response to changes in nutritional state (unfed vs. well fed), and this in turn affects food search behavior. We cloned a honey bee ortholog of dg2 (AmG2) which showed significant homology to PKG genes from other organisms. Using real-time quantitative PCR, we measured mRNA levels in the brains of individual foragers and "nurse" bees that tend brood. Nurses work only in the hive and consequently obtain all of their food from other bees and from stores in the hive, while foragers collect nectar and pollen outside. AmG2 mRNA was significantly higher in the brains of foragers than nurses. Using a well established social manipulation to produce precocious foragers, we further showed that this difference in gene expression is associated more with behavioral state than with age. Precocious foragers had forager-like levels of AmG2 mRNA, significantly higher than nurse bees of the same age. AmG2 expression was also found to be sensitive to nutritonal state, but foragers had higher AmG2 brain expression, regardless of nutritional state. These correlative results suggest that modulation of AmG2 expression and perhaps other aspects of the cGMP/PKG pathway play a role in the regulation of division of labor. They also provide a hint of an evolutionary conserved mechanism for the modulation of food search behavior in flies and bees.

[2189] A DELETERIOUS GENETIC ELEMENT PROMOTES MULTIPLE-QUEEN ASSOCIATIONS IN THE FIRE ANT SOLENOPSIS INVICTA

M. C. Mescher & K.G. Ross, Dept. of Entomology, University of Georgia, Athens, Ga. 30602. Email: mcm@arches.uga.edu.

The fire and Solenopsis invicta exhibits distinct monogyne (single queen) and polygyne (multiple queen) social forms. Recent research has revealed that colony social form is determined by a simple mendelian element tightly linked to the locus Gp-9. The Gp-9^b allele confers the polygyne social phenotype on its bearers and is associated with numerous features of queen reproductive biology and worker behavior. Paradoxically, this allele remains at high frequency in wild populations despite acting as a recessive lethal. We discuss the role of $Gp-9^{k}$ in determining colony social form and present a conceptual model of social evolution by which a selfish genetic element linked to $Gp-9^b$ may spread within populations, despite deleterious effects on individual reproductive success, by promoting polygyne social strategies that are successful in competition with the monogyne form at the level of selection between colonies. By making polygyne social strategies obligate to carriers of the allele, Gp-9^b may also explain a second seemingly paradoxical feature of the social biology of S. invicta, the lack of relatedness among nestmate queens. We further discuss the possibility that the $Gp-9^b$ allele, which is entirely restricted to the polygyne form, may be involved in the evolution of a large group of linked alleles which represent a suite of adaptations to the polygyne social environment. It seems possible that selfish genetic elements like $Gp-9^b$ that are involved in conflicts across multiple levels of biological organization may play a general role in the evolution of social organization and other complex biological phenomena. Index terms: Solenopsis invicta, polygyny, selfish genes, social organization

[2191] COMPLEX PATTERNS OF DIFFERENTIATION IN FRAGMENTED HABITATS

F.M.Sene, Dept. of Genetics, FMRP, Univ.São Paulo, Ave.Bandeirantes, 3900, CEP 14049-900, Ribeirão Preto, SP, Brazil, email: famesene@usp.br

The actual distribution of cactus breeding populations and species of the genus Drosophila is mainly due to paleoclimatic events in the Quaternary period: South America became cold and dry in the glacial periods and hot and wet in the interglacial periods. There were at least 4 main cycles. The last cold-dry cycle period occurred about 18,000 and 13,000 years ago. During this period the vegetation adapted to dry conditions expanded its distribution and the *Drosophila* species associated to this vegetation followed its expansion becoming large populations. In the following hot-wet period, the same vegetation contracted its distribution and consequently, this situation caused population fragmentation, restricting the populations area in relicts or refugia. These relict areas have relief and soil features propitious for the relict survival and it is possible to affirm that relict areas observed today were also relictual in the previous cycles. Small populations, presenting fluctuation in the population size, have been compared to insular geographic isolated populations which makes this situation very promising for studying population differentiation. During the cold-dry period, if the populations came into contact, we can expect all possible kinds of consequences, depending on the differentiation level achieved during the geographical isolation, from reproductive isolation to population fusion. Since this habitat fragmentation presents a mosaic situation, several contact events might occur simultaneously at different areas and the consequences might be diverse in different regions. Only the extreme cases (fusion or reproductive isolation) make the consequences easier to be analyzed. The intermediary stages allow introgression creating complex situations since the introgression level depends on factors as genomic balance of populations, selection, and genetic drift. The phylogenetic relations inferred by one or several markers might be falsified by introgression of different parts of the genome. The refugia have been considered as areas where populations have been cyclic isolated, and the main question on this context is to investigate if the present observed differentiation is a consequence of the last isolation period or a previous one. Since each population has an independently evolutionary history and the number of populations is enormous, any attempt to establish general theories for a better understanding of the enormous biological diversity of the South American populations might not represent any biological meaning.

Index terms: Introgression, Drosophila, paleoevents, speciation, biodiversity.

[2192] BREEDING SITES AND SPECIATION IN THE DROSOPHILA REPLETA SPECIES GROUP

C. R. Vilela¹, ¹Departamento de Biologia, Instituto de Biociências, Universidade de São Paulo, Caixa Postal 11461, São Paulo – SP, 05422-970, Brazil. E-mail crvilela@ib.usp.br

The Drosophila repleta species group is endemic to the New World and includes 92 species which are mostly cactophilous at least during their larval stage. The geological and climatic events responsible for the desertification of several areas of the Americas may have allowed the burst of speciation in the Cactaceae (ca. 2000 species) and, accordingly, in the cactophilous section of the repleta group. Although much has to be discovered regarding to the specificity between the flies and their hosts, the orthodox model of allopatric speciation seems to have played an important role in the process. Several genetic markers analyzed for some cactophilic southamerican species, although not always congruent, revealed some differentiation correlated with the present patched distribution of their hosts. Paleoclimatic studies revealed an alternation of cold-dry and hot-humid climates at least four times during the pleistocene. These climate cycles have been considered a likely cause for the fragmentation, expansions and contractions of the distribution of the dry-adapted vegetation and, as a result, that of the associated flies. Different selective pressures in patched areas associated with low or complete absence of alele flow probably gave conditions for genetic differention and speciation to occur. On the other hand, one example which seems, at first sight, to be in favor of the sympatric model of speciation is that of one pair of species *D. nigrospiracula 1 D. mettleri*, which live in the Sonoran Desert in association with decaying saguaro, cardon and hecho cacti and the moist soil beneath them, saturated by fermenting juice from the necrotic tissues. The adults of the first Drosophila species prefer to feed on the rotting cacti while those of the latter are found both on the cacti and on the soil. Moreover, the first one has emerged only from decaying cacti while the latter, only from the moisted soil beneath them, thus indicating a distinct niche separation related to the same (sympatric) host plants. However, although morphologically very similar, and belonging to the same subgroup, the two species are not each other's closest relative. Moreover, some unexpected associations are known. The larvae of D. carcinophila, endemic to some Caribbean islands, live in the nephric groove of the land-crab Gecarcinus ruricola and pupariate glueing on the inner surface of the crab's third maxillipeds. D. eleonorae and two undescribed, and closely related species, are cavernicolous and depend on vampire guano to complete their larval stage, being apparently sympatric two by two. In both cases the excretory products provide an ideal medium for the culture of microorganisms upon which the larvae feed. Index terms: Drosophila eleonorae, Drosophila carcinophila, cacti, crabs, vampires.

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[2193] GENETICAL AND MORPHOLOGICAL DIFFERENCES IN ANASTREPHA FRUIT FLIES: RACES OR SPECIES ?

D. Selivon, Depto. de Biologia, Univ. São Paulo, C.P.11461, São Paulo, SP, 04522-970, Brazil, E-mail dselivon@usp.br.

The basic question to understand the mode and process of speciation in natural populations is related to the knowledge of how gene flow is reduced between populations in such way that they became committed to different evolutionary paths. Hence, different models of speciation invoke distinct mechanisms of gene flow reduction, and when these models are applied to groups of organisms their specific and distinctive biological characteristics must be considered. There are species of tephritid fruit flies which are univoltines and monophagous frequently occurring in temperate regions while other species are multivoltines and polyphagous, generally from tropical and subtropical regions. Rhagoletis is an example of the first case, in which the host-races of R. pomonella are well known. The races present genetical differences related to the choice of host plants, eclosion time and other characteristics associated with the host phenology. These evidences were interpreted according to the model of sympatric speciation. Other species of Rhagoletis may also have evolved in the absence of geographic isolation. Sibling species are usually sympatric and speciation is accompained by host shifts, thus suggesting a sympatric mode of speciation. In the second case, is included the genus Anastrepha with species commonly showing a large geographic distribution in the tropical and subtropical regions of the American Continent. Taken as example A. fraterculus (lato sensu), which occur from southern USA to northern Argentina, two populations were found in a single non-commercial orchard showing different biological characteristics and using different host plants, guavas and oranges. However, detailed studies revealed that they are not host races, but indeed two cryptic species of the "Anastrepha fraterculus complex". Similar cases seem to exist in other species of Anastrepha. It is already known that variation in host plants exploitation by a species do exists, but this variability seems to be related to geographical and ecological parameters. Moreover, two species which are predominantly allopatric may use different host when in sympatry. The data so far obtained indicate that if polymorphisms associated to specific host plant do exist in Anastrepha, they must be rare since up to the moment they were not observed. Hence, the characteristics so far described for the species of Anastrepha, favour allopatry as the mode of speciation of this group of fruit flies. Index terms: sympatry, allopatry, speciation, host races, polymorphism

[2194] LAZY EVOLUTION: CRETACEOUS/TERTIARY BIOGEOGRAPHY IN THE NEOTROPICAL REGION

D. S. Amorim. Depto. de Biologia-FFCLRP, Universidade de São Paulo, Av. Bandeirantes 3900, 14.040-901 Ribeirão Preto SP, BRAZIL. E-mail: dsamorim@usp.br.

Since species ceased to be accepted as fixed, created entities to be ever-changing, splitting systems -mainly with Wallace and Darwin's contributions-, the question of speciation occupied a large amount of printed pages in the literature. This includes topics as modes of speciation (in a geographic sense), modes of isolation (in a geographical, cytological and behavioral perspective), areas of origin etc. The particular point of temporal scale of biological evolution has always been a difficult question. Physicists criticized Darwin last century because his theory demanded a too large span of time compared to the life of the sun... As noted by Lakatos, in the development of scientific theories, not all earlier ideas and misconceptions are automatically removed from the set of paradigms upon which new theories are based on. Early in the XIXth century, creationists suggested that life would have been created some few thousand years ago. Early evolutionists began to stretch out this time to many thousands years. Along this century, most evolutionists rejected that the main recent groups of animals and plants would be already present when continents were in contact, even when their distribution would strongly suggest it (e.g., with circumantarctic, transtropical, and holarctic distributions). A considerable number of recent evolutionary reconstructions associate great part of observable biogeographic patterns with Late Pleistocene paleoclimatic events. If groups originated quite recently, the speed of evolution to produce available biodiversity would be considerably high. However, not all interpretations point this way. Modern biogeographical methods showed that common, repeated biogeographical patterns have high probability of having been caused by geologic/geographic events with which they are corologically and cronologically congruent. Hence, the disjunctions seen in many intercontinental distribution patterns of vertebrates and invertebrates should be actually attributed to tectonic fragmentation -meaning Mesozoic origin of such groups. This brought up quite harsh reactions in the literature. Biogeographic reconstructions of Neotropical groups of mammals and insects using these methods showed detailed internal congruence, as well as congruence with Cretaceous/Early-Mid Tertiary geologic events. This points to a much older origin of many groups until recently supposed to be Pleistocene or Late Tertiary. Consequently, evolution would nuch slower than supposed by most evolutionists to date, so the complex biodiversity seen today would have been slowly constructed along the past many million years.

Financial support: CNPq

Broad examination of chromosome numbers (haploid n) as seen in spermatogenesis of Neotropical butterflies has given a general view of the patterns of variation found at different levels. The mode is n = 29.31 (normal in Lepidoptera), shown by a third of the 1100 species examined; 12% had n = 14-16, and only 12% had n > 31. Most Hesperidae and Papilionidae (primitive families) remained near n = 30; non-Coliadine Pieridae and Lycaenidae varied more, often tending towards the mid-20s, and a derived group (the genus Heliconius), though very constant at n = 21, suddenly radiates in its terminal branch through 33 and 37 to 56-62. Satyrinae and Ithomiinae (Nymphalidae) showed the most variable numbers. In Lycaenidae and Nymphalidae, varying numbers of microchromosomes are occasionally seen in different dividing cells of a single individual (such as in the Heliconiini genera Laparus and Neruda, 19-33 chromosomes, or the Ithomiinae Eutresis (30-40) and Scada batesi (31-43). Nymphalidae vary rarely within populations (conspecific individuals of Philaethria dido showed n = 21, 52, and 68), more frequently between geographical subspecies (in the Ithomiinae Melinaea ludovica, 17-24, or Hypothyris ninonia, 15-24), often between species in a genus (Ithomiinae, Forbestra with two species showing n = 9 + microchromosomes, the third with n = 60-65; Satyrinae, *Taygetis* with all numbers from 8 to 23, outliers at 26 and 31; *Pareuptychia* species, from 8 to 44), and usually between genera (advanced Nymphalidae usually show n=30-31, but Catonephele is stable at n = 15, also shown by the Amazonian genera Vila, Asterope and Baeotus; the Amazonian derivative of Catonephele (Nessaea) halves again to n = 7-8). Within the most advanced Ithomiine tribe (Godyridini), evolution can lead to great increase the most advanced thouman the (total) turns), evolution can react to great increase in number (Godyris, 24 to 120), decrease (Hypoleria, 45 to 8), or return to the mode (Pseudoscada and Heterosais, constant at n = 30-31). Occupation of a new adaptive zone, explosive species radiation, or formation of well-differentiated lineages do not necessarily lead to observable cytogenetic differences, but widespread lineages often show aneuploidy in the Amazonian and Andean members in relation to the Atlantic forest populations, suggesting ancient and effective interruption of gene flow. It is not yet possible to predict the direction, magnitude, or most probable lineage for chromosome change accompanying evolution of Neotropical butterflies

Index terms: Aneuploidy, Ithomiinae, Heliconiinae, Atlantic forests, Variation in n.

[2196] NEW APPROACHES TO LONG STANDING PROBLEMS IN THE CHROMOSOME INVERSION POLYMORPHISM OF *DROSOPHILA WILLISTONI*

V. L. S. Valente, Departamento de Genética, Instituto de Biociências, Universidade Federal do Rio Grande do Sul. Porto Alegre, BRAZIL, valente@if1.if.ufrgs.br. Financial support: CNPq, FAPERGS, FINEP and PROPESQ-UFRGS.

The traditional view on the genesis of paracentric inversions in *Drosophila* is that they are the result of two independent chromosomal breaks followed by re-connection of the broken parts of the chromosome in an inverted orientation in relation to neighboring areas. From this point of view, the multiple inversions found in many *Drosophila* species (that have served as a base for the construction of phylogenies) must have happened sequentially and not through the simultaneous occurrence of multiple breaks. Break-point coincidence in successive inversions has been attributed to events happening at different times, suggesting that each naturally segregating inversion is a consequence of a unique event and with all the copies of a specific inversion having a common origin, the resulting sequence being a reflection of a prior rearrangement in a specific individual. This traditional view have been revised in the last decades, based on the discovery of the potential of transposable elements (TEs) to induce chromosomal breaks and rearrangements. The apparent non-randomness of inversion break points is the strongest argument against the independent origin of these rearrangements, the existence of "hot spots" is either a consequence of chromosomal structural flaws or of an agent capable of producing changes at specific sites on the chromosome. "Hot spot" of inversion break points are conserved in natural populations by natural selection, probably because they occur at favorable positions on the chromosome. Few studies until now performed presented conclusive evidences of the involvement of TEs in the generation of chromosomal inversions segregating in natural populations. D. *willistori* is a Neotropical widely distributed species characterized by an enormous amount of chromosomal inversion polymorphism of D. *willistori*, we tried to contribute the knowledge of the role of TEs in the generation and evolution of the chromosomal aversion polymorphism of D. *willistori*, and analysed the cosincidence of the inversion b

[2195] CYTOGENETICS OF NEOTROPICAL BUTTERFLIES: PATTERNS OF EVOLUTIONARY DIVERSIFICATION IN CHROMOSOME NUMBERS

[2197] NATURAL SELECTION EFFECTS ON INVERSION SIZE IN DIPTERA

M. Cáceres, A. Barbadilla & <u>A. Ruiz</u>, Dept. de Genètica i de Microbiologia, Univ. Autònoma de Barcelona, 08193 Bellaterra (Barcelona), Spain.

Most species of the Drosophila genus and other Diptera are polymorphic for paracentric inversions. Despite many years of intensive research, very few general principles have been found, besides the notion that some kind of balancing selection is responsible for the maintenance of these polymorphisms. A common observation is that successful inversions are of intermediate size. This suggests that natural selection discriminates among inversions of different sizes, favoring those of intermediate physical length. We tested the hypothesis that the selected property is the recombination length of inversions, not their physical length. If this were the case, physical length of successful inversions should be negatively correlated with recombination rate across species. This prediction was tested by a comprehensive statistical analysis of inversion size and recombination map length in 12 Diptera species (ten Drosophila species and two Anopheles species) for which appropriate data are available. An a priori criterion, based on their geographical distribution and population frequency, was used to classify polymorphic inversions either as successful (82) or unsuccessful (125). Total recombination map length of each species was estimated from the published linkage map data. We have found that (1) there is a wide variation in recombination map length among species; (2) physical length of successful inversions varies greatly among species and is inversely correlated with the species recombination map length; and (3) neither the among-species variation in inversion length nor the correlation are observed in unsuccessful inversions. The contrasting results between successful and unsuccessful inversions rule out any mutational cause and point to natural selection as the most likely explanation for these results. Two opposite forces are presumably acting on inversion length. On one side, the selective advantage of an inversion due to its recombination-reducing effect increases with length. On the other side, its detrimental effect on fertility due to four-strand double crossovers also increases with length. The net result is an optimal recombination length which varies among species. Our analysis provides the strongest and most extensive evidence in favor of the notion that the adaptive value of inversions stems from their effect on recombination. Index terms: Diptera, inversion length, recombination, natural selection

[2198] MORPHOLOGICAL CORRELATES OF CHROMOSOME INVERSION GENOTYPES

L. B. Klaczko, W. N. Souza & L. M. Hatadani., Departamento de Genética e Evolução, Instituto de Biologia, Univ. Est. Campinas, UNICAMP, Cx. Postal 6801, Campinas 13083-970 SP, Brazil. E-mail: LBK@unicamp.br. Financial support: CNPq, CAPES, FAEP-UNICAMP, FAPESP.

For more than 10 years we have been engaged in the study of *Drosophila* mediopunctata as a model organism for Population Genetics. This species has 6 pairs of chromosomes: 5 acrocentrics and a dot (which does not undergo polytenisation). Chromosome II is highly polymorphic for inversions (Peixoto and Klaczko 1990). It can be didactically divided in two regions that do not overlap and which should allow recombination between them. In the distal region we found 9 inversions (*DA*, *DI* etc.). In the proximal region there are also 9 inversions of different 3 phylads (*PA*, *PB*, *PC*). There is a very strong linkage disequilibrium between distal and proximal inversions in spite of the possibility of recombination.

In a previous study (Bitner-Mathé et al. 1995) we analyzed males collected on three different occasions, looking at their chromosome inversion genotypes and taking body measurements. Using PCA we found that shape is affected by inversion genotypes and for size there is an interaction between genotype and collection date.

There are black spots in each of the last 3 tergites of *D. mediopunctata.* But, this character is variable: one finds flies with no spots, up to flies with three spots. We have carried out a genetic analysis finding that chromosomes II, III and V affect the character and the second has the largest effect. Through a series of back-crosses to a marker-strain, we transferred various second chromosomes to a single genetic background. They were then made autozygous and the flies, raised in standard conditions, observed for their phenotype. So far we have analyzed 5 strains *DA-PAO/DA-PAO* and 6 strains homozygous for inversions of the *PC* phylad. In the first set we found 4 strains with few spots and 1 with three spots. The opposite was found in the second masociation of the genetic factors conditioning the polycromatism and the inversions.

[2199] INVERSION POLYMORPHISM AND EVOLUTIONARY RELATIONSHIPS OF DROSOPHILA SPECIES IN THE SALTANS SUBGROUP (SALTANS GROUP)

II. E. M. C. Bieudo, UNESP, Rua Cristóvão Colombo 2265, 15054-000, São José do Rio Preto, SP, Brazil. E-mail: bicudo@ bio,Ibilce.unesp.br.

The understanding of the evolutionary relationship between organisms is central in evolutionary biology. Several methods involving morphological traits, isozyme data, chromosomal variations, reproductive compatibility and molecular studies have been used for recovering evolutionary history of organisms. We will discuss evolutionary relationships in the saltans subgroup based on chromosomal polymorphism data. The saltans subgroup is one of the five subgroups included in the saltans group. Seven species are members of this subgroup: D. saltans, D. prosaltans, D. lusaltans, D. septentriosaltans, D. austrosaltans, D. nigrosaltans and D. pseudosaltans. They are exclusively found in the Nearctic and Neotropical regions, extending from Mexico to the South of Brazil and Paraguay, also including the Caribbean Islands. The seven species are morphologically very similar; for their correct classification spermatecae and male genitalia have to be examined. The metaphase plate configuration is the same for the seven species: two metacentric and one acrocentric chromosome pairs. Intraspecific analysis of inversion polymorphism studied in the salivary gland chromosomes of 49 strains of the seven species showed a total of 26 heterozygous inversions. D. prosaltans, the species with the largest distribution area presents the greatest chromosomal variability, 14 inversions, seven of them in the XL arm. The interspecific differentiation in the subgroup was studied by analysis of inversion configurations in hybrids and by comparison of the band pattern sequence with the standard sequence of D. prosaltans, chosen as the basic configuration. A considerable degree of sequential homology was observed, mainly for the chromosome III. Only three interspecific arrangements were found among the seven species showing that this was the most stable chromosome in the course of evolution within the subgroup. The opposite occurred with the X chromosome that was the chromosome subject to the greatest change. Considering together, intra and interspecific data suggested that *D. prosaltans* may be the stem population in the saltans subgroup. It could have originated first D. pseudosaltans. A second ancestor derived from *D. pseudosaltans* could give rise to the other five species. Because information on biochemical and morphological variability, reproductive compatibility, esterases and DNA sequence are also available they can be used for conclusions regarding the relationships of the seven species, reinforcing the idea that different sets of data reflect different aspects of the history of the same taxa. Index terms: Drosophila prosaltans, D. saltans, genetic divergence, phylogeny

[2200] CLINES, LEAPS, GAPS AND REVERSES IN INVERSION POLYMORPHISM

W. J. Etges¹, M. Levitan², ¹Dept. of Biological Sciences, Univ. of Arkansas, Fayetteville, AR 72701, USA, E-mail wetges@comp.uark.edu; ²Depts. of Cell Biology/Anatomy and Human Genetics, Mt. Sinai School of Medicine and the City Univ. of New York, New York, NY 10029, E-mail max.levitan@mssm.edu.

Drosophila inversion polymorphism has long provided understanding of the forces maintaining genetic variability in nature. Local inversion polymorphism can be shaped by both natural and sexual selection. Patterns of geographic variation and degree of population structuring, such as clines, are usually not caused by random events. Clines are, in some cases, apparent from only a few sampled populations. In a few species the number of studied populations has been expanded. These can strengthen the earlier noted clines, but they frequently reveal significant deviations from them. One of the most extensively studied in this regard is D. robusta. To date 132 populations, covering almost its entire range in North America east of the Rocky Mountains, have been sampled. Gene arrangement XL-1, representing a large inversion of the middle of the left arm of its metacentric X-chromosome, for instance, has been known to exhibit a north-south cline since the earliest reports by H. L. Carson and H. D. Stalker, being completely absent in the southernmost localities but reaching 100 percent in many of the northernmost ones. Placed on a latitudinal grid, however, some areas exhibit reverse clines, and many others deviate significantly from the frequencies expected from their geographic positions. Some populations that fit the predominant cline show unusual changes over very small distances. Similar mixed signals are found in the distributions of several autosomal arrangements with north-south clines and in XR-1, an arrangement with a predominant east-west cline. In other well-studied species such as cactophilic D. mojavensis and D. pachea, inversion polymorphisms exhibit steep clines overlaying significant population structure influenced by local adaptation and host cactus use. The data suggest strong ecological forces that modify or even reverse apparent clinal variation and shape fine-scale population structuring.

[2204] CONTRIBUTION OF MOLECULAR MARKERS IN BLOWFLIES

A.M.L. Azeredo Espin, Lab. Gen. e Biol. Mol. Animal, DGE/CBMEG, UNICAMP, P.O. Box 6109, Campinas, SP, Brasil, CEP 13083-970, e-mail: azeredo@obelix.unicamp.br. Financial Support: FAPESP, PADCT-CNPq.

The family Calliphoridae (blowflies) reponsible for myiasis can be divided into three functional groups based on their larval feeding habits: saprophages, facultative ectoparasites and obligate parasites. In Brazil, the screwworm fly Cochliomyia hominivorax is one of the most devastating insect pests, as it infest open wounds of man and warm-blooded vertebrates, causing great profit losses for cattle breeders. At the genetic level, investigations of natural populations have been conducted in some geographic populations of screwworm flies from South, Central and North America and Africa based on classical approaches and molecular markers. Investigations of natural populations of blowflies have been limited to the analysis of the population natural populations of blowflies have been limited to the analysis of the population dynamics and behavior of caliphorids, including *Chrysomya* species. These species are of considerable medical, forensic and sanitary importance. Until recently, *Chrysomya* flies were restricted to the Old World tropics. The introduction of four species of this genus, in the last two decades, in the Western Hemisphere, has been spectacularly successful. *C. megacephala*, *C. albiceps*, and *C. putoria* were introduced, around 1975, in Southern Brazil and since then they have spread rapidly in the transfer of the spread of the across South America. A fourth species, C. rufifacies, was collected in Costa Rica in 1978. Recently, the newly introduced Chrysomya species have been considered effective competitors of the widespread native saprophagous blowflies species. Remarkably little is known about the genetic structure of blowflies and intraspecific differentiation in Old World and Neotropical populations. Most genetic work on differentiation in insects species has focused on searching for genetic markers, such as mtDNA and nuclear DNA by RFLP, PCR, RAPD and sequencing approachs to recover the genetic information and geographic structure of populations. Because of its unique characteristics, mtDNA is a valuable tool for studying molecular evolution and phylogenetic relationships. This study provides the complete sequence of the mitochondrial genome of *C. hominivorax* and a population genetic analysis of *Cochliomyia* and *Chrysomya* species based on PCR-RFLP of mtDNA and sequences of specific genes and control region. Comparisons were made with the mtDNA of other insects including others blowflies species on the basis of genome size and organization, DNA and putative amino acid sequence data, nucleotide substitutions, codon usage and bias, and pattern of AT enrichment. The contribution of Calliphoridae mtDNA data will be discussed in terms of recover genetic and multiphoridae mtDNA data will be discussed in terms of recover genetic and evolutionary informations concerning the pattern of introduction, colonization and dispersion of blowflies in Brazil.

[2207] RETROTRANSPOSON MEDIATED HYBRID INSTABILITY IN DROSOPHILA

A. Fontdevila, Grup de Biologia Evolutiva, Departament de Genètica i Microbiologia, Universitat Autònoma de Barcelona, Bellaterra (Barcelona) Spain

Hybrid instability refers to the general condition of hybrids to undergo changes in mutation and recombination rates that may lead to a rapid genome repatterning. Conditions promoting this instability may be diverse and are still not well understood, but often they have been associated to transposition increase of mobile elements. Drosophila buzzatii and D. koepferae (Drosophilade, Diptera) are two cactophilic sibling species originating from the desserts of NW Argentina. Hybridization between D.buzzatii males and D.koepferae females yields fertile females and sterile males. Backcross hybrids show high chromosomal instability, evidenced by a high rate of new chromosomal rearrangement production. Osvaldo is a retrotransposon isolated from D.buzzatii. Its molecular structure has been reported and shows all the features of a retrovirus. Studies with backcross hybrids have shown that Osvaldo transposes at high rates in hybrids between D.buzzatii and D. koepferae. Since evidence is increasing that mobile element transposition induces many point mutations and chromosomal rearrangements, our results, in conjunction with other similar experiments with hybrids of other species, suggest that hybrid instability can be mediated by increasing rates of mobile element transposition. Recently, an increasing number of species originated by hybridisation is being described, so the possibility exists that transposon mediated hybrid instability represents the initial step to speciation.

[2206] HOST CONTROL OF COPIA RETROTRANSPOSITION RATE IN DROSOPHILA MELANOGASTER

S.V. Nuzhdin, S.G. Pardue, J.P. Gonzales & R. Ng, Dept Evolution & Ecology, Univ California at Davis, Davis, CA.

For most retrotransposons including *copia*, the average rate of transposition in natural populations is 10^{-5} - 10^{-4} per copy per generation. Among laboratory lines, however, the rate of *copia* transposition strongly varies. We are pursuing genetic analysis of the differences between two parental lines with transposition rate of zero (Oregon R) and 10^{-2} (2b). Previously, we constructed 98 recombinant inbred lines from these parental lines. Lines were scored for 126 molecular markers, *copia* transcript level, and *copia* transposition rate. *copia* transposition rate was controlled by interacting factors mapping to the region 27B-48D on the second and 61A-65A and 97D-100A on the third chromosomes. High *copia* transcript level was not required for transposition. Here, we report data on the level of reversly transcribed extrachromosomal *copia* DNA. We show that one of large-effect factors maps more precisely to near section 43 and accounts for a ten-fold difference in the level of *copia* reverse transcription. We further show that *copia* transpositions are not limited to a particular sequence variant, and reject the hypothesis of a master copy.

[2208] MOLECULAR AND EVOLUTIONARY ANALYSIS OF DIVERSE FAMILIES OF MOSQUITO TRANSPOSABLE ELEMENTS AND POTENTIAL APPLICATIONS

Z. Tu, Department of Biochemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061, USA

Transposable elements, or mobile genetic elements, proliferate by replicative transposition and can make up a large fraction of the genome. We have so far discovered many families of transposable elements in the yellow fever mosquito, *Aedes aegypti*. Many of these novel transposable elements are associated with genes and/or other repetitive elements. We are further analyzing the diversity, characteristics, and distribution of these elements. We are also comparing similar families of transposable elements in different mosquitoes to understand the evolution of these elements as well as the evolution of their host genomes. Finally, we are actively exploring the possibility to use some of the transposable elements as transformation tools or genetic markers.

Index terms: Aedes aegypti, genome, evolution, repeats

[2209] TRANSPOSABLE ELEMENT ABUNDANCE, DISTRIBUTION AND EVOLUTION IN TEPHRITID FLIES

L.M. Gomulski, C. Torti, A.R. Malacrida & <u>G. Gasperi</u>, Department of Animal Biology, University of Pavia, P.zza Botta 9, I-27100 Pavia, Italy, E-mail: gasperi@unipv.it

The fast colonizing species, Ceratitis capitata, can be considered a predictive model for studies of the effects of environmental factors on genetic stability and on the transfer efficiency of new genetic traits introduced by biotechnology. The medfly, C. capitata has over the last hundred years, greatly extended its range from its native source area, in S.E. Africa to include the Mediterranean basin, South and Central America and Australia. The very high genetic variability detected in the African native populations may reflect the genetic plasticity of this polyphagous species, that in a very short time has reached an almost cosmopolitan geographic distribution. Drift and bottleneck effects may have contributed to the genetic changes in the derived populations; a balance between drift and migration has not yet been reached in recently colonized areas. We cannot exclude that transposable elements (TEs) could help some populations to restore their genetic variability after a bottleneck and to adapt to changing environments. In *C. capitata* there is indirect evidence that endogenous families of transposable elements are still actively transposing as documented by hybrid dysgenesis phenomena and frequently occurring genomic instabilities. In this context we have isolated and determined the chromosomal distribution of hobo related sequences from C. capitata. Highly differentiated elements of the mariner and Tc1 superfamily are widespread in the medfly genome. The copy numbers of each of the elements are very different, but no significant differences were detectable between native, ancient and newly derived populations, indicating that the medfly's rapid colonization process has had little affect on their abundances. The distribution patterns of the elements vary greatly with respect to their euchromatic/heterochromatic localizations and they are distinctive and specific for each element. Based on our data on different mariner elements we propose a model in which the abundances and distributions of these elements are regulated primarily by selection against deleterious effects due to meiotic ectopic recombination, with genetic drift playing a minor role. The extension of these analyses to other related Tephritid species including Ceratitis rosa, Trirhithrum coffeae and Bactrocera spp. has permitted us to relate the evolution of transposable elements with the divergence of the host species.

Index terms: Ceratitis capitata, medfly, mariner, Hobo, Tc1.

[2210] TRANSPOSABLE ELEMENTS IN CULICINES MOSQUITO GENOMES : CLASSICAL AND ODD STRUCTURES, HIGH COPY NUMBER AND ROLE IN POPULATION POLYMORPHISM

<u>C. Feschotte</u>, C. Cagnon, S. Karama & C. Mouchès, Laboratoire Ecologie Moléculaire & Faculté Sciences et Techniques Côte-Basque, BP 1155, F64013 Pau -France Tel (33) (0)5 59 92 31 43 - Fax (33) (0)5 59 80 83 11 - e-mail claude.mouches@univ-pau.fr

Transposable elements characterized in Culex and Aedes mosquitoes belong to numerous families and contrast with those of other Diptera, as Drosophila or Anophelines, in being reiterated in high copy number. Moreover, several of these highly reiterated elements share original structures and/or belong to families rarely described among insects (e.g. MITEs, SINEs, 'gag only' retroelements, etc.). Insertion polymorphism analyses at the white locus suggest that recent massive transposition and retroposition events might play a major role in the processes that ensure the adaptative success of these vectors.

[2211] ZAM, A RETROVIRUS FROM DROSOPHILA MELANOGASTER

C. Vaury¹, S. Desset¹, C. Meignin¹, C. Conte¹ & P. Leblanc², ¹INSERM U384, Faculté de Médecine, 28 Place H. Dunant, 63000 Clermont-Ferrand, France, E-mail Chantal. VAURY@inserm.u-clermont1.fr; ²INSERM U412, 46 Allée d'Italie, 69364 Lyon Cedex 07, France.

ZAM is a new retroelement of *Drosophila melanogaster*. It was identified as a mutational insertion at the *white* locus. It displays all the structural features of a vertebrate retrovirus. Its three open reading frames encode predicted products resembling the products of the *gag*, *pol* and *env* genes of mammalian retroviruse. Its transcription gives rise to a 8.6kb full-length RNA and a 1.7 kb spliced message for the *env* gene. The latter encodes an envelope protein that is typical of elements having an extracellular phase of the life cycle. When tracing ZAM mobilization, we have shown that all components necessary to assemble ZAM particles, ie ZAM full length RNA, Gag and Env polypeptides are co-expressed in a small set of follicle cells surrounding the oocyte. In this somatic lineage of cells, ZAM particles have been detected by electron microscopy and found to leave the somatic cells and enter the closely apposed oocyte where genomic insertions take place. The potential ways a retrovirus may infect the germ line of its host will be discussed in light of our results. Index terms: *Drosophila melanogaster, Retrovirus, ZAM, retrotransposons*.

[2212] CODON USAGE OF TRANSPOSABLE ELEMENTS AND HOST GEMONE

E. Lerat^{1,2}, C. Biémont² & <u>P. Capy</u>¹, ¹Laboratoire Populations, Génétique et Evolution, Centre National de la Recherche Scientifique, 91198 Gif/Yvette Cedex, FRANCE, E-mail capy@pge.cnrs-gif.fr; ²Laboratoire Biométrie et Biologie évolutive, Centre National de la Recherche Scientifique, UMR 5558, Université de Lyon I, 69622 Villeurbanne Cedex – FRANCE.

Codon usage of transposable elements (transposons, LTR and non-LTR retrotransposons) were compared with those of genes of several hosts including *Drosophila melanogaster*, Caenorhabditis elegans *Saccharomyces cerevisiae*, *Escherichia coli*, *Homo sapiens sapiens*, *Arabidopsis thaliana*. Comparison was done from a multivariate statistics. We have shown that the codon usage of the host genes differ from those of transposable elements (TE) mainly in the third base of the codons. Transposable elements are generally AT-rich independently of the host genome and element class. A detailed analysis of the *P* element in several *Drosophila* transfers. Comparison of relative bias of TEs compared to those of the host genes could be useful to understand the dynamics (within a species) and evolution (between species) of TEs.

Index terms: Codon usage, ransposable elements, Drosophila melanogaster, host genes, correspondence analysis

[2213] TRANSPOSONS ARE IMPLICATED IN THE GENERATION OF NATURAL CHROMOSOMAL REARRANGEMENTS IN INSECTS

M. Cáceres, J. M. Ranz, A. Barbadilla & <u>A. Ruiz</u>, Dept. de Genètica i de Microbiologia, Univ. Autònoma de Barcelona, 08193 Bellaterra (Barcelona), Spain

Chromosomal changes are a common feature of insect evolution. Paracentric inversions are particularly abundant in the genus Drosophila both as intraspecific polymorphisms and fixed interspecific differences. The origin of such chromosomal rearrangements is uncertain. Transposable elements (TEs) were first shown to mediate chromosomal rearrangements in laboratory populations of Drosophila melanogaster and in situ hybridization studies provided circumstantial evidence of their presence around the breakpoints of some natural inversions. However, despite these observations, unequivocal evidence for the implication of TEs in the origin of natural chromosomal rearrangements has been until recently elusive. No association was found between middle repetitive sequences and inversion breakpoints in D. subobscura and D. pseudoobscura. Also, the first two studies which sequenced the breakpoints of natural inversions did not detect traces of TEs. We have cloned and sequenced the breakpoints of the most common inversion in the populations of D. buzzatii, named 2j. Both breakpoints of the sequenced 2j chromosome contain relatively large insertions of DNA, which are not present in the 2 standard chromosome (lacking the inversion). The insertion in the distal breakpoint (392 bp) represent a defective copy of a transposon named *Galileo*. That in the proximal breakpoint (4,319 bp) contains also a copy of *Galileo* plus another five copies belonging to three other TEs. Both DNA blocks are flanked by two pairs of 7 bp target site duplications which were presumably generated upon insertion and later exchanged during the inversion event. Therefore the inversion arose by ectopic recombination between the two copies of Galileo that were in opposite orientations. Characterization of the structural and nucleotide variability around the inversion breakpoints in a geographically diverse set of chromosomal lines has shown that all chromosomes carrying the 2j inversion are monophyletic, i.e. inversion 2j arose only once. It has also revealed a striking structural variability at the inversion breakpoints of the 2j chromosomes due chiefly to the presence of several TE insertions. Altogether, at least 20 different insertions representing 8 types of transpososons have been found. This suggests that the 2j inversion breakpoints are hotspots for transposon insertion.

Index terms: Drosophila buzzatii, transposons, chromosomal rearrangements.

[2214] MOLECULAR EVOLUTION AND GENETICS OF NEOTROPICAL ANOPHELINE MALARIA VECTORS

J.E. Conn, Dept. Biology, March Life Sciences Bldg., Univ. of Vermont, Burlington, VT, USA 05405-0086.

Systematics has been an important tool for clarifying the diversity and relationships of neotropical anophelines in the subgenus Nyssorhynchus. Anopheline mosquito taxa are known to include many species complexes, whose members differ in vectorial capacity, distribution and ecological requirements. The documentation of these differences and the evolutionary histories of members are a critical first step prior to testing evolutionary and ecological hypotheses about malaria transmission. Our work has examined and clarified the systematics of Anopheles darlingi, Anopheles aquasalis, Anopheles nuneztovari and reestablished both Anopheles trinkae and Anopheles dunhami as distinctive species. In addition, the molecular data set from our phylogenetic hypothesis of this important subgenus demonstrates that several additional taxa may not be monophyletic (Danoff-Burg and Conn, unpub. data). This underscores the need for further work on these taxa, some of which are important regional malaria vectors. At the population level, my main questions concern structure and gene flow. We have focused on three species with highly differentiated ecologies: A. aquasalis is primary coastal and is the only neotropical anopheline to tolerate high salinity breeding sites; A. nuneztovari generally breeds in sunlit pools and has a seemingly disjunct distribution (Amazonian Brazil vs. Venezuela and Colombia); A. darlingi is highly anthropophilic, very broadly distributed, and breeds in forested riverine environments as well as pools formed during road construction throughout the Amazon. We have found significant variance components both among populations within neotropical biomes and within populations (P < 0.001) for all three species. We have also hypothesized that the presence of highly divergent haplotypes in single populations (one of the contributing factors to significant intrapopulation structure) may be the result of historical waves of colonization by these vagile organisms, with subsequent selective extinction of some lineages. We have suggested that distinctive histories detected by mitochondrial DNA analysis may have influenced the different levels of gene flow in two closely related regional malaria vectors with partially overlapping distributions and similar ecologies . To elucidate the potential effect of population structure on malaria transmission, my laboratory has developed microsatellite primers (the first for a neotropical malaria vector). Using these powerful, highly variable, population-level molecular markers we are currently examining population structure and gene flow in A. darlingi in endemic malaria areas in Amazonian Brazil separated by the Amazon River.

[2215] CHROMOSOMAL POLYMORPHISM AND SPECIATION IN ANOPHELES GAMBIAE

G. C. Lanzaro¹, Y. T. Touré², F. Tripel¹ & C. E. Taylor³, ¹Center for Tropical Dis., Univ. Texas Med. Branch, 301 University Blvd., Galveston, TX; 77555-0609 USA; ¹Malaria Res. & Training Center, Fac. Médecine & de Pharmacie & d'Odonto-Stomatologie, Bamako, B.P. 1805, Mali; ³Dept. Organismic Biol., Ecol. & Evol., Univ. CA, Los Angeles, CA, 90095-1606 USA.

The population structure of Anopheles gambiac s.s. is unusual, with populations being composed of "chromosomal forms". The names BAMAKO (B), MOPTI (M) and SAVANNAH (S) have been applied to forms in West Africa. Studies of karyotype frequencies at sites where the 3 forms occur in sympatry revealed significant departures from the Hardy-Weinberg equilibrium. Specifically, heterokaryotypes representing hybrids between the S form and the other 2 were under-represented and B/M hybrids were never observed. This was inferred to result from partial reproductive isolation between S and the other forms and complete isolation between the B and M forms. Recently, the status of S hybrids has been questioned, so that in fact reproductive isolation between all 3 forms may be complete. However, hybridization experiments involving crosses between forms result in viable offspring indicating a lack of post-mating reproductive barriers between them, at least in the lab. Estimates of genetic distance and descriptions of population structure based on isozymes also suggest that deficiencies in the frequencies of certain karyotypes may not be the result of reproductive isolation. It should be emphasized that although these studies do not support reproductive isolation among forms, they do not disprove it. For example, pre-mating barriers may isolate subpopulations, even if post-mating mechanisms have not evolved, and isolation may be too recent to be detected by isozymes. It has been recently reported that RAPD and ribosomail RNA gene regions are diagnostic for the B and M forms, leading to the suggestion that these 2 represent species. We have recently completed studies to estimate levels of gene flow (N,m) among forms. These studies have included both "indirect" and "direct" methods. The indirect methods include mark-releaserecapture studies to estimate effective population size (N₄) and migration rate (m). In addition, we have made direct observations of mating among forms by genotyping sperm extracted from field collected fema

[2216]MOLECULAR PHYLOGENY OF THE BACTROCERA TAU SPECIES COMPLEX

S. Thanaphum, Department of Biology, Faculty of Science, Mahidol University, Rama VI, Rajdhavee, , Bangkok 10400, Thailand, E-mail testn@mahidol.ac.th

Tephritid fruit flies are important and very diverse pest of crops in Southeast-Asia. Although most tephritid species could potentially damage fruits, only several of them ruin major agricultural commodities. *Bactrocera tau* represents an example of an important tephritid pest. It shows a preference for attacking the fruits of Cucurbitaceae. The *B. tau* species identifications suggests that there may be a complex of widely distributed species. Biological understanding of systematics and evolution at the species complex level is fundamentally important to pest management programs as well as species concepts. The existence of a *B. tau* species complex status had initially been suggested by some biological differences such as host-plant preferences, karyotypes, and mophological studies. However, evolutionary genetic relationships among species in a complex could be better studied using DNA markers. Part of a heat shock cognate 70 kDa like gene (hsc70) was developed and used as a DNA marker. The hsc70 DNA sequences were used to reconstruct phylogenetic relationship of the *B. tau* at the level of species in the complex and/or populations. All molecular phylogenetic tree topologies show congruence results with high confidence when we use neighbor-joining, maximum parsimony, and maximum likelihood analyses. Thus, this part of hsc 70 may be a suitable phylogenetic marker for the study of *B. tau* species complex status.

Index Terms: Tephritid fruit fly, Bactrocera tau, heat shock 70 kDa gene, molecular phylogeny, species complex

[2217] HAT MEDIATED TRANSFORMATION OF INSECTS

D. A. O'Brochta¹, P. W. Atkinson², ¹Center for Agricultural Biotechnology, University of Maryland Biotechnology Institute, Plant Sciences Building, College Park, MD 20742, USA, E-mail obrochta@umbi.und.edu; ²Dept. of Entomology, Univ. of California, Riverside, CA 92521, USA.

The hobo, Ac, Tam3 (hAT) family of transposable elements has representatives in many organisms including vertebrates. Their widespread distribution is likely due in part to their ability to transpose when introduced into a new host. This property has also made them useful as gene vectors. The hAT element Hermes has received the most attention as a non-drosophilid insect gene vector and it continues to hold great promise as a versatile tool for creating transgenic insects. Hermes was originally isolated from the housefly, Musca domestica but has since been shown to be capable of undergoing transpositional recombination in approximately 10 species of insects from 3 orders. The limits of this element's host range remain undetermined. As with other elements, the rates of Hermes movement vary from species to species. In some strains of Drosophila melanogaster transformation rates of 100% have been found. Transformation rates of non-drosophilid insects with the same vector have been considerably lower. Aedes aegypti has consistently been transformed with Hermes at How the host influences integration rates is not rates of approximately 2%. understood but clearly this clement is capable of efficiently integrating into chromosomes. Some aspects of the behavior of Hermes are clearly host-independent. For example, this element consistently prefers to integrate into DNA of a particular sequence regardless of the host. The mechanism by which transposable elements integrate into a target molecule can proceed by a number of mechanisms. Hermes, like other elements of this type, appears to move via a cut-and-paste mechanism, whereby the element is excised from the donor site at positions defined by the terminal inverted repeats of the element. But many elements also have alternative mechanisms that can be used under certain conditions. Hermes appears to have at least two mechanisms by which it can transpose. In all insects tested Hermes undergoes cut-and-paste type movement. In mosquitoes a second mode of integration has also been detected that appears to be a form of replicative transposition. Finally, gene vectors constructed from transposable elements belonging to large element families have a chance to encounter one of their relatives present in the host insect being transformed. We have begun to explore the potential consequences of such an encounter and have found that in some cases the elements can interact in such a way as to destabilize each other. The interactions we have observed are not reciprocal. The significance of these observations will be discussed in relation to the planned uses of transgenic insects in the field.

[2218] THE *MINOS* TRANSPOSABLE ELEMENT AS A TOOL FOR INSECT TRANSFORMATION

C. Savakis, University of Crete and Institute of Molecular Biology and Biotechnology, Foundation for Research and Technology Hellas, Heraklion, Crete, Greece. E-mail: savakis@imbb.forth.gr

Minos, a Type 2 transposable element from Drosophila hydei, is transpositionally active in several insect species, including Diptera (Drosophila melanogaster, Drosophila virilis, Ceratitis capitata, Aedes aegypti, Anopheles gambiae and Anopheles stephensi) and Lepidoptera (Spodoptera frugiperda and Bombyx mori). Using established germ line transformation procedures, Minos vectors have been used for construction of stable transgenie D. melanogaster, C. capitata (the first non-Drosophilid insect for which mobile element-mediated transformation has been demonstrated) and, more recently, Anopheles stephensi. Expression of the white gene and of several constructs containing the Green Fluorescence Protein is routinely used to detect transformation. In jection of *in vitro*-synthesized Minos mRNA in preblastoderm embryos containing Minos transposon insertions results in high frequency mobilization of the transposon. In the Medfly, Ceratitis capitata, Minos-mediated transformation has been used to express genes in inducible, tisue-specific and sex specific manner. Applications of Minos-mediated transgenesis in the insect sciences and in applied entomology will be discussed. In addition to gene transfer, random chromosomal insertions of Minos vectors can be used to introduce mutations in diverse insect species. Possible applications of transposon-mediated mutagenesis for functional genome analysis in insects will be discussed. [2219] FRUIT FLY TRANSFORMATION WITH PIGGYBAC: PERSPECTIVES AND CONSIDERATIONS

A. M. Handler¹, S. D. McCombs² & R. A. Harrell¹, ¹Center for Medical, Agricultural, and Veterinary Entomology, USDA-ARS, Gainesville, FL 32608, USA, E-mail handler@nersp.nerdc.ufl.edu; ²Dept. of Entomology, University of Hawaii, Honolulu, HI 96822, USA

The ability to achieve efficient germline transformation in nondrosophilid insects has become feasible with the transposon-based vector system called piggyBac, originally isolated from the cabbage looper moth, *Trichoplusia ni. piggyBac* vectors were created by insertion of markers including white genes and a green fluorescent protein (g/p) gene, either individually or ln combination. With an hsp70-regulated helper transposase, the Mediterranean (*Ceratifis capitata*), Caribbean (*Anastrepha suspensa*), and oriental (*Bactrocera dorsalis*) fruit flies were transformed, in addition to *Drosophila melanogaster*. The ability of a moth vector system to function in several dipteran species is encouraging for its function in other dipterans, and possibly other insect orders. This is supported by the original transformations mediated by a self-regulated transposase helper, indicating that *piggyBac* retained autonomous function in another insect order. Subsequently, evidence from several groups showed *piggyBac*-inediated transformation of the oriental fruit fly, Southern DNA hybridization controls in non-transgenic strains showed that *jiggyBac* to closely related elements previously existed in this species, and this was the first detection of *piggyBac* present wild and mutant strains, with intact and defective elements. Analysis of 1.5 kb *piggyBac* PCR sequences in several *B. dorsalis* strains indicated a -95° nucleotid and amino acid sequence identify between the elements in *T. ni* and *B. dorsalis*. This was further supported by sequencing of genomic clones indicating the same inverted terminal repeats and TTAA insertion site. Further surveys by PCR and hybridization indicated that *piggyBac* exists throughout the *B. dorsalis* strans of distantiy related species is not surprising, and it is likely to have occurred by horizontal transmission. The apparent discontinuity of *piggyBac*, or related transpecies is range of function, and onignared to sinilarly active transposon vectors, the existence of *pig*

[2220] MARINER MOBILITY IN AEDES AEGYPTI

C. J. Contes¹, N. Jasinskiene² & A. A. James², ¹Dept. of Entomology, Texas A&M Univ., College Station, TX 77843-2475, E-mail: c-coates@tamu.edu; ²Dept. of Mol. Biol. & Biochem., Univ. of California, Irvine, CA 92697.

The Mosl mariner element from Drosophila mauritiana was used to produce germline transformants of the yellow fever mosquito, Aedes aegypti. A white eyed strain of Ae. aegypti, kh*, was used as the recipient strain. The D. melanogaster cinnabar gene was used as the transformation marker and was able to rescue the eye color mutation. Molecular analysis using Southern blot and Inverse Polymerase Chain Reaction (IPCR) techniques revealed that the integration events were occurring at TA nucleotides as expected. The transformation rate in this initial experiment was approximately 4%. This is significantly lower than comparable experiments performed in *D. melanogaster* with the *Mos1* transposable element system. In aneffort to improve the *Mos1*-mediated transformation rate in *Ae. aegypti*, experiments were performed with purified recombinant Mos1 transposase. The rate of germline transformation was increased by 2-fold and the number of transgenic G1 individuals that were produced in each transgenic family was increased 7.5-fold, when compared with the experiment using a helper plasmid as the source of transposase. However, Southern blot and IPCR data revealed that a number of the integration events mediated by the recombinant transposase, were not a result of an expected cut-and-paste transposition event. Experiments are in progress to produce variants of Mos1 that show increased transpositional activity following mutagenesis. It has been postulated that strains of mosquitoes that can no longer transmit certain pathogens could be genetically engineered and used to spread the refractory phenotype throughout a wild population. This will require a driving mechanism to spread the refractory gene. Experiments are in progress to assess the ability of a marked autonomous Mos1 element to spread through cage populations of Ae. aegypti. Index terms: Genetic transformation, Transposable Element, Transposition.

[2221] BACULOVIRUS-MEDIATED GENE TARGETING IN THE SILKWORM

11. Mori & M. Yamao, Department of Applied Biology, Kyoto Institute of Technology, Kyoto 606-8585, Japan, E-mail hmori@ipc.kit.ac.jp

Targeted disruption of an endogenous gene would permit analysis of gene function through the production of gene-knockouts in the silkworm, *Bombyx mori*. In addition, homologous recombination of a foreign gene downstream from a powerful promoter, such as the fibroin promoter, would allow large-scale and constitutive production of a useful protein in the silkworm. The green fluorescent protein (GFP) gene was inserted into fibroin light (L)-chain gene. The L-chain/GFP chimeric gene was used to replace with the polyhedrin gene of *Autographa californica* nucleopolyhedrovirus (AcNPV). This recombinant virus was used to target the L-chain/GFP gene to the L-chain region of the silkworm genome. Silkworm larvae were infected with the recombinant virus and genomic DNAs from their progenies were screened for the desired targeting event. This analysis demonstrated that the chimeric gene had been integrated into the L-chain gene on the genome by homologous recombination and stably transmitted through generations. The chimeric gene was expressed in the posterior silk gland and the gene product was spun into the cocoon layer. In order to produce several useful proteins in the silkworm, these genes were also inserted into L-chain gene and the polyhedrin gene of AcNPV was replaced with the chimeric genes. Screening of the desired gene targeting event and the useful protein-expressed silkworm under control of L-chain gene or as in progress.

Index terms: Bombyx mori, silkworm, gene targeting, Autographa californica nucleopolyhedrovirus.

[2222] INSECT TRANSCENESIS: BACULOVIRUSES MEET TRANSPOSONS FOR BENEFICIAL INVASIONS

J. P. Farrell¹, W. Wang¹, L. Swevers^{1,2}, Y. Hashimoto³ & <u>K. Iatrou^{1,2}</u>, ¹Department of Biochemistry and Molecular Biology, University of Calgary, 3330 Hospital Dr. NW, Calgary, AB T2N 4N1, Canada, E-mail iatrou@ucalgary.ca; ²Institute of Biology, National Centre for Scientific Research "Demokritos", PO Box 60228, 153 10 Aghia Paraskevi Attikis, Greece, E-mail iatrou@mail.demokritos.gr; ³Department of Applied Biology, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606, Japan.

Using as model the domesticated silkmoth Bombyx mori, we are developing a new system that can be used for achieving easy and efficient transformation of a variety of lepidopteran insects. This system, termed Baculovirus Artificial Chromosome (BVAC), is based on the use of engineered baculoviruses (BmNPV in the case of Bombyx) that can infect and replicate into the host cells but cannot complete their infection cycle and kill the infected host because of a single virus gene deletion, that removes an important function required for the onset of late viral gene expression. BVACs and recombinant versions of them containing transgenes of choice placed under the control of relevant insect promoters, are propagated in insect cell cultures stably transformed with the missing viral function. When host insects are infected with recombinant BVACs by simple injection into late larval or pupal abdomens, the BVACs and associated transgene(s) are transmitted into essentially all the cells of the host including those of the gonad, which can transmit the BVACs to the next generation through mating of infected hosts with uninfected insects. To circumvent the inherent limitation of BVAC episomal inheritance (and loss upon transmission via repeated cell division), we are incorporating into BVACs a transposition system that can direct the integration of the transgene(s) into the genome of infected cells. Having demonstrated that the Mos1 Mariner transposase system of Drosophila mauritiana can direct efficient excision and transposition events in a silkmoth cell line (Wang, Swevers & Iatrou, Insect Mol. Biol., In Press), we are know attempting the insertion of this transposase system into the genome of our basic BVAC vector system. As it now stands, the BVAC system can be used for continuous high level expression of transgene products of interest in insect cell cultures in vitro and in live hosts in vivo. We anticipate that the incorporation of the transposition system into the basic BVAC vectors, will result in the generation of a major new transformation system that allows for efficient generation of transgenic lepidopteran insects with minimal effort.

Index terms: Bombyx mori, transformation, BmNPV, Mariner, expression system.

Symposium and Poster Session

[2223] THE INTEGRATED AREA-WIDE APPROACH TO INSECT PEST MANAGEMENT, PROSPECTS FOR ITS APPLICATION TO TSETSE

<u>J. Hendrichs</u>¹, U. Feldmann¹ & A. S. Robinson², ¹Joint FAO/IAEA Division, P.O. Box 100, A-1400 Vienna, Austria, E-mails: J.Hendrichs@iaea.org & U.Feldmann@iaea.org; ²FAO/IAEA Agriculture and Biotechnology Laboratory, A-2444 Seibersdorf, Austria, E-mail: A.Robinson@iaea.org

Conventional IPM is usually a localized and uncoordinated suppression response by individual farmers against a segment of an insect pest population that has exceeded an economic threshold level. As long as the farmer's neighbours do not join in the efforts, such farm-by-farm intervention will be of short lived effectiveness as pest insects will continue to re-invade the farm from the surroundings, resulting in the need for repeated control actions. However, when farmers in a given area apply coordinated IPM against the total population of a key pest, including non cultivated habitats and unmanaged properties, the control achieved will be much more effective. With this lower density of an entire pest population, more selective, preventative and less insecticide-reliant management tactics become feasible for the target key pest. To cope with current environmental, economic and global trade challenges, commercial producers are increasingly having to collaborate and to organize into associations, a trend which is strongly encouraging farmer participation in area-wide approaches to IPM. Tsetse flies, *Glossina* spp., vectors of African trypanosomoses, devastating diseases of man and livestock, representing a major obstacle to development in 38 African countries south of the Sahara. Research efforts to develop vaccines have been unsuccessful and have largely been abandoned. Current local control efforts are costly and are hampered by drug resistance in trypanosomes, side effects of continuous insecticide use, expansion of fly distribution into new agroecosystems, and lack of sustainability. In order to feed their growing human populations, Governments either have to continue expanding low-productive livestock/farming systems into wildlife areas or to promote intensified systems in existing agricultural areas and thus reduce the need of agricultural expansion into wildlife areas. The latter involves improved cattle breeds and requires tsetse management on an area-wide basis. An integrated, area-wide approach is highly appropriate in view of the transboundary nature of the problem and has been successfully demonstrated on Zanzibar. It involves vector suppression using insecticide on livestock or on attractive artificial targets, followed by the aerial release of sterile male tsetse. SIT, the final component of such an integrated areawide campaign, is environment-friendly and can lead to the creation of sustainable, tsetse free areas.

Index terms: Glossina spp., area-wide IPM, SIT.

[2224] ANALYSIS OF GENETIC VARIABILITY AND MATING BEHAVIOUR OF ANASTREPHA FRATERCULUS (DIPTERA, TEPHRITIDAE) WITHIN THE FRAME OF CONTROL PROGRAMS

J. C. Vilardi, Depto. Cs. Biológicas, Fac. Cs. Exactas y Naturales, Universidad de Buenos Aires, 1428 Buenos Aires, Argentina. E-mail vilardi@bg.fcen.uba.ar.

The neotropical tephritid genus Anastrepha includes many economical important species. A. fraterculus, the South American fruit fly is the most common and economically important pest for the fruit-bearing species of the neotropical region. Evidence from different sources, including variation in pest status, morphology, karyotypes, isoenzymes, mitochondrial DNA, and cuticular hydrocarbons, indicate that the nominal A. fraterculus comprises multiple cryptic species. Control strategies used for this species are mostly based on conventional insecticides. Developing genetic or biological control programs require a deeper knowledge of its taxonomy, behaviour and genetic diversity. The research conducted at our laboratory involves two main approaches, genetic variability and mating compatibility between natural populations of this species. Isozymal studies to asses the distribution of the genetic variability within a natural population (Yuto, Jujuy, Argentina) inidcated a significant substructuration evidenced by a remarkable homozygote excess. This result was related with the continuous host shifts undergone by this fly depending on fruit availability throughout the year. When seven populations belonging to different biogeographic provinces in Argentina were compared, genetic similarities ranged within values expected for conspecific populations. The phenogram obtained by UPGMA among populations were in rough agreement with the expected from geographic distribution. Experiments of sexual compatibility between two geographically isolated populations (Yuto in North West, and Concordia in East Argentina) were conducted under field cage conditions. The indices of reproductive isolation (ISI, RII, I) do not show behavioural incompatibility between them. Males from both populations show the same preferences respect to place and time for lekking, calling, and mating. The results from isozymal and behavioural studies indicate that the Argentinean populations of A. fraterculus so far studied would constitute a single biological species. However, the indices MRPI and FRPI indicate significant differences in mating propensity which may produce sexual selection. Males and females from Yuto mated 4 times as frequently as those from Concordia. These behavioural differences may be the consequence of genetic mechanisms that could affect the efficiency of laboratory strains selected for adaptation to mass rearing conditions.

Index terms: isozyme, mating compatibility, sexual selection.
[2225] SUCCESSFULLY MANAGING LEPIDOPTERAN PESTS WITH GENETIC METHODS: THE FUTURE IS NOW

S. Bloem¹, J. E. Carpenter², F. Marec³ & K. A. Bloem⁴, ¹USDA-APHIS-NBCI, at NFREC-Monticello, Univ. of Florida, Rt. 4, Box 4092, Monticello, FL 32344, USA; ²USDA-ARS-IBPMRL, P.O. Box 748, Tifton, GA 31793, USA; ³Institute of Entomology, Czech Academy of Sciences, Branisovska 31, CZ-37005 Ceske Budejovice, Czech Reability, USDA-APHIS-NBCI, at Florida A&M Univ., CESTA, Tallahassee, FL 32307, USA; E-mail: ^{1, 4}ksbloem@nettally.com; ²icarpent@tifton.cpes.peachnet.edu; ³marec@entu.cas.cz.

Genetic pest suppression is unique among biological control methods in that it involves the release of genetically modified insects to control the same species. These methods are unparalleled in their specificity and safety because only the targetspecies is affected. Lepidopterans are the most important pests of many major crops, forests and stored products. Safe and pest specific control tactics against these ubiquitous pests are constantly being sought. Three genetic methods have been developed and field-tested against Lepidoptera, and of these, radiation-induced inherited sterility (or F1 sterility) is considered to be the most promising. F1 sterility can be readily combined with other biological controls such as pheromone mating disruption and natural enemies. In the application of F1 sterility the radiation dose is lowered so that the released insects are partially sterile or adjusted so that the females are completely sterile and the males partially sterile. The radiation-induced deleterious effects are inherited for 1 or more generations. As such, releasing partially sterilized insects offers far greater suppressive potential than using fully sterile insects. The genetic basis of F1 sterility in Lepidoptera will be discussed and the advantages of this genetic control method will be illustrated using examples from both perennial (apples and dates) and annual (corn and cole crops) cropping systems. In the face of growing concerns surrounding the use of genetically modified crops, the presence of pesticide residues on exportable commodities, the development of pesticide resistance, the U.S. Food Quality and Protection Act, and environmental, ground water and worker safety issues we argue that now is the time to increase our commitment to the use of genetic methods in controlling Lepidoptera.

Index Terms: area-wide control, Helicoverpa zea, Cydia pomonella, Plutella xylostella, Ectomyelois ceratoniae.

(2226) GENETIC AND MOLECULAR APPROACHES IN SUPPORT OF THE STERILE INSECT TECHNIQUE

G. Franz & C. Caceres, IAEA, FAO/IAEA Agriculture and Biotechnology aboratory, A-2444 Seibersdorf, Austria, E-mail g.franz@iaea.org.

For several insect species, including the screwworm fly and the Mediterranean fruit fly, the Sterile Insect Technique is an established technology to eradicate or suppress pest populations. For other species the method has also been shown to work successfully (e.g. tsetse fly) and it can be expected that this technology will become the future method of choice. It is environmentally friendly and, especially in the medium and long term, more cost effective than the traditional application of insecticides. Unlike the latter strategy, the Sterile Insect Technique is applied also outside of the area of direct commercial interest, i.e. the entire pest population is targeted. At its heart the Sterile Insect Technique is a genetic method as it relies on radiation induction of dominant lethal mutations that are introduced into the target population via the release of large numbers of irradiated insects. Mass rearing of insects is also subject to genetic effects, e.g. inbreeding, which can lead to the production of non-competitive insects. Other components of the Sterile Insect Technique are subject to genetic/molecular investigation or modification. These include the molecular analysis of the target populations and the development of maleonly strains. These genetic and molecular approaches to improve the Sterile Insect Technique will be reviewed.

Index terms: Ceratitis capitata, Sterile Insect Technique, area wide, genetics, molecular biology

[2227] RAPD MARKERS FOR GENETIC POPULATIONS STUDIES IN AEDES

C. F. J. Ayres, <u>M. A. V. Melo</u>, L. Régis & A. F. Furtado, Dept. de Entomologia, Centro de Pesquisas Aggeu Magalhães/FIOCRUZ, Av. Moraes Rego, CEP-50670-420, Recife, PE/Brasil, e-mail: tans@cpqam.fiocruz.br. Supported by CNPg/FIOCRUZ.

The genus Aedes contains many species, which are implicated in the transmission of diseases of public health importance, as yellow fever, dengue and haemorrhagic dengue fever. Historically, dengue has been controlled mainly by the use of measures against its vectors. Nowadays it has been shown that new weapons must be employed. The understanding of the patterns of vectorial dispersion, gene flow and the molecular basis of the genomic flexibility of vectors and consequently the mechanism ensuring the population diversity is important for the development of effective mosquito control strategies. A study on the genetic variability and structure of Aedes aegypti population from Brazil (Amazonas, Pernambuco and Alagoas), Ae. albopictus population (Rio de Janeiro) and Ae. taeniorrhynchus population (Pernambuco) was conducted using Random Amplified Polymorphic DNA (RAPD). Ten arbitrary primers were tested and 4 were reproducible, 3 of which were abele to differentiate populations of *Ae. aegypti* based on diagnostic bands. The intrapopulation similarity index (F) and polymorphism (P) was F=0,80; P=73% for *Ae. aegypti* populations and F= 0,81; P = 76% and F= 0,68; P = 93% for *Ae. taenirrhynchus* and *Ae. albopictus* populations, respectively. The results demonstrate that RAPD markers are an important tool to detect population differences, what is of fundamental importance in epidemiology studies of relationship between geographic populations and vectors dispersal. Index terms: Aedes, polymorphism, RAPD-PCR, genetic variability

[2228] ABOUT GENETICAL VARIABILITY OF CODLING MOTH POPULATIONS INHABITING IN DIFFERENT CONDITION

A.A. Azizyan ,A.S. Akopyan & A.R. Ter-Hovhanessyan, Institute of Zoology NAS Armenia , Mchitar Heratsi 89,ap.6,Yerevan,375025,Armenia

The quantitative dependence of duration of the periods of development poikilotherm organisms from complex changes of ecological parameters is known. Life cycle of codling moth in conditions of a climate of various geographical zones is determined in basic two parameter: being provided with warmth and duration of light day. According to the standard technique of prognosis the phenoecology of insects, the reactivate them begins at set in of steady temperature of air 10° C. of insects, the reactivate them begins at set in or steady temperatures of all 10 ce. The amount of warnth necessary for passage of separate stages the onlogeny of codling moth, is characterized by the following sizes of the sum of effective temperatures (SET): a beginning the fly of the butterflies – 90-110° C, mass fly of butterflies - 150-190° C. The aim of this work was the comparative study of phenoecology of different populations of codling moth in valley and mountain zones depending on the ecological factors. The received results have shown significant of a deviation of settlement dates from actual for a mountain zone, Development of codling moth generation after diapause in a mountain zone start in the period, when daily average temperature of air was kept at a level 7-8° C. The beginning of pupa formation is characterized SET - in mountain zone 6-12°C, and in valley - 45-55°C, the beginning of butterflies fly - in mountain zone -60-80° C, in valley-110-130° C. The received distinctions in actual phenology dates of development of two different populations depending on SET, have shown, that the development of an insect depends not only on a complex of the ecological factors, but also from genetically predetermined of phenology peculiarities of each population. The phenology peculiarities of development of a mountain population of codling moth as against to prognosis it is possible to consider as the hereditary adapted reaction to low temperatures in a mountain zone.

[2229] OPTICAL PROPERTIES OF *MORPHO TYPE* SCALES. MULTILAYER AND GRATING MODEL

<u>S. Berthier⁽¹⁾ & P. Lalanne⁽²⁾, (1) Laboratoire d'Optique des Solides, Univ. P. et M. Curie, case 80, 4 place Jussieu, F75252 Paris cedex 05, France. E-mail: berthier@ccr.jussieu.fr, (2) Inst. d'Optique, Univ. Paris 11, bat. 503, BP 147, 91403 Orsay cedex, France.</u>

Butterfly scale ultrastructures leading to iridescent effects are numerous : thin films and multilayers give rise to interferences, grating to diffraction, and small particles to diffusion. Although some butterfly pigmentary colours appear bright and highly visible, their absolute visibility is substantially inferior to those wing colours generated by optical interferences or grating diffraction and they generally lead to poor iridescent and polarisation effects. If both optical interference and grating diffraction lead to sheer brightness, the spatial dispersion of the light, necessary to enhance the viewing angle over witch they are visible, is very different. When the origin is purely interferential (*Uraniidae* are common examples : the upper membrane of the scale acts as a quasi continuous dielectric multilayer, or Bragg mitror) the reflection is high but specular and it severely restricts the solid angle over witch the light is reflected. Long range communication would be limited in this case. The spatial dispersion of the light is then generally assumed by the convexity of the scales about their transversal (*Christridia*) or longitudinal (*Procris statice*) axis. The situation is quite different for the *Morpidae* where the multilayer structure lies in the ridge of the generally plane basal scales. Depending of the species, the spacing between ridges lies in the range 0.5 to 1 µm, each ridge acting as a Bragg mirror. The whole scale acts now as a grating inscribed in a Bragg mirror, giving rise to a wavelength selective grating. The dispersion is now assumed by diffraction and some time by diffusion by the upper transparent cover scales. The modellastion of this structure is much more complicated and most of the authors neglect the grating effect and only deal with the multilayer model. SEM and TEM images of *Morpho menelaus* are first presented and the optical structure model deduced. We then present hemispherical reflectivity can be modelised by both the multilayer and the grating models. Modelisation

[2230] POLYMORPHIC MICROSATELLITE MARKERS TO ASSESS THE GENETIC VARIABILITY IN THE MEDITERRANEAN FRUIT FLY, CERATITIS CAPITATA, SPECIES RANGE

M. Bonizzoni¹, L. Zheng¹, F. Sebastiani¹, C.R. Guglielmino³, L.M. Gomulski¹, G. Gasperi¹ & <u>A.R. Malacrida</u>¹, ¹Dept. of Animal Biology, University of Pavia, 27100 Pavia, Italy, ²Dept. of Epidemiology and Public Health, Yale Univ., New Haven, CT 06520, USA, ³Dept. of Genetics and Microbiology, Univ. of Pavia, 27100 Pavia, Italy

Polymorphism at 16 simple sequence repeat (SSR) markers was investigated in 122 C. capitata flies from 4 regions throughout the species range: Africa (Kenya and Reunion), extra-Mediterranean island (Madeira), Mediterranean basin (South Italy and Greece) and Latin America (Peru). The number of alleles per locus, the variance in repeats count, the gene diversity and the Rst values were not homogeneously distributed over the 16 loci, indicating that different genomic regions contributed differently to the differentiation among populations. The degree of genetic variability in the medfly species range was assessed by measuring the number of effective and actual alleles and the heterozygosity at these 16 loci. The greatest number of SSR alieles and the highest levels of heterozygosity were found in the native African region; furthermore a large number of Kenyan and Reunion variants appeared to be private or rare. The decrease in genetic variation, at the microsatellite loci analyzed, found in the derived populations (Madeira, South Italy, Greece and Peru) appeared to be consistent with their demographic history. Similar results were obtained both with allozyme, sigle-copy DNA and RAPD markers. Given their high degree of polymorphism, SSR markers appear to be the ideal tools to detect population differentiation on a small geographic scale and of recent infestation events of the Mediterranean fruit fly.

Index terms: Medfly, Ceratitis capitata, microsatellite polymorphism, colonization

[2231] PREDATION AS A POST-MATING ISOLATION MECHANISM IN IELICONIUS CYDNO AND H.MELPOMENE

Y.I.Bull & J.L.B. Mallet, Galton Laboratory, Department of Biology, University College London, 4 Stephenson Way, London NWI 2HE, UK. E-mail bullv@naos.si.edu

Speciation is thought to be driven by a range of pre and post-mating isolation mechanisms acting as barriers to gene flow. A number of studies have used the broadly sympatric Müllerian mimic species, *Heliconius cydno* and *H.melpomene* which hybridise in the wild at a frequency of around 1:1000. These studies aimed to determine the relative importance of ecological divergence, assortative mating and sterility in keeping the two species distinct (Jiggins & Naisbit, unpublished). However, the major selective factor thought to control *Heliconius* hybrid numbers is strong frequency-dependent selection on colour patterns (McMillan *et al* 1997, Chai 1986), a hypothesis which has thus far remained untested. It is thought that novel colour patterns arising in hybrids will be at a frequency-dependent disadvantage when they are found alongside commoner forms, and will therefore be selected against, as predators fail to recognise novel patterns as unpalatable (Greenwood *et al* 1989). A field study aimed at testing this theory was conducted by Mallet and Barton (1989), however the fate of the butterflies was not directly observed, so that direct evidence for preferential selection by colour pattern is lacking. We present the results of experiments conducted using caged birds to assess the relative importance of predation as a post-mating isolation mechanism in *H.cydno* and *H.melpomene*. Index terms: speciation, hybridisation, frequency-dependent selection.

[2232] GENETIC CONSTRAINTS IN THE SPECIALIZATION PATTERN OF AN APHID

P.P. Caballero, C.C. Ramírez & H.M. Niemeyer, Laboratorio de Química Ecológica, Departamento de Ciencias Ecológicas, Universidad de Chile, P.O. Box 653, Santiago, Chile. E-mail paulac@abulafia.ciencias.uchile.cl

Aphids (Homoptera, Aphididae) have an important degree of specialization, which is frequently related with a higher performance on the host in which they are specialized (established host) than on other host plants (novel host). Nevertheless, considerable evidence of changes in host use after experience (i.e. during ontogenetic development) on novel hosts suggests experience as a mechanism able to modify the specialization degree. The aim of this work was to study the effect of experience on a novel host on the specialization pattern of the aphid Rhopalosiphum maidis. R. maidis commonly occurs in Chile on johnsongrass (Sorghum halepense) but rarely on wheat (Triticum durum) despite the proximity of these two species. Intrinsic rate of population increase of 23 PCR-identified clones of R. maidis from johnsongrass, was evaluated on johnsongrass (established host) and on wheat (novel host), before and after experience for 20 generations on wheat. The pre-reproductive period and the fecundity of these 23 clones were also evaluated. Before the period of experience on wheat there was a negative correlation between fecundities on both host plants. Differential survival of clones was also evidenced: only 8 of 23 initial clones survived 20 generations on wheat. After the period of experience on wheat survival on wheat increased while performance was no affected, and performance on johnsongrass increased while survival was no affected. It is suggested that both genetic constraints and experience affect host use capacity and specialization pattern. Index terms: Rhopalosiphum maidis, specialization pattern, experience

[2233] GENETIC MARKERS IN CONGENERIC HERBIVORES: FINE-SCALE POPULATION STRUCTURE

<u>A. Caldas¹</u>, **D. Hawthorne¹**, & P. Barbosa¹, ¹Dept. of Entomology, Univ. of Maryland, College Park, MD 20742-4454, USA, E-mail: ac182@umail.umd.edu

We are investigating the population structure and patterns of relatedness among individuals of the noctuid moths Zale galbanata and Zale lunata using microsatellite markers. These two species co-occur in our two study sites at Patuxent Wildlife Research Center in southern Maryland. Although Z galbanata is a maple specialist, at our sites it only uses box elder (Acer negundo) despite the presence of other maple species. Preliminary laboratory experiments show that larvae die when offered leaves from other maples, which suggests population differentiation. Zale lunata, on the other hand, feeds on a variety of plants, including maples, but in our study sites it was never found on box elder in 8 years, but rather on black willow (Salix nigra). Larvae from these two species were collected from numbered trees of box elder and black willow at the two sites, approximately 3 km apart. Nine microsatellite markers have been isolated from a partial genomic library, and at least six of them are polymorphic to various degrees. These loci are being used to characterize variation of individuals within and between localities and levels of genetic relatedness among individuals obtained from the same tree. These data will be used to evaluate the influence of population structure and genetic relatedness on the rates of parasitism observed in these moths. Further studies with individuals from other localities will enable us to identify population processes responsible for this apparent host plant specialization. Index terms: Zale galbanata, Zale lunata, Noctuidae, parasitism, relatedness.

Symposium and Poster Session

[2235] POLYTENE CHROMOSOMES OF CULEX QUINQUEFASCIATUS (DIPTERA: CULICIDAE)

J. Campos¹, C.F.S.Andrade¹ & S.M. Recco-Pimentel², ¹Dept. of Zoologia, Iust. of Biology, State Univ. Campinas, P.O. Box. 6109, Campinas, SP CEP 13083-970, Brazil, E-mail jairocag@unicamp.br; ²Dept. of Celular Biology, Inst. of Biology, State Univ. Campinas, Campinas, SP CEP 13083-970, Brazil.

Dipteran polytene chromosomes are an excellent material for detailed approaches in species complex determination as well as structural and functional cytogenetics. Such material has become presently available for gene location in relation to insecticide resistance in *Culex* molecular cytogenetics studies. The species status in the *Culex pipiens* complex has been controversial and the use of polytene chromosomes for cytogenetic analysis has been difficult for the Culicinae subfamily because of methodological problems. The pupal Malpighian tubule polytene chromosomes maps were obtained for *Cx. quinquefasciatus* collected and maintained at the University of Campinas campus. The chromosome maps for this species were constructed and compared with published data for *Cx. pipiens* pipiens and *Cx. p. quinquefasciatus*. Although the banding patterns are conserved among species, analysis of structural variations for bands and interbands showed differences apparently related to their physiological stages. Configurations for the centrometric regions occurring among larval and pupal chromosomes showed more similarities than those between pupal and adult chromosomes. The Malpighian tubule polytene chromosomes of 20 to 48 hours old pupae provided the best cytogenetic analysis. Their use for *in situ* hybridization of vectorial competence probes is discussed. Index terms: cytogenetics, *Culex pipiens*, mosquitoes

[2234] PROTEIN PURIFICATION AND CONA CLONING OF SALIVARY GLANDS COMPONENTS OF ANOPHELES DARLINGI

E. Calvo, P. M. Ribolla, S. Daffre & O. Marinotti, Department of Parasitology, Institute of Biomedical Sciences. University of São Paulo. Av. Lineu Prestes 1374, Cidade Universitaria. CEP 05508-900, São Paulo, Brazil . E-mail: ccalvo@lineu.icb.usp.br. Finantial support: FAPESP, UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases.

Malaria remains the most prevalent and devastating insect-borne parasitic disease of humans, with more than 300 million cases worldwide reported yearly. The mosquito *Anopheles darlingi*, is the principal vector of human malaria in Brazil, where the number of cases has grown dramatically in the last 30 years. Four to five hundred thousand cases per years have been reported this decade. Salivary glands homogenates of the adult female *Anopheles darlingi* mosquitoes were fractinated using reverse-phase high performance liquid chromatography column. Four fractions were purified to homogeneity and their anino acid sequences determined by Edman degradation. Fragments with high degree of similarity with D-7 related proteins and gVAG allergen form *Anopheles gambiae*; and a metallothionein-like proteins were specific primer for 3'-RACE amplification of salivary glands cDMAs. A PCR amplified fragment (750 bp) from *Anopheles darlingi* was cloned and partially sequenced, showing high degree of homology with a D-7 related protein 2 from *Anopheles gambiae*; conhology with a D-7 related protein 2 from *Anopheles gambiae*; by protein, is specifically expressed in salivary glands. A PCR aregulated the constrained the protein was cloned and partially sequenced, showing high degree of homology with a D-7 related protein 2 from *Anopheles gambiae*; cDNA. This D-7-like protein, is specifically expressed in salivary glands of *Aedes aegypti* and *Culex quinquefasciatus* mosquitos. The presence of D-7 like genes expressed in different species of hacmatophagous mosquitoes, suggest that D-7 protein would play some essential role in the salivary gland functions, probably related with blood feeding.

[2236] MALE COURTSHIP SONG PATTERN OF THE *DROSOPHILA* SERIDO AND *DROSOPHILA* SP D (*REPLETA* GROUP) IN A HYBRID ZONE AREA

A.M.Cansian¹ & <u>F.M.Sene²</u>, ¹Dept. of Biology, FFCLRP, Univ. of São Paulo, Ave. dos Bandeirantes 3900, CEP: 14040-901, Ribeirão Preto, SP, Brazil Email: marfisa@rgm.fmrp.usp.br; ²Dept. of Genetics, FMRP, Univ. São Paulo, Ave. Bandeirantes, 3900, CEP 14049-900, Ribeirão Preto, SP, Brazil. Financial Support: CNPq, FAPESP, FINEP, CAPES and USP

The species Drosophila serido and Drosophila sp D belong to the buzzatii cluster of the repleta group endemic to South America. They are distributed in a zone of xerophytic vegetation and show a close association with some cactus species. The species distribution reflects the fragmentary distribution of its host plants, which appears to be in accordance with the climatic history of South America. Data from polytene inversions and multivariate acdeagus analysis showed the existence of a zone of secondary contact between Drosophila serido and Drosophila sp D in the Atlantic coast of Santa Catarina and Rio Grande do Sul states. This natural zone of hybridization is promising for studying evolutionary changes and speciation through the evolution of pre-mating barriers. In order to get more information on this situation, six populations were analysed based on the male courtship song pattern. The analysis cover the Atlantic coast populations of the state Santa Catarina and Rio Grande do Sul included at the zone of secondary contact. The male courtship song parameters analysed were: - intrapulse interval (PI); - interpulse interval (IPI); parameters analysed were: - intrapulse interval (PI); - interpolae interval (NI), intrapulse frequency (IF). Statistical comparisons among the populations showed significant differences concerning the three analysed parameters. The IPI was the most differentiated parameter among the species (ANOVA p<0.01), suggesting its importance for the female discrimination. The IPI parameter between Drosophila sp D and populations from contact area are also significantly different (ANOVA p<0.001). In addition, the low intraespecific variability on both PI (ANOVA p=0.682) and IPI (ANOVA p=0.348) showed in the two species was also observed in others species subgroups and it could be explained by strong selection acting on the song parameters. The relationship among morphology, inversion, male courtship and speciation are sometimes difficult to evaluate in a hybrid zone context, and the present study shed more light to elucidate the species differentiation process. Index terms: zone of secondary contact, speciation, cactus breeding species.

[2237] MOLECULAR STUDIES OF SEX-SPECIFIC GENES IN THE INSECTS C. CAPITATA AND BACTROCERA OLEAE

G. Christophides¹, D. Lagos¹, E. Zakynthinos¹, C. Savakis² & <u>K. Komitopoulou</u>¹, ¹Univ. of Athens, School of Biology, Dept. of Genetics and Biotechnology, Greece. ²Institute of Molecular Biology and Biotechnology, Foundation of Research and Technology, Crete. E-mail:akomitop@biology.db.uoa.gr.

A multigene family encoding Male Specific Serum Polypeptides (MSSPs) was characterized in the medfly C. capitata. The family comprises seven members classified, according to sequence similarity, in three subgroups, MSSP- α , MSSP- β and MSSP-y. Sequence analysis data and secondary structure predictions showed that these genes belong to the Odorant Binding Protein family of insects. Expression pattern analysis showed that certain MSSP genes appear to be expressed in distinct sex- and tissue-specific manner. Transformation analysis of the regulatory elements of the gene MSSP-02 was performed using two overlapping fragments fused to the lacZ reporter gene. A functional dissection of the promoter was identified. Sequences located between +37 and -283 are responsible for a basic male fat body expression pattern, although a temporal shift to later period was observed, compared to the endogenous synthesis of MSSP polypeptides. The region from -283 to -522 causes a five-fold increase to the transgene expression predicting the presence of enhancing regulatory elements. Moreover, this region corrects the temporal profile possibly due to the existence of early activating elements. The MSSP-a2 promoter may prove to be a useful tool for the controlled expression of selectable genes, such as the Adh gene. The -283/+37 promoter fragment was used to drive the basic male fat body expression of Drosophila Adh gene in medfly transgenic flies established after Minos germline transformation. It was demonstrated that the enzyme is active in the transgenic flies, leading to an approximately two-fold increase of the total ADH enzyme activity in males compared to the females. These results suggest that the long promoter fragment,-485/+37 should be able to confer a ten-fold expression of the Adh gene in transgenic strains. We have extended our studies in sex-determining genes, in a very related species of economic importance, B. oleae. We have isolated by PCR and RT-PCR, using the appropriate synthetic oligonucleotides, three gene fragments. Two of them, after subcloning and sequencing, were found to be homologous to the double-sex gene, while the third, is homologous to the sex-lethal. One embryonic and two adult cDNA libraries, a male specific and a female specific are under construction for the purpose of the isolation of the complete cDNA clones corresponding to these genes.

[2238] IDENTIFICATION OF *TRICHOGRAMMA* BASED ON THE SEQUENCE OF THE ITS2 REGION OF THE rDNA, WITH A NEW RECORD FROM RRAZIL

<u>A. LCiociola Jr¹</u>, R. B. Querino¹, R.A. Zucchi¹ & R. Stouthamer ², Departmento de Entomologia, Fitopatologia e Zoologia Agrícola. Caixa Postal 9, CEP:13.418-900, ESALQ/USP, Piracicaba-SP, Brazil. E-mail: ciociola@carpa. ciagri.usp.br;
 ²Department of Plant Sciences, Laboratory of Entomology, Wageningen-UR Centre, P.O Box 8031, 6700EH Wageningen, The Netherlands.

Historically the identification of *Trichogramma* has been very difficult. Specialists after 1970, used the male genitalia to identify different species, which was a major improvement in the identification of these minute wasps. However, the preparation for correct identification is time consuming. For a quick and routine identification of *Trichogramma* species we used a new molecular technique. The sequence of the ITS2 (internal transcribed spacer 2) region of the rDNA is useful to distinguish between some species from Brazil. Using the sequence of this region together with taxonomic identification is that it's quick and with some lab routine we can use it without problems. The specific primers used for *Trichogramma* spp. in this study amplified the DNA of 5 of the Brazilian recorded species of *Trichogramma*. This technique can also be used to check possible contaminations in lab rearings. Based on this technique we are discussing a new record of *Trichogramma* species in Brazil. Index terms: Trichogrammatidae, molecular technique, biological control.

[2239] RIBOSOMAL DNA VARIATION IN NATURAL POPULATIONS OF DICHROPLUS ELONGATUS (ORTHOPTERA: ACRIDIDAE)

M. Clemente, <u>M. I. Remis</u> & J. C.Vilardi, Lab. Genética de Poblaciones, Depto. Cs. Biológicas, Fac. Cs. Exactas y Naturales, Pabellón II, Ciudad Universitaria, Buenos Aires, 1428, Argentina. E-mail: mariar@bg.fcen.uba.ar.

Dichroplus elongatus is a phytophagous South American grasshopper widely distributed in Argentina which exhibits parallel polymorphisms for B chromosome and supernumerary segments. In the last years, the analysis of restriction fragment length polymorphisms (RFLP) of mitochondrial DNA (mtDNA) showed that the distribution patterns of haplotipic variation in chromosomally polymorphic populations may be explained by ecogeographic factors. In the present work, we reported a RFLP analysis of ribosomal DNA (rDNA) variation in the same populations. In this study we analyzed the genetic relationship among populations and the relative importance of different evolutionary forces and concerted evolution in the genetic differentiation of an intergenic spacer region (IGS). The study involved 156 individuals from 13 populations of *D. elongatus* belonging to three biogeographic provinces from Argentina (Las Yungas, El Espinal and Pampeana) were analyzed. The 0.8kb cloned sequence from a 26s intergenic spacer region from the Caledia captiva rDNA was used as probe. A total of 21 restriction fragments were obtained by simple digestion with five enzymes (BamHI, EcoRI, Pstl, HindIII and XbaI). All the enzymes but BamHI exhibit intra and interpopulation variation. The average number of length variants produced per individual was from 13.8 to 8.6. The populations of "Las Yungas" exhibited the higher value of average number of variants per individual (11.6) in comparison with Espinal (10.1) and Pampeana (9.6) provinces. The intra and interpopulation variation was analyzed by two distance indices: i) Lynch (1990), based on presence and absence of bands, and ii) Hedrich (1983) that takes into account differences in band intensities. The highest values of intraindividual and intrapopulation variability were observed in populations of Las Yungas. The Neighbor-Joining trees based on Lynch and Hedick distances were very similar showing high genetic distance between the two northwestern populations of Las Yungas. Both populations are also highly differentiated from the remaining ones. Regression analysis of band frequencies on geographic and climatic variables employing the stepwise selection procedure revealed that the average number of length variants produced per individual is significantly associated with altitude and the frequency of some restriction variants show a significant regression on altitude and temperature. The high level of intraindividual, intra and interpopulation variation would imply that concerted evolution are not efficient in this species. The disagreement between rDNA and mtDNA distribution patterns, suggests that adaptive factors may affect the rDNA variation limiting the effects of stochastic factors.

[2240] SEXUAL SELECTION ON MORPHOMETRIC AND CHROMOSOME VARIABLES IN *LEPTYSMA ARGENTINA* (ORTHOPTERA)

P. C. Colombo, S. M. Pensel & <u>M. I. Remis</u>, Depto Cs. Biologicas, Fac. Cs. Exactas y Naturales, Universidad de Buenos Aires, 1428 Buenos Aires, Argentina, E-mail: mariar@bg.fcen.uba.ar.

The South-American species Leptysma argentina carries a polymorphism for a centric fusion between chromosomal pairs 3 and 6 of the basic complement (fusion 3/6) that has been found throughout most of the species' distribution area. Simultaneous cytogenetic and morphological studies revealed that fusion 3/6 significantly increases morphometric variables in males. A study of selection components showed that the fusion is positively selected for longevity, the actual target being a morphometric variable, namely thorax height. In the present study both the effect of fusion on morphometrical variables in females as well as the effect of body size and karyotype on mating success in both sexes were analysed. The experimental design consisted in placing a number of wild caught males and females (usually 10 of each) in mating cages during a period of time; when a match was formed they were taken out and assigned absolute fitness 1, and the other individuals were assigned fitness 0. Cytological preparations were made by squashing some testicular follicles (in males) or gastric caeca (in females) in acetic haematoxylin. Both males and females were measured with a binocular microscope for length from the fastigium to the third coxa (L), third femur length (FL), third tibia length (TiL), thorax length (TxL), thorax height (TH) and total length (TL). First, exomorphological effects of the fusion in females were examined. The MANOVA and individual ANOVAs revealed that there were significant differences between karyotypes for FL, TiL, TxL and TL. The influence of the fusion in females, as had been detected for males, leads to a significant and additive increase in body size. Secondly, the morphometric variables and the fusion were examined with respect to their effect on male choice selection. The analysis of standardised selection differentials (S') -assessed through the correlation of each trait along with relative fitness- showed that directional selection operated significantly and positively on FL. TiL, TxL, TxH and TL. The analysis of the selection gradient (D') -which estimates direct and indirect effects of directional selection- showed a significant effect of selection on FL, TxL and TL. Our results indicate therefore that the differences in those traits have the greatest contribution to fitness variation in males, the selective effects on the other morphometric traits being indirect ones. Thirdly, a similar analysis of mating success in females revealed only indirect effects for TxL and TL. In conclusion, it can be said that differences in some body size related traits could be due to the karyotype both in males and in females, and that FL, TxL and TL were detected as targets of sexual selection in males.

[2241] ORIGIN AND DISPERSAL OF THE COTTON BOLL WEEVIL (COLEOPTERA: CURCULIONIDAE) IN SOUTH AMERICA: A miDNA PHYLOGEOGRAPHIC STUDY

V. A. Confalonieri¹, M. A. Scataglini¹ & <u>A. A. Lanteri²</u>, ¹Dep. Cs. Biol., Fac. Cs. Exactas y Naturales, Univ. de Bs. As., Ciudad Universitaria, 1428 Buenos Aires, Argentina; ²Dep. Cient. Entomol., Museo de la Plata, UNLP, 1900 La Plata, Argentina.

The boll weevil Anthonomus grandis Boheman, is the most harmful insect pest of cotton in America. Since its first report damaging that culture, there have been considerable efforts to address the question of its place of origin, original hosts and pathways of dispersal. Most authors proposed that the boll weevil was indigenous to tropical lowlands of Mexico, and reached its present distribution by extending its range northward, to Southern United States, and southward, to Brazil, Paraguay and Argentina. The hypothesis of north american dispersal is well supported by data on host plants and geographic variation of morphological characters, and would have taken place, in both, prehistoric and historic times. On the contrary, the presence of would have taken place, in boar, premisions and mistoric times. On the contrary, the presence of the boll weevil in South America would be associated to cotton cultivation, and the insect would have been introduced from Southeastern USA. Our results of RAPD's analyses on populations from Argentina, Brazil and Paraguay, compared with samples from the USA and Mexico, made us to proposed that some south american populations from none cultivated areas, are more related to mexican samples than to those on cotton cultures from its own geographic region. The main goal of the present contribution is to test the hypothesis on the origin of South American boll weevil populations, by means of a phylogeographic analysis using sequences of the mitochondrial gene Cytochrome Oxidase I (COI). We analyzed 30 individuals of five natural populations from Tecomán (Colima, Mexico), Lubbock (Texas, USA), Londrina (Paraná, Brazil), Caacupé (Cordillera, Paraguay), and Puerto Iguazi (Misiones, Argentina). All samples were collected on cotton cultures, except the latter, occurring on native plants. COI sequences correspond to bp 1720-2020 (numbers according to *Drosophila yakuba*) and were aligned using CLUSTAL W 1.6. The genetic relationships of the 17 haplotypes found, were inferred by cladistic analysis, using exhaustive search of PAUP 4.0 (Beta 4a). Tecomfan and Pto. Iguazd display the highest number of haplotypes and sequence divergence, typical of boll weevils from cotton areas of Brazil and Paraguay were introduced from USA. On the other hand, weevils collected on native plants from Pto. Iguazá would correspond to an ancestral population, established prior to cotton cultivation. Index terms: Cytochrome Oxidase I, DNA Sequencing, Anthonomus grandis.

[2242] CHARACTERIZATION OF MOLECULAR MARKERS ON CHRYSOMYA ALBICEPS BY PCR-RFLP OF MITOCHONDRIAL DNA

F. F. Conte, A. C. Lessinger, A. C. M. Junqueira & A. M. L. Azeredo-Espin, Lab. Genética Animal, DGE/CBMEG, Univ. Estadual de Campinas, P.O. Box 6010, Campinas, SP, Brasil, CEP 13083-970. E-mail: azeredo@unicamp.br. Financial support: Fapesp, Capes, PADCT-CNPq.

The species Chrysomya albiceps, one of the most abundant and economically important blowfly from Africa, was probably introduced into Brazil around 1975 with refugees from Angola and Moçambique. The adults of C. albiceps feed and breed in carrion, feces, urban garbage and carcasses and have a medical-veterinary importance due to its synanthropic and endophilic behavior, acting as potentially important mechanical vector of pathogens. C. albiceps, such as Chrysomya putoria and Chrysomya megacephala, is an effective competitor and has a considerable autonomous dispersal ability that could be causing the displacement of the Brazilian native populations of blowflies that share the same ecological niche. Due to these characteristics the study of C. albiceps evolutionary dinamics is a very important subject. The analysis of specific regions of the mitochondrial DNA (mtDNA) provides an efficient approach in order to identify informative molecular markers for evolutionary studies. The aim of this work is to characterize the mtDNA of C. albiceps using the PCR-RFLP technique. The specific mDNA regions analyzed were the control region (A+T rich region) and the subunits I and II of the cytochrome oxidase c (COI/II). The amplification of COI/II region and the control region resulted in 2200 bp and 320 bp PCR products, respectively. Preliminary results for COI/II region using EcoRI and Sau3AI have shown two restriction sites for Sau3AI (fragments with 1000bp, 600bp and 500bp). The A+T rich region was digested with DraI and SspI, resulting in the identification of one site for SspI that provides the 180 bp and 110 bp restriction fragments. The importance of this work concern the characterization of diagnostic molecular markers useful for species-specific identification of C. albiceps, improving the analysis of forensic fauna, contributing in the resolution of taxonomic conflicts with Chrysomya rufifacies, and for understanding the evolutionary context of introduction.

Index terms: Chrysomya albiceps, blowflies, mtDNA, PCR-RFLP, molecular markers.

[2243] THE IDENTIFICATION OF TRANSPOSABLE ELEMENTS IN THE GENOME OF THE MALARIA VECTOR, ANOPHELES GAMBIAE

J. M. Crampton^{1,2}, R. J. Parkes¹, J. M. Kirk¹ & A. M. Warren¹, 'Liverpool School of Tropical Medicine, Pembroke Place, Liverpool, L3 5QA, UK. ²School of Biological Sciences, Univ of Liverpool, Crown St., Liverpool, L69 7ZB, UK.

The focus of our research is to identify endogenous transposable elements in mosquito vector genomes, with a particular emphasis on the major malaria vector Anopheles gambiae. Our interest in these elements is twofold. First, we are interested in their potential as DNA vectors for the genome manipulation of this insect. Second, such elements represent a potentially important source of genetic variation in these insects, which will have relevance to their evolution and their ability to act as vectors of malaria. We have used a PCR based approach to identify and characterise two classes of transposable element in *An. gambiae*. The first is *Salto*, a *Ty-copia* element closely related to copia and 1731 from D. melanogaster. The element is actively transcribed, and present in variable copy number and location in An.gambiae strains. The second element is Frisky, a Tc1-like element. This transposable element is bounded by 27bp inverted terminal repeats and has a single open reading frame with the potential to encode a 331 amino acid protein showing similarity to other Tc1-like transposases. It is present in low copy number in a number of species within the An. gambiae species complex. The structural features of both elements will be described and discussed in the context of the evolution of such elements and their potential as DNA vectors for genome manipulation.

index terms: Ty-copia transposable elements; Tc1 transposable elements; genome manipulation

[2244] EXPRESSION OF PAIRED GROUP III GENES AND THE EVOLUTION OF SEGMENTATION

G. K. Davis¹, C. A. Jaramillo¹, & N. H. Patel^{1,2}, Committee on Developmental Biology, ²HHMI and Dept. of Organismal Biology and Anatomy, University of Chicago, 5841 S. Maryland Ave. MC1028, IL 60637, USA., E-mail npatel@midway.uchicago.edu

The Drosophila Pax genes paired, gooseberry, and gooseberry-neuro encode a family of transcription factors, each containing both a DNA-binding paired domain and a paired-type homeodomain. paired acts as one of several pair-rule genes to define the boundaries of future segments via the activation of segment polarity genes, including gooseberry. gooseberry-neuro is a gene of yet undefined function expressed later in the developing nervous system. The protein products of these genes are both similar in sequence and functionally equivalent, as the coding regions have been shown to be functionally interchangeable between the different cisregulatory regions (Xue and Noll, EMBO, 15, 3722-3731, 1996). Because of their importance in segmentation and the potential for using these genes to address questions regarding the evolution of pair-rule function and the homology of segmentation, we have begun to study the expression of these genes in several insects, including the grasshopper, Schistocerca americana, and the beetle, Tribolium castaneum. We have used degenerate PCR to clone members of this family from Schistocerca, and have developed a cross-reactive antisera to study expression in a number of different arthropods. We will present expression data from a number of animals and discuss the implication of these results for understanding the evolution of segmentation.

Index terms: Drosophila melanogaster, Tribolium castaneum, Schistocerca americana, paired, gooseberry.

[2245] ABSENCE OF GENIC VARIABILITY FOR SIX ENZYME SYSTEMS IN MYCETOPHYLAX SP. (HYMENOPTERA, FORMICIDAE)

<u>E. Dichl-Fleig</u> & Ed. Dichl-Fleig, Lab. de Genética: Setor de Insetos Sociais, C.C. da Saúde, Univ. do Vale do Rio dos Sinos. C.P. 275 São Leopoldo 93001-970 RS – Brasil, E-mail: ediehl@cirrus.unisinos.br.

The tribe Attini, which belongs to the subfamily Myrmicinae, is restricted to the Americas comprising thirteen genera of fungus grower ants. Amongst those Atta and Acromyrmex are noticeable for their phylogenetic position as the higher attine and for being recognized as serious economic pest. Mycetophylax, another attine genus, in turn is included among the lower attines using plant material in decomposition, insect remains and excrements as substratum for growing its fungus. It is mainly found in sandy areas of low vegetation such as the north seacoast of Rio Grande do Sul state. As part of a greater project which aims at describing the isoenzyme genic variability and the social structure of the attines, workers (153), gynes (32) and queens (10) from 39 Mycetophylax sp. colonies were all analyzed for the enzyme systems Malate dehydrogenase (MDH) and Superoxid dismutase (SOD). From those same colonies, 18 were analyzed for α -Glycerophosphate dehydrogenase (α -GPDH) and 19 for Aldehyde oxidase (AO), Alcohol dehydrogenase (ADH) and Octanol dehydrogenase (ODH). To analyze α -GPDH, ADH and ODH 6% polyacrylamide gels were used with Roose & Gottlieb (1976) buffers; for AO, MDH e SOD, 8% polyacrylamide gels with Poulik (1957) buffers. Enzymes were run at 4°C, at 10 V/cm until the front line reached 8 cm from the application point. Staining techniques followed Ayala et al. (1972) for AO, ADH, ODH, α-GPDH and MDH; white light was used for SOD. All six systems showed to be monomorphic, excluding the possibilities to determine the colony mating structure. In one of the 39 evaluated colonies, two queens were found which indicates that polygyny may be true for Mycetophylax sp. This data differ from what is known for Atta and Acromymnex which present isoenzyme polymorphism, especially for the systems α -GPDH and MDH, besides the high frequency of polygynic colonies of Acroinymex. Both the isoenzyme analyses and the bioecological studies shall be extended to other Attini genera giving support for a phylogenetic analysis of this tribe.

Index terms: Myrmicinae, Attini, isoenzyme polymorphism, mating structure

[2246] THE EVOLUTION OF HOST PLANT BREADTH IN DIABROTICITES (COLEOPTERA : CHRYSOMELIDAE)

A. Eben & A. Espinosa de los Monteros, Instituto de Ecología, A.C., Km 2.5 Antigua carretera a Coatepec, 91000 Xalapa, Veracruz, Mexico, E-mail: astrid@ecologia.edu.mx

Specialization toward a limited range of host plants has been viewed as evolutionary dead end in herbivorous insects. Beetles of the subtribe Diabroticites (Chrysomelidae : Galerucinae) are found to have a variable number of host plants. Several species are oligophagous on Cucurbitaceae or Graminaceae, whereas others are polyphagous. The association of Diabroticites with bitter Cucurbitaceae was interpreted as an example for chemically mediated plant-insect coevolution. This hypothesis is based on experiments with a limited number of species distributed in the USA, where they were introduced from Mexico and Mesoamerica together with corn and squash. We recovered a maximum parsimony phylogeny of 19 Mexican Diabroticite species from 6 different genera based on 472 bp of COI and 45 external Our results corroborate the current taxonomical morphological characters. arrangement. The evolutionary scenario depicted from this phylogeny allows to conclude that the genus Acalymma speciated after the specialization of ancestral Diabroticites on Cucurbitaceae. An ancestor which was specialized on Cucurbitaceae gave rise to the polyphagous genus *Diabrotica*. Within this genus, the basal species have a host range from polyphagous to narrow, feeding on Graminaceae, Leguminosae or a few other families. The species in the virgifera group have a host plant range restricted to Graminaceae. Nevertheless, all species feed on bitter cucurbits in the wild. Our data corroborate the hypothesis, that the kairomonal response to secondary compounds in Cucurbitaceae is a relic of the ancestral host plant association. Furthermore, specialization is not a dead end in the evolution of Diabroticites. Instead, host plant range became restricted and broadened several times within the evolution of the subtribe.

Index terms: Acalymma, Amphelasma, Diabrotica, Gynandrobrotica, Paratriarius

[2247] RAPID GENOME SHUFFLING BY TRANSPOSABLE ELEMENTS: WHAT CAN WE LEARN FROM CULEX PIPIENS MOSQUITOES?

<u>C. Feschotte</u>, C. Cagnon, I. Desmons, S. Karama & C. Mouchès, Laboratoire Ecologie Moléculaire, Université de Pau, BP 1155, 64 013 PAU, France, E-mail: cedric.feschotte@univ-pau.fr.

The genome of C. pipiens is larger than those of some more extensively studied diptera, such as Drosophila or Anopheline mosquitoes. This difference is due to higher amount of repetitive DNA, which is organized in a short interspersion pattern. However, little is known about the molecular processes involved in the shaping of the C. pipiens genome. The only sizeable genomic data available for C. pipiens was the previous characterization of a DNA region (25-kb) which is amplified in an organophosphate insecticide resistant population. This region contains the esterase B1 gene (2.8-kb) and also a high density of transposable elements (TEs) in its flanking regions. As TEs make up most of the dispersed fraction of the repetitive DNA, our working hypothesis is that TE amplification and mobility can promote rapid and extensive reshuffling of the C. pipiens genome. Two families of elements, Juan and CM-gag, were first characterized. Both are found in high copy number in the C. pipiens genome and were recently amplified by retroposition, a process which was already shown to play a major role in the evolution and plasticity of vertebrate genomes. Recently, we have cloned a 15-kb region encompassing the white gene of C. pipiens and found that insertions of various and numerous TEs have occurred in introns 1 and 2, leading to a spectacular enlargement of these regions compared to the Drosophila and Anopheline homologues. Some of these TEs belong to large families of retroelements (LINEs and SINEs) whereas others are non-autonomous elements with inverted-repeats that share structural similarity to MITEs, a novel class of ubiquitous and highly abundant elements in plant genomes. Culex MITEs are found in high copy-number and some families have a recent amplification history (1). Despite evidence for recent mobility of these MITEs, no element has been found to encode a protein; therefore, we do not know how they have transposed and have spread in the genome. Structural analysis indicate that some of these mosquito MITEs may have originated from pogo-like DNA transposons, as it was previously demonstrated for a plant MITE family (2). [2248] ECOLOGICAL FACTORS VERSUS MACRO-EVOLUTIONARY FORCES: A CASE STUDY OF THE BUTTERFLIES OF THE GENUS ACTINOTE (LEPIDOPTERA: NYMPHALIDAE) IN SOUTHEASTERN BAZIL

R.B.Francini, Museu de História Natural, FAFIS, Univ. Católica de Santos, Rua Euclides da Cunha, 247, 11065-902, Santos, SP, Brasil, E-Mail francini@unisantos.com.br, Financial support: BIOTA-SP (FAPESP)

The data from a phylogenetic analysis of 58 characters of the larvae and imagines of 17 species of *Actinote*, using *A.manita* as the functional out-group was compared with 46 ecological and ethological characters. The plant genus *Mikania* was the most used as larval food plant (with 14 species used by *Actinote*) followed by *Eupatorium; Trichogonia*, Erigeron, and Senecio contributed only one species each. Nearly all Actinote species used Engreta, and seneric contributed only one species each. Nearly an Activity species used only one genus of larval food plant, but the species with wide geographic distribution can use more than 3 genera. Many of these plants are more widespread than the Activities species that use them. Most of the hostplants are common in secondary successional environments, but a few grow inside the forest or in swamps. Some species in the genus Actinote are useful as ecological indicators but in a limited fashion. A.zikani indicates environments with constant water supply (rain, fog, or swamp areas). Another two species, *Actinote* ca. *terpsinoe* and *A.morio*, indicate environments with greater water deficit and lower precipitation, including savanna (Cerrado) and semi-deciduous montane forest. Based on MRR data of *A. pellenea pellenea* (Parque Estadual Xixová-Japui, São Vicente, SP) and *A. zikani* (Paranapiacaba, Sto. André, SP), a potential "explosive" capacity was showed, allowing that even the rarest species in areas of variable relief and unstable appear to be the demographic pattern of all Actinote populations. These include populations occupying relatively small areas (usually less than 1 ha) and characterized by a rapid initial growth of adult numbers (usually < 10 days). The assemblages in high (between 1200-2000 m) and cold (mean annual temperature < 18° C, with possibility of frost) areas have short adult generations (usually < 20 days) with a larger peak in the summer (December, when all the univoltine species are on the wing), and another small peak in autumn (April-May). In these places, the species populations of the orange-red and black-iridescent mimetic groups are residents (based on at least 3 years of observations) while the species of the other mimetic groups appear only in lower density, represented usually by solitary females. Because all *Actinote* species are considered unpalatable (they are cyanogenic), these taxocenes condition the learning patterns of potential butterfly predators. The population features combined with the slow larval development of most species, suggest that *Actinote* have a demographic pattern resembling that of butterflies of the temperate regions.

Index terms: food-plants, explosive populations, demographic patterns

[2249]PHYLOGENETIC RELATIONSHIP AMONG STINGLESS BEE SPECIES INFERRED BY MITOCHONDRIAL DNA RESTRICTION FRAGMENT LENGTH POLYMORPHISM

F. O. Francisco, R. Weinlich, D. Silvestre, D. R. Cunha & <u>M. C. Arias</u>, Dept. de Biologia, Inst. de Biociências, Univ. de São Paulo, Caixa Postal 11461, São Paulo, SP, 05422-970, Brasil, E-mail: Igea@ib.usp.br.

The systematic and phylogenetic relationship among stingless bees is still a controversial subject. Only few phylogenetic studies have been published and are based on morphological characters. Molecular techniques have been recently used trying to solve phylogenetic and population dynamics questions of several organisms. The mitochondrial DNA (mtDNA) is one of the most used molecular tools and its analysis has already proved its potential to solve genetic and phylogenetic issues among species and subspecies of Apis. One characteristic of the mtDNA is to have, in the same molecule, some conserved regions and others that accumulate rapidly base substitutions. The RFLP (Restriction Fragment Length Polymorphism) technique allows to approach this molecule as a whole, including the variable and conserved regions. Thus, in the present work we used RFLP technique to analyze the mtDNA of five species of Plebeia, six of Melipona and one of Schwarziana; Apis mellifera was used as outgroup. The mtDNA of these species was extracted and then digested with seventeen restriction enzymes. Using the results of single and double digestions, restriction maps were constructed. This was a crucial step to be assured that we were comparing the same sites, according to their positions. Approximately twenty restriction sites per species were located and as a result of these comparisons a binary matrix was built. The genetic distances between pairs of species were calculated. As expected, the distances among species of the same genus were smaller than the ones among species of different genera. The binary matrix was also used to infer phylogenetic relationship by using the softwares PAUP Star (version 4.0b3) and RESTSITE (version 1.1). Trees were generated by parsimony and genetic distance methods. The results of this work revealed the potential of mtDNA RFLP analysis to infer the relationship among stingless bee species. The inclusion of other species of these genera will undoubtedly strengthen the phylogenetic relations of this group and improve our comprehension about its evolution and biogeography. Index terms: Meliponinae, phylogeny, RFLP, mtDNA, evolution

[2250] MITOCHONDRIAL DNA SEQUENCES OF TRIATOMINAE (HEMIPTERA: REDUVIDAE): PHYLOGENETIC RELATIONSHIPS

<u>B. A. García¹</u>, E. N. Moriyama² & J. R. Powell², ¹Cátedra de Química Biológica, Facultad de Ciencias Médicas, Universidad Nacional de Córdoba, C.C. 35, Suc. 16, 5016 Córdoba, Argentina, E-mail: bgarcía@biomed.uncor.edu; ²Department of Ecology and Evolutionary Biology, Yale University, New Haven, Connecticut 06520-8106, USA.

The phylogenetic relationships among fifteen species of the genus *Triatoma* were inferred based on the mitochondrial DNA sequences. The species included eleven belonging to the infestans complex (T. infestans, T. guasayana, T. sordida, T. platensis, T. brasiliensis, T. rubrovaria, T. vitticeps, T. delpontei, T. maculata, T. patagonica, and T. matogrossensis) and other four of the same genus but of different complexes (T. circummaculata, T. protracta, T. dimidiata, and T. mazzottii). We also used three species of other genera as possible outgroups (Mepraia spinolai, Panstrongylus megistus, and Rhodnius prolixus). We have sequenced both strands of mtDNA fragments of the 12S and 16S ribosomal RNA genes (342 and 509 bp, respectively) from each of the eighteen species, and of the cytochrome oxidase I (COI) protein coding gene (1,447 bp) from nine of the species studied. The sequences were obtained from two individuals per species in all cases. Interspecific distances (maximum likelihood, Felsenstein 1981) varied from 0.00 to 18.79% for 12S, 0.20 to 21,95% for 16S, and 0.30 to 20.60% for COI. Phylogenetic trees were inferred from aligned sequences by the neighbor-joining (Saitou & Nei 1987) and maximum parsimony (Swofford 1993) methods. The 12S, 16S, and COI gene sequences were studied individually, and combined as follows: 12S+16S, and 12S+16S+COI. All the phylogenetic trees inferred from the molecular sequence data had a cluster of *T. infestans, T. platensis*, and *T. delpontei* supported by high bootstrap values, as well as *T. sordida* with *T. matogrossensis*. Other well supported nodes, in the trees obtained from both combined data sets, are those clustering: (i) T. guasayana, T. circummaculata, T. rubrovaria, and T. patagonica, (ii) the ((infestansplatensis) delpontei) clade and the other species of Triatoma analyzed (except T. vitticeps, T. dimidiata, T. mazzottii, and T. protracta), (iii) T. vitticeps as the sister taxon of the clade that contains all the other species belonging to the infestans complex studied plus T. circummaculata, and (iiii) T. dimidiata and T. mazzottii. Index terms: Phylogeny, 12S, 16S, cytochrome oxidase I.

[2251] CYTOGENETIC STUDIES OF POLYTENE CHROMOSOMES IN THE TSETSE FLIES GLOSSINA AUSTENI AND GLOSSINA PALLIDIPES

A. Gariou-Papalexiou, G. Yannopoulos & <u>A. Zacharopoulou</u>, Dept. of Biology, Division of Genetics, Cell and Developmental Biology, University of Patras, Greece. E-mail: zacharop@upatras.gr. *This work is being supported by FAO/IAEA Joint*.

Polytene chromosome analysis has application both to formal and population genetics. In many insect vectors of diseases the analysis of polytene chromosomes has provided the key tool to unravel many important epidemiological and speciesrelated questions, particularly mapping and isolating of any endogenous gene(s) involved in their vectoring capacity. In addition, polytene chromosomes have been proved essential for elucidating phylogenetic relationships among taxa, based on their chromosome structure. Polytene chromosomes in two tsetse species, Glossina austeni and Glossina pallidipes have been analysed and chromosome maps have been constructed, with the aid of Photoshop software package. The three long polytene elements, representing the X and the two autosomes, L1 and L2, were numbered into 100 divisions. In accordance with the system in Drosophila, the divisions were numbered from the telomere of the left arm of the X chromosome to the telomere of the right arm of L2. Characteristic features of each chromosome are described. Chromosomal homology between G. austeni and G. pallidipes has been determined by comparing chromosome banding pattern. Extensive similarities exist, especially in the tips of the chromosomes, indicating that they must share a common ancestor. In addition numerous chromosome rearrangements have been observed which should have occurred since the separation of the two species. Furthermore, in situ hybridization technique, which allows the accurate localization of any cloned DNA sequence, has been applied on tsetse polytene chromosomes. Several cloned tsetse genes provided to us, have been tested by in situ and their cytological position will be given

[2252] A NOVEL GENE UP-REGULATED DURING RECOVERY FROM COLD-SHOCK IN DROSOPHILA

S. G. Goto, C. O. Masahito & T. Kimura, Graduate School of Environmental Earth Science, Hokkaido University, Sapporo, Hokkaido 060-0810, JAPAN, E-mail goto@ees.hokudai.ac.jp

Cold tolerance has been extensively studied in insects mainly focusing on accumulation of cryoprotectants and maintenance of the fluidity of cellular membranes. However, the mechanisms of cold tolerance still remain unclear in Drosophila. Recently, expression of stress proteins has been received attention as a mechanism to rescue proteins or cells from cold injury. However, our previous results showed that the relation between the expression of *HSP70* mRNA and cold tolerance was not so rigid in some *Drosophila* species. Here I report an attempt to find genes that are specifically expressed after cold-shock in *Drosophila melanogaster* using subtraction and differential screening techniques. Experimental flies were reared at 25 °C (continuous light) from the egg stage to the 7-day adult stage, exposed to cold (0 °C) for 8 h, and thereafter allowed to recover at 25 °C for 2 h. mRNA was extracted from these flies and then subjected to subtraction and differential screening using mRNA extracted from flies without cold treatment as a control. As a result, four gene fragments were obtained. By Northern hybridization, at least a gene was shown to be considerably up-regulated at the transcription level during recovery from cold-shock. cDNA of this gene was 1,151 bp in length with an ORF of 834 bp, which encodes 278 amino acids. The nucleotide and amino acid sequences shared low homology to other genes and proteins so far known. The molecular weight of the deduced polypeptide was 29.4 kDa and the estimated p/ was 3.85. The protein had several motifs concerning post-translational modification. In addition, a proline rich region that has been reported to be involved in protein-protein interactions was also observed. Moreover, there was a signal peptide in N-terminus and therefore the protein would be secret to the extracellular fluid or hemolymph. We will discuss the function of the gene in relation to the acquisition of cold tolerance.

Index terms: Drosophila melanogaster, cold-shock, cold tolerance, subtraction, differential screening.

[2253] POSSIBILITIES OF HOST ADAPTATION IN THE CABBAGE APHID, *BREVICORYNE BRASSICAE*

E.C. Greatorex & <u>G.M. Tatchell</u>, Entomological Sciences Dept., Horticulture Research International, Wellesbourne, Warwick, CV35 9EF, UK, E-mail mark.tatchell@hri.ac.uk

Adaptation to host plant species has been reported widely in phytophagous insects. However, the extent to which these adaptations are due to the genetics of the herbivore and its genetic environment (i.e. the plant genotype) or are a response to true environmental effects (i.e. seasonal weather effects on both herbivore and plant) require elucidation. The Brassicaceae and Brevicoryne brassicae system was selected as a model system to test the hypothesis that adaptation to heterogeneity in their environment in asexually reproducing plant herbivores is driven by host plant diversity. Closely related Brassica crop plant species, with similar morphology but different genome organisations, were planted in replicated plots at two locations in the UK shortly before colonisation by B. brassicae would be expected. Samples of B. brassicae were collected from each plant genotype at intervals throughout the growing season and individuals were genotyped using a suite of microsatellite markers to determine the variation in the population due to abiotic environmental factors. Correlations between the presence of particular aphid genotypes and particular host plants were investigated to determine whether there are host plant adapted genotypes of aphid. Potentially host-adapted clones of B. brassicae were established from the different plant genotypes at the end of the season and were genotyped. These clones were used in controlled laboratory experiments in which they were switched between plant genotypes to determine the relative intrinsic rate of increase, r_m , a measure of their fitness. These experiments have determined the effect of host plant genotype on the herbivore and support the findings from the field experiments. The implications of these findings to the deployment of plant varieties resistant to insects, either through genetic modification or conventional breeding, are discussed.

Index terms: Aphididae, microsatellites, Brassicaceae, genotype

[2254]CYTOTAXONOMY AND HOMOSEQUENTIAL SPECIES OF THE Simulium perflavum SPECIES GROUP (DIPTERA: SIMULIIDAE) FROM BRAZIL AND VENEZUELA

N. Hamada¹, P. H. Adler² & M. E. Grillet³, ¹Inst. Nac. Pesquisas da Amazônia/CPEN, Caixa Postal 478, 69011-970 Manaus, AM, Brazil, E-mail nhannada@inpa.gov.br.; ²Clemson Univ., Dept. of Entomology, Clemson, SC, 29634 USA; ³Inst. Zoología Tropical, Univ. Central de Venezuela; Ap. 47058, Caracas 1041-A,Venezuela.

The Simulium perflavum species group includes Simulium maroniense, Simulium rorotaense, Simulium kabanayense, Simulium suarezi, Simulium trombetense, Simulium perflavum and Simulium ignacioi. The objective of this study is to examine cytologically all of the known species in the S. perflavum species group, to provide new information on geographical distribution, and to re-evaluate at the cytological and morphological levels the specific status of S. ignacioi, which was formerly considered synonymous with S. rorotaense. The black fly specimens were collected in Brazil and Venezuela. In Venezuela, the species S. maroniense, S. suarezi, S. kabanayense and S. ignacioi were collected in Bolivar state (Oct. 1996, Feb. 1998, Oct. 1998), and S. maroniense was collected in Amazonas state (Oct. 1996). In Brazil, the species S. trombetense was collected (Oct. 1998) in one stream in Serra do Cachimbo, state of Pará; S. rorotaense was collected (Aug. 1998) in Oriximiná County, Pará state and Apuí County (July 1998), Amazonas state, and S. maroniense was collected in Apui County, southern portion of Amazonas state, (July 1998) and in São Gabriel da Cachoeira County, northern portion of Amazonas state, (Nov. 1998, Nov. 1999). Larvae were fixed in Carnoy fixative and larval chromosomes were stained using the Feulgen process. The species in this species group have few polymorphisms, the most polymorphic species being S. maroniense. Simulium rorotaense, S. kabanayense and S. suarezi are chromossomally homosequential, although they can be distinguished by conventional morphological characters, such as gill filament number and shape. Simulium ignacioi has a fixed inversion on chromosome arm IIL that distinguishes it from S. rorotaense, besides the fact that it has a lower number of gill filaments (mean number = 16) than S. rorotaense (mean number = 20). Chromosomal rearrangements, such as inversions, are believed to be important in the speciation of black flies; however, because three species in the S. perflavum group are homosequential, rearrangements appear not to have been a driving force in speciation for some members of this species group.

[2255] HOST GENETICS AND THE CONTROL OF LIFE HISTORY TRAITS IN THE YELLOW FEVER MOSQUITO AEDES AEGYPTT INFECTED WITH NOSEMA ALGERAE MICROSPORIDIA

M. H. H. Hansen¹ & J. C. Koella², ¹Dep. of Zoology, Univ. of Aarhus, Universitetsparken B135, DK-8000 Aarhus C, Denmark; ²Laboratoire d'Ecologie, Univ. Pierre & Marie Curie, CC237, 7 Quai St. Bernard, 75252 Paris Cedex 5, France.

Virulence, defined as a parasite mediated reduction in host fitness, results from changes in the host life history caused by the parasite. Thus, understanding how parasites affect host life history is crucial to understanding the evolution of virulence. The phenotypic characters of hosts infected by parasites may be viewed as extended phenotypes influenced by both host and parasite genes. Since host life history affects the lifetime reproductive success of both host and parasite, conflicting selection pressures acting on the two genotypes will lead to a coevolutionary conflict of interests over the control of host traits. The ecology and life histories of both host and parasite influence the outcome of this conflict. Using the yellow fever mosquito Aedes aegypti and its microsporidian parasite Nosema algerae, we investigated the genetic basis of host control of life history traits. We compared groups of infected and uninfected half-sibs, performing a quantitative genetic analysis of traits of importance to both host and parasite life history. Furthermore, we investigated the effect of demographic and environmental factors on correlated host life history traits in infected versus uninfected hosts, providing an impression of the interacting selective forces operating in this host-parasite system.

[2256] EXPLORING THE MITOCHONDRIAL GENOME OF ANASTREPHA SUSPENSA

M.A. Heath, R.J. Schnell & Cecile Olano, USDA, ARS, SHRS, 13601 Old Cutler Rd., Miami, FL 33157, USA.

DNA sequences from the mitochondrial genome of Anastrepha suspensa for regions of the cytochrome c oxidase I, II and III genes, the large-subunit rRNA gene, the small-subunit rRNA gene, the cytochrome B gene, the tRNA leucine 2 gene, the tRNA lysine gene, and the NADH dehydrogenase subunit I gene have been obtained. These sequences have been mapped to restriction fragments. Comparisons of the DNA sequences and the restriction map from Anastrepha suspensa to those known from other tephritid fruit flies are also presented.

key words: Caribbean fruit fly; mitochondrial DNA; restriction maps

[2257] MORPHOLOGY AND GENETICS OF THE NEWLY DISCOVERED INTERSEX IN THE SILKWORM, *BOMBYX MORI*

M. Hirokawa, H. Tanaka & A. Shimazaki, Lab. of Genetic Resources, Natl. Inst. Seric. Entomol. Sci., 6585 Kobuchisawa, Kitakoma, Yamanashi, 408-0044, Japan, Emailhirok@nises.affrc.go.jp.

As a sexually abnormal individual with both sexual characteristics, sex mosaic and intersex are known in some species of insects. However, in Bombyx mori, only the sex mosaic had been reported. Morphology and genetics of the intersex newly discovered in *Bombyx mori* were investigated. The number of abdominal segments with the scales of a normal moth is seven in female and eight in male. Whereas, in the intersex moths, the eighth abdominal segment with the scales varied in manifestation from undetectable traces on their back to the complete structure. In the external sexual organs, both female and male organs were mixed. In the internal sexual organs, most of them had ovaries and many of them had a seminal vesicle of the male organ. Since the fertile moths as female were found in the intersex, the sexuality of the offspring from the cross intersex x male was examined. Intersex and male appeared at a ratio of approximately 1:1. When the males from this cross were crossed with normal females, the sex ratio of male and female was 1:1 and no intersex was observed in the offspring. To confirm the sex chromosome constitution of each individual, the intersex was crossed with the male carrying the recessive sex-linked translucent larval skin gene, od. In the offspring of the cross intersex (Z+W) x male (Z^{od}Z^{od}), translucent skin larvae (Z^{od}W) became intersex moths, and normal skin larvae (Z⁺Z^{od}) became male moths. If the "intersex" is a sex mosaic genetically constructed from two synkaryons, the sex mosaic larvae constructed from two kinds of the cells with the genotypes both $Z^{\alpha d}W$ and $Z^{\dagger}Z^{\alpha d}$ should appear. But such a mosaic individual had never appeared. Since nearly all the ZW individuals became intersex and all the ZZ individuals became male without carrying any sexually transforming genes, the existence of the interesex was confirmed in Bombyx mori, moreover, the intersexuality gene, Isx, was confirmed to be located on the W chromosome of the intersex, too.

Index term: sex mosaic, W chromosome

[2258] DIFFERENTIATION AND IDENTIFICATION OF *AEDES AEGYPTI* POPULATIONS IN TAIWAN

C. M. IIo¹, C. Y. Chang¹, Y.C. Su² & E. L. Hsu², ¹Dept. of Parasitology, Natl. Yang-Ming Univ., 115 Sec. 2, Li-Nung St., Shih-Pai, Taipei (112), Taiwan, ROC, Email vector@ym.edu.tw, ² Dept of Entomology, Natl. Taiwan Univ. Taipei, Taiwan, ROC.

The abdominal scaling pattern of the adult mosquito, Aedes aegypti is highly variable. Hartberg et al. (1986) proposed a simplified system of classification based on the McClelland' 30 groups and designated as CKM. In this system, only the number of tergites with additional white scaling is considered. The extent of white scaling on the tergites is distegarded. This allows for classification using eight different classes, ranging from 0 to 7. In this study, scale patterns of the abdominal tergites in adults were identified and ranked by CKM system for 8 populations of Ae. acgypti collected from southern and southeastern parts of Taiwan. We did not find any individual with the scale at CKM 0 in these natural populations. In general, there were 75% of these adults ranked at CKM 1and 25% or less of the individuals ranked at CKM 2 to CKM 7. However, in the population from Taitung County, we found that the scale patterns were more diverse than that of other areas. They were 47%males and 37% females having the white scale at CKM 2 to CKM 7. Cluster analyses revealed that there were two major groups existing in the natural populations. But, differences of scale pattern were not detected from the individuals collected peri-domestically and domestically. In the meanwhile, five laboratory colonies were compared with the natural populations, we found that colonies from Kenya and Gambia had 11% and 26% individuals at CKM 0, respectively. However, colonies from Puerto Rico and small Liu-Chiu Isle. Which locating in Pintung County had a similar scale pattern as that of Kaohsiung, population, and colony from Hainan Isle where is near Mainland China was similar to that of Taitung population. Moreover, a technique, random amplified polymorphic DNA (EAPD) developed by William et al (1990), was also used to detect the genetic variability for Kaohsiung population and the laboratory colonies. Genetic distance dendrograms were constructed based on the unweighted pair-group mean of the percent of match using the total set of fragments. Our results revealed that colony from Gambia and Puerto Rico was a sister group, population from Kaohsung was closer to this sister group, than that of colony from Kenya or Heinan.

Index terms: Aedes aegypti, abdominal scale pattern, RAPD.

[2259] MOLECULAR CLONING OF NEUROPARSIN PRECURSOR CDNAS IN THE DESERT LOCUST SCHISTOCERCA GREGARIA

T. Janssen, L Claeys, G. Simonet, A. De Loof & <u>J. Vanden Broeck</u> Lab. for Developmental Physiology and Molecular Biology, Zoological Institute K.U.Leuven, Naamsestraat 59, B-3000 Leuven, Belgium.

The pars intercerebralis (PI) is one of the brain regions that contain perikarya of neurosecretory cells. The neurosecretory material is stored in the corpora cardiaca (CC) until it is released into the hemolymph. Peptidic factors originating from the PI and released at the CC are called "parsins". Neuroparsin A (NPA) and neuroparsin B (NPB) are two 8 kDa neurohormones that were initially isolated from the corpora cardiaca (CC) of the migratory locust, Locusta migratoria (Girardie et al., 1987). NPA is an 83-residue polypeptide that co-exists with several N-terminally truncated isoforms in CC-extracts. DNA sequencing revealed that both neuroparsins are cleavage products of a 107-aa precursor polypeptide. This precursor consists of a secretory signal peptide and NPA. NPB is the result of a partial metabolic conversion (enzymatic proteolytic cleavage) of NPA. In Locusta migratoria, these purified neuroparsins exhibit anti-juvenile, antidiuretic, hyperglycemic, hyperlipemic and neurotopic activities. Recently, Girardie et al. (1998) also determined the amino acid sequence of NPA (NPB) in the desert locust, Schistocerca gregaria. The sequences of Locusta and Schistocerca neuroparsins are similar. Based on this sequence information, we have cloned the neuroparsin precursor cDNA of Schistocerca gregaria. Interestingly, a combined approach of PCR and RACE has led to the identification of additional cDNA sequences encoding different neuroparsin-related precursors (NPP). The deduced amino acid sequences of the NPPs range in length between 103 and 111 residues. All Schistocerca NPPs share the same secretory signal sequence and contain 11-12 cystein residues at conserved amino acid positions. For each precursor, specific cDNA probes were generated and the tissue- and stage-dependent (larval stages, moulting cycle and reproduction cycle) distribution of the distinct NPP-transcripts was analyzed by northern blot experiments. The results show that some NPP transcripts are exclusively expressed in the brain, whereas others also occur in a variety of other tissues, including the fat body and the testes. Furthermore, the level of NPP-transcripts generally was higher in males than in females.

[2269] EVOLUTION OF LARVIFORM MALES IN THE INBREEDING BARK BEETLE OZOPEMON: FIERCE FIGHTERS OR JUST WEIRD?

B. H. Jordal^{1,3}, R. A. Beaver², B. B. Normark³ & B. D. Farrell³, ¹Dept. Zoology, University of Bergen, Allegt. 41, N-5007 Bergen, Norway, E-mail: bjarte.jordal@zoo.uib.no; ²161/2 Mu 5, Soi Wat Pranon, T. Donkaew, A. Maerim, Chiangmai, S0180, Thailand; Museum of Comparative Zoology, Harvard University, 26 Oxford St., Cambridge 02138 MA, USA.

Bark and timber beetles of the weevil subfamily Scolytinae exhibit a wide range of different mating and genetic systems, as well as different courtship behaviors and use many different woody substrates for breeding. Perhaps the most successful clade (among the 5800 species described) includes almost 1400 species of regular inbreeders with female biased sex ratios, and where haplodiploidy is the only known genetic system. Basal to, or nested basally within this clade, is the remarkable bark beetle genus Ozopemon, for which an earlier designation of males had been discarded, and some entomologists even believed that males did not exist. A strange creature with fully developed aedeagus, strongly modified pronotum and head, and larviform abdomen, was first described as the male of O. brownei, by Francis Browne; this suggestion was later set aside by Roy Crowson who assigned the weird looking male to the Histeridae, based on a single morphological character. With the evidence provided here, the long standing controversy over the assessment of these enigmatic males has come to a solution. Based on recently obtained DNA sequence data, as well as detailed examination of genital and proventricular characters, we have shown that these strange and fierce-looking creatures are indeed males which have sisters with normal adult bark beetle morphology. Here, we report on two more species, now three in total, having males assigned to the females. The larviform males show a gradual character transformation in the head region, from the adult-like antennae and labium in O. obanus, to the larviform homologs in the two other species. The unique modification of these males is one the most dramatic ontogenetic transformation known for any adult male insect, and extends the range of known modifications of males in inbreeding bark beetles. Moreover, the modification of Ozopemon males is the most extreme example of what WD Hamilton defined as adaptations to an ideal extreme biofacies of inbreeding and arrhenotoky. Also, the rather unique combination of fighting characteristics (e.g. enlarged mandibles) and neoteny, makes sense in the light of similar seraglio situations observed for other insects in confined habitats, where precocity, winglessness and fighting are advantageous in the males. We summarize the most obvious alternative explanations for the evolution of larviform males in this genus, and compare these males to other male forms of related hapiodiploid species. Index terms: haplodiploidy, inbreeding

[2261] RECOVERY OF MITOCHONDRIAL DNA SEQUENCES FROM MUSEUM SPECIMENS: METHODS AND EVOLUTIONARY PERSPECTIVES

A.C.M. Junqueira, A. C. Lessinger & A. M. L. Azeredo-Espin, Lab. Genética Animal, DGE/CBMEG, Universidade Estadual de Campinas, P.O. Box 6109, Campinas, SP, Brasil, CEP 13087-970. E-mail: anacmj@aol.com. Financial support: FAPESP, PADCT/CNPq.

Recent advances in molecular biology have allowed the extraction and analysis of DNA from well preserved museum specimens. The optimization of DNA extraction methodologies is crucial to recover the genetic information preserved in the tissues due to the fractionation and degradation of DNA over the time. The efficient amplification by PCR provides a direct recovery of short intact DNA sequences, and the mitochondrial DNA (mtDNA) increases the chances for amplification due to its high copy number. The comparison of three techniques for DNA extraction have shown that the DNAzol reagent was the most efficient in retrieval of DNA from museum specimens, although the Chelex extraction procedure has been currently the most frequently approach reported. We have successfully amplified mtDNA sequences from eight species of mylases-causing-flies: Cochliomyla hominivorax, Cockliomyia macellaria, Lucilia eximia, Hemilucilia segmentaria, Chrysomya putoria, Chrysomya megacephala, Chrysomya albiceps (Diptera: Calliphoridae) and Dermatobia hominis (Diptera: Oestridae). Dried pinned and alcohol preserved specimens ranged in age from 10 to 53 years. Total Genomic DNA was used to amplify specific regions of mtDNA genes: 137, 160 and 310 bp of Cytochrome oxidase subunit II (CO II), 194bp of Cytochrome oxidase subunit I (CO I), 330bp of a sequence including the rRNA 16S and NADH subunit I, and 345bp of Cytochrome b (Cyt b). These fragments have been cloned in pUC 18 / Sma I and the sequences were obtained by automated sequencing. Preliminary results based on BLAST analyses have shown that amplified fragments have high sequence identity with the homologous regions of ntDNA of other species of mylases-causing flies, an indication that contamination has been efficiently avoided. The D. hominis COII 160bp fragment presents sequence identity with Lucilia illustris (89%), Lucilia sericata (86%), Phormia regina (86%), Chrysomya albiceps (85%), and Chrysomya rufifacies (84%). The cloning and sequence analyses are allowing the characterization of amplified mtDNA regions from museum specimens, in order to compare data from different species, providing a picture of genetic changes and elucidating evolutionary questions

Index terms: intDNA, myjases, PCR, DNA extraction, museum specimens, diptera.

[2262] HEAT SHOCK RESPONSE IN THE MEDITERRANEAN FRUIT FLY: GENES, PROMOTERS AND THERMOTOLERANCE

K. Kalosaka , G. Kokolakis , M. Theodoraki , G. Chrysanthis , A. Zacharopoulou & <u>A. Mintzas.</u> Dept. of Biology, Univ. of Patras, Patras 26 500, Greece. E-mail mintzas@upatras.gr.

The response of cells or organisms to heat shock and other environmental stresses is connected to the induction or enhancement of the synthesis of a number of proteins, called heat shock proteins (HSPs). HSPs, via their chaperoning effects on proteins, protect cells from many forms of stress-induced cell damage. Members of the HSP families play also central roles in a constantly increasing number of cellular activities under non-stress conditions. We are interested to investigate the relationship between hsp gene expression and thermotolerance in the Mediterranean fruit fly (medily), a major agricultural pest, and to assess the efficacy of the promoters of the hsp genes as drivers for conditional and constitutive expression of any transgene in this species. Eight heat-inducible puffs have been identified on the medfly larval salivary gland polytene chromosomes and several *hsp* genes (*hsp* 83, *hsp* 70 and two small *hsp* genes) have been cloned and characterized. The medfly *hsp* genes exhibit maximum expression between 36-39 °C, approximately 2-3 °C higher than the optimum temperature of their D. melanogaster homologs. Structural analysis revealed a number of heat shock elements (HSEs) in the 5' flanking region of these genes. The function of the hsp70 promoter was studied in vivo, in transiently transformed medfly embryos, using the chloramphenicol acetyl transferase gene as a reporter. Our transient expression data indicated that a 106 bp region of the hsp70 promoter that includes two HSEs is necessary for the function of the medfly hsp70 promoter and that additional sequences upstream of the HSEs are required for maximum activity. Furthermore, our data indicated that the efficiency of the medfly hsp70 promoter for driving constitutive and heat-inducible gene expression in the medfly is higher than the efficiency of the heterologous D. melanogaster promoter. To complement these results, stable transformants are currently being generated by germline transformation. To test whether the expression of the hsp genes is related to the development of thermotolerance, the heat shock protein and RNA levels are being compared to the survival of the medfly under various stress conditions in embryos, larvae and adults. Results from these experiments are going to be presented. Index terms: Ceratitis capitata, hsp gene expression, hsp promoters.

[2263] CONCENTRATED EXPRESSION OF THE GENES FOR PROTEINS INVOLVED IN CALCIUM SIGNALING IN THE MUSHROOM BODIES OF THE BRAIN OF THE WORKER HONEYBEE APIS MELLIFERA L

<u>A. Kamikouchi¹, H. Takeuchi¹, S. Natori², K. Sekimizu¹ & T. Kubo¹, ¹Grad. Sch.</u> Pharmaceu. Sci., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113-0033, Japan; and ²Natori Special Lab., RIKEN, Wako-shi, Saitama, 351-0198, Japan.

The honeybee is a social insect and various exquisite social behaviors are performed by their colony members. To analyze the molecular basis of such social behaviors of the honeybee, we searched for genes that are expressed selectively in the paired mushroom bodies, putative memory and sensory integration centers of the insect brain, of the honeybee. As results, we found that genes for three proteins involved in the intracellular Ca²⁺ signaling pathway, inositol 1,4,5-trisphosphate receptor, Ca³⁺/calmodulin-dependent protein kinase II (CaMKII) and protein kinase C (PKC), were expressed selectively in the mushroom bodies of the honeybee brains.^(1,2) We also found that specific activities of CaMKII and PKC are higher in the mushroom bodies than in those of the optic and antennal lobes of the worker bee brain⁽²⁾. The intracellular Ca²⁺ signaling pathway is reported to be involved in neuronal plasticity in various higher organisms. Taken together, our results suggest that the function of the intracellular Ca²⁺ signaling pathway and thus the synaptic plasticity of the intrinsic neurons of the mushroom bodies (the Kenyon cells) are enhanced in comparison with other neuronal cell types in the honeybee brain.

Index terms: social insect, gene expression, specific activity, synaptic plasticity

[2264] MOLECULAR IDENTIFICATION OF THE ANOPHELES FUNESTUS GROUP IN SOUTHERN AFRICA

L.L. Kockemper¹ & R.H. Hunt¹ & M. Coetzee¹, ¹Department of Medical Entomology, SA Inst. for Medical Research, P.O. Box 1038, Johannesburg, 2000, South Africa. E-mail: entosafr@global.co.za

Three main vectors transmit malaria in Africa. Two of these belong to the Anopheles gambiae complex, An. gambiae s.s and An. arabiensis. The third main vector is An. funestus. Anopheles funestus belongs to the An. funestus group of species and is less well studied than the An. gambiae complex due the major problems experienced in identifying members within the group. Eight species are recognized within the An. funestus group based on morphological differences in the immature stages. Historically identification of wild females of the An. functus group necessitated obtaining eggs and rearing the progeny in the laboratory. This process is time consuming and success rates are limited. The use of banding arrangements on the giant polytene chromosomes proved to be very successful and more rapid than rearing progeny. Polytene chromosomes, however, have the disadvantage of being limited to female mosquitoes at a specific stage of their gonotrophic cycle. Another disadvantage is the presence of homosequential chromosome arrangements existing between two species in the group, An. funestus and An. vaneedeni. Using available molecular methods we developed an molecular assay able to distinguish between the members of the An. funestus group most commonly found in southern Africa, An. funestus, An. vaneedeni, An. rivulorum, An. leesoni and An. parensis. This assay does not depend on age or sex of the specimen and does not require specialized preservation methods. The SSCP-PCR assay distinguished between An. funestus, An. vaneedeni, An. rivulorum and An. leesoni. A variable domain in the 28S gene, D3, was amplified and due to sequence differences present between the species resulted in different mobilities during electrophoresis. This assay however could not distinguish between An. vaneedeni and An. parensis. The second PCR assay used primers amplifying the ITS2 region which produced a product that differed in size between the two species. Studies are underway to determine the reason for the size difference, but it is likely to be the addition of a repeat sequence within the region. Previous research on An. funestus group collected indoors automatically assumed them to be An. funestus s.s. However, vectorial studies on An. funestus in Senegal, showed that within this species there might be other populations present not contributing equally towards malaria transmission. Using these molecular tools we are now able to monitor the An. funestus group within the malarious areas of South Africa and determine if any members of the group apart from An. funestus play a role in malaria transmission.

Index terms: mosquitoes. PCR-SSCP, malaria

[2265] CLONING OF THE ACIDIC RIBOSOMAL P-PROTEINS IN THE SILKMOTH BOMBYX MORI

S. Kouyanou-Koutsoukou¹, A. Zaniou¹, P. Athanasakis¹ & M. E. Gagou², ¹University of Athens, Department of Biology, Division of Genetics and Biotechnology, Panepistimiopolis, Athens, Greece. ²Institute of Molecular Biology and Biotechnology, Foundation of Research and Technology, Crete, Greece. E-mail: skougian@biology.db,uoa.gr

The eucaryotic ribosomes contain a family of acidic phosphoproteins P1 and P2 that form the lateral stalk of the large subunit with the ribosomal phosphoprotein P0, similarly to L7/L12 and L10 proteins of Escherichia coli. The ribosomal stalk is involved in the interaction of the elongation factors with the ribosome and the GTP hydrolysis during protein synthesis. We have cloned the P-proteins, CcP1, CcP2 and CcP0 of the medfly Ceratitis capitata and showed that they can complement P-protein defficient strains of the yeast Saccharomyces cerevisiae, forming an heterogenous ribosomal stalk. To perform an in vivo functional analysis of the Pproteins in another insect of economical importance, we isolated genomic and cDNA clones of the genes of the ribosomal proteins P1, P2 and P0 of the silkmoth Bombyx mori, using homologous probes, prepared by PCR. We used as template genomic DNA of B. mori and primers of synthetic oligonucleotides, similar to the conservative regions of the ribosomal P-protein genes of C. capitata, most Drosophila melanogaster and other eucaryotic organisms. Three PCR products of 151 bp, 313 bp and 500 bp were synthesized for the P1, P2 and P0 genes of B. mori, respectively. Sequencing analysis and determination of their predicted amino acid sequence showed that they code for open reading frames, while comparison with the homologue P-proteins genes of C. capitata and D. melanogaster showed great similarity. The homologous probes were used for the screening of a genomic and a Agt11 cDNA library of B. mori, that led to the isolation of one recombinant genomic clone for the P2 gene and two recombinant cDNA clones, for the P1 and P0 genes, respectively. Sequence analysis and alignment of the nucleotide sequences of the P1, P2 and P0 genes and of the deduced amino acid sequences of the proteins with published sequences of *C. capitala*, *D. melanogaster* and other eucaryotic organisms showed considerable similarity. The P2 gene is introlless, while the characteristic structural domains of the hinge and carboxy-terminal regions have been well conserved in all proteins. All three genes were cloned in expression vectors pT7/7 and expressed in Escherichia coli BL21(DE3) strains. Their products, with MW of 18 kD (P1), 15 kD (P2) and 34 kD (P0) were subjected to Western blot analysis with specific polyclonal and monoclonal antibodies.

[2266] DROSOPHILA BUZZATH EVOLUTION IN BRAZIL REVISITED: HIGH SATELLITE DNA HOMOGENEITY AMONG POPULATIONS

<u>G.C.S. Kuhn</u> & F.M.Sene, Dept. of Genetics, Univ. of São Paulo, Ave. dos Bandeirantes, 3900, CEP 14049-900, Ribeirão Preto, SP, Brazil, E-mail: gcskuhn@rgm.fmrp.usp.br. Financial support: FAPESP, CNPq, FINEP, CAPES and USP

Drosophila buzzatii is a world-wide cactus-breeding species probably originated in the Argentinean Chaco. In South America, outside Chaco, D.buzzatii populations have been found in Bolivia and Brazil. D.buzzatii reached Brazil most probably in two ways: in an ancient one, D.buzzatii followed the expansions of the distribution of the xerophytic formations within paleoclimatic cycles during the Quaternary Period; the recent one was a consequence of the anthropogenous dispersal of the Opuntia host plants, which is also believed to be the way D.buzzatii colonized the Old World. In literature only limited data sets are available about the evolutionary relationships among Brazilian populations. Some allozyme and chromosomal data showed that at least two Brazilian populations (i.e. Northeastern and South-coast populations) present differentiation which is in accordance with the ancient way of colonization. satellite DNA sequences often show rapid turnover between even closely related species. For that reason, satDNA sequences seems to be a suitable fast-evolving marker for discriminating populations. In order to get additional information on the evolution of D.buzzatii in Brazil, we compared a previously described D.buzzatii satellite DNA sequence, named pBuM189, among 6 populations which cover D.buzzatii known Brazilian geographical distribution. In addition, one population from Argentina was included in the sample. The pBuM189 satDNA consists of repetition units 189bp long which are tandemly arranged with a high copy number in the genome of D.buzzatii. The nucleotide sequences of 32 selected clones (representing 32 repeat units independently obtained) showed a high degree of sequence similarity among the 7 analyzed populations (95% on average). The observed variability is mainly due to nucleotide substitutions. No specific population feature was observed after the sequence alignment. Genetic distances among the 32 pBuM189 satDNA clones were calculated according to Kimura's "two-parameter method" and used to construct UPGMA and Neighbor-Joining dendograms. No specific clustering of any group of sequences was observed. The absence of specific populations features was specially surprising in the Northeastern and South-coast populations, since they would be somehow expected from allozyme and chromosomal data. However, one Argentinean repeat unit (of four sequenced repeats) shows a remarkable variability compared to the other repeats (25% on average). This result makes it interesting to include more Argentinean populations samples into these studies.

[2267] INCOMPLETE DOMINANCE OF SOME MORPHOLOGICAL CHARACTERS IN HYBRIDS OF DROSOPHILA VIRILIS GROUP

<u>A.M.Kulikov¹</u>, A.I.Mel'nikov¹, N.G.Gornostnev² & V.G.Mitrofanov¹, ¹Institute of Developmental Biology, Moscow, 117334 Russia, E-mail: alex@ibrran.msk.su; ²Institute of Ecology and Evolution, Moscow, 117071, Russia.

We studied two morphological characters of male genitalia of sibling species of *Drosophila virilis* group: the shape of apical claw of aedeagus and absence/presence of hairs on dorsal surface of aedeagus. It was found that the claw of *virilis* phylad species is distinctly more narrow than in *montana* phylad where it is massive and broad with the exception of *D.ezoana* having no claw. The shape of claw of *D.virilis* Sturt. is intermediate between two phylads. The hairs on dorsal surface of aedeagus lack in species of *virilis* phylad except of *D.lummei* where they are rare; these hairs are dense in species of *montana* phylad. The heritability of both characters was studied in hybrids F1 of *D.virilis* x *D.lummei* and the shape of claw also in hybrids of *D.virilis* x *D.novamexicana*. We found that the shape of the claw was intermediate in F1 hybrids and expression of presence of the dorsal hairs also showed incomplete dominance with 50% penetrance in hybrids.

Index terms: Drosophilidae, male genitalia, heritability.

[2268] A MOLECULAR PHYLOGENY OF NOTONECTIDAE (HETEROPTERA) USING 16S RNA

E. C. Larsen, BSLC, University of Chicago, 924 E. 57th St., Chicago, IL 60637, USA, E-mail eclarsen@midway.uchicago.edu.

There is no modern phylogeny for the backswimmers, a cosmopolitan group of predaceous aquatic insects. The accepted taxonomy of this family is two subfamilies and eight genera. Notonectinae is comprised of Notonecta, Enithares, Nychia, and Martarega, and Anisopinae is comprised of Paranisops, Walambianisops, Anisops, and Buenoa. Hungerford (1933) proposed a phylogenetic arrangement with the following sister taxa: Notonecta and Enithares, Martarega and Nychia, Anisops and Buenoa. There has been no cladistic treatment of morphology or DNA to test this arrangement. Species groups have been proposed in Buenoa (Truxal 1953) and Anisops (Brooks 1951), but no relationships of these groups to the rest of the respective genera were proposed. I have sequenced a portion (ca. 600 bp) of the mitochondrial gene for 16s RNA from 29 species of Notonectidae from 4 of the 8 genera. An additional 12 individuals from 9 related families have also been sequenced for use as outgroups. The sequence data were analyzed with PAUP 4.0, using bootstrapping and branch and bound algorithms. Notonectidae is not monophyletic as Enithares falls in a clade with the Naucoridae. The most parsimonious tree does not support the subgenera of Notonecta, but that tree is not dramatically shorter than a topology consistent with existing subgenera. One of Truxal's species groups within Buenoa is supported (margaritacea, scimitra, albida, and uhleri), but it appears derived rather than "primitive" as supposed by Truxal. More species are needed to examine the other six species groups and their relationships to each other. More taxa and sequence data from another gene are required for a more complete and rigorous phylogeny of this family. Index terms: systematics, backswimmers, Buenoa, Notonecta

[2269] GRAM-NEGATIVE BACTERIA BINDING PROTEIN, A PATTERN **RECOGNITION RECEPTOR FOR LIPOPOLYSACCHARIDE AND II-1,3-**GLUCAN, WHICH MEDIATES THE SIGNALING FOR THE INDUCTION OF INNATE IMMUNE GENES IN DROSOPHILA MELANOGASTER CELLS

W. J. Lee¹, P. T. Brey², B. Lemaitre³, K.-B. Nam¹, K.-H. Choi¹, S.-J. Han², J.-H. Ryu¹Y.-S. Kim¹, ¹Lab. of Immunology, BK21 Center for Medical Science and Medical Research Center, College of Medicine, Yonsei Univ., CPO Box 8044, Seoul, South Korea, E-mail wijeel@yumc.yonsei.ac.kr; ²Laboratoire de Biochimie et Biologie Moléculaire des Insectes, Institut Pasteur, 25, rue du Dr. Roux, 75724 Paris, France, and ³Centre de Génétique Moléculaire, Centre National de la Recherche Scientifique, 91198 Gif-sur-Yvette, France.

Pattern recognition receptors, non-clonal immune proteins recognizing common nucrobial components, are critical for non-self recognition and the subsequent induction of Rel/NF-DB-controlled innate immune genes. However, the molecular identities of such receptors are still obscure. Here, we present data showing that Drosophila possesses at least three cDNAs encoding members of the Gram-negative bacteria binding proteins (DGNBPs) family, and one of which, DGNBP-1, has been characterized. Western blot analysis, flow cytometric analysis and confocal laser nicroscopic analysis demonstrate that DGNBP-1 exists in both a soluble and a glycosylphosphatidylinositol-anchored membrane form in culture medium supernatant and on Drosophila immunocompetent cells, respectively, DGNBP-1 has a high affinity to microbial immune elicitors such as lipopolysaccharide (LPS) and □-1,3-glucan whereas no binding affinity is detected with peptidoglycan, □-1,4glucan or chitin. Importantly, the overexpression of DGNBP-1 in *Drosophila* immunocompetent cells enhances LPS- and \Box -1,3-glucan-induced innate immune gene (NF-DB-dependent antimicrobial peptide genes) expression, which can be specifically blocked by pretreatment with anti-GNBP-1 attibody. These results suggest that DGNBP-1 functions as a pattern recognition receptor for LPS from Gram-negative bacteria and -1,3-glucan from fungi, and plays an important role in non-self recognition and the subsequent immune signal transmission for the induction of antimicrobial peptide genes in Drosophila innate immune system. Index terms: Drosophila, GNBP, innate immunity, Pattern Recognition.

[2270] CHRYSOMYA (CALLIPHORIDAE) MITOCHONDRIAL DNA CONTROL REGION: CHARACTERIZATION OF C. MEGACEPHALA IRNA REPEAT

A. C. Lessinger, A. C. M. Junqueira, F. F. Conte & A. M. L. Azeredo-Espin, Lab. Genética Animal, DGE/CBMEG, Univ. Estadual de Campinas, P.O. Box 6010, Campinas, SP, Brasil, CEP 13083-970. E-mail: lessinge@unicamp.br. Financial support: CAPES, FAPESP, PADCT/CNPg

The mtDNA control region (or A+T-rich region) of the blowfly C. megacephala have been previously characterized, resulting in a total size of 986 base pairs (bp). However, a revised analysis of this data provided the identification of $tRNA^{le}$ complete sequence inside the control region B domain. This tRNA-sequence secms to represent a second copy of this gene, since the partial 5' end of the original tRNA was assigned adjacent to the A domain, as characterized for other Calliphoridae species. Comparative analysis provided 100% of sequence similarity between the two tRNA genes from C. megacephala and approximately 95% of sequence similarity when compared with C. hominivorax $tRNA^{le}$ gene. Secondary structure prediction were performed using the tRNAscan-SE software in order to characterize tRNA structural loops (D loop, anti-codon loop, variable loop, and TwC loop). This analysis resulted in a typical "cover-leaf" configuration (cove score = 21.68), with the identification of the same anti-codon (GAT) assigned for *C. hominivorax* tRNA^{lle} gene. Differences between the tRNA^{lle} genes of *C. megacephala* (repeat) and *C.* hominivorax, refer to two transitions $(A \rightarrow G)$ and one insertion (A) that occurred: 1in the D loop arm, 2- between the D loop and the anti-codon loop, and 3- between the $T\psi C$ loop and the anti-codon loop, respectively. None of this mutational events seem to affect the secondary structures configuration and this tRNA^{1k} repeat may represent a functional copy. There were two PCR amplified products for C. megacephala mtDNA control region, one of which were initially interpreted as PCR non-specific band. However, preliminary sequence data from this "non-specific" 300 bp PCR product recovered from *C. megacephala* control region amplification, provide the accurate identification of partial tRNA^{the} sequences, however this could be due to the annealing of PCR primers in the second tRNA copy. The occurrence of this tRNA repeat could be responsible for technical difficulties in amplifying *Chrysomya* mtDNA control region, especially with primers anchored in the tRNA^{the} sequences. Preliminary results based on the characterization of the mtDNA control region of C. albiceps and C. putoria have provided an amplified product of approximately 300 bp, how this results are related to the C. megacephala control region evolution is under investigation.

SCREWWORM FLY

CALLIPHORIDAE)

lessinge@unicamp.br

This study provides the complete sequence of the mitochondrial genome of Cochliomyia hominivorax (Diptera: Calliphoridae), which presents 16.022 bp in size, a typical Brachycera gene content of 13 protein-coding genes, 2 rRNA genes, 22 tRNAs and a major non-coding region (A+T rich region), organized as reported for Drosophila mtDNA. Intergenic non-coding regions and overlapping sequences account for a total of 138 and 37 nucleotides, respectively. Non-optimal codon usage patterns are commonly observed for C. hominivorax mitochondrial genes, as frequently reported for other metazoan mtDNA. The biased composition of C. hominivorax mitochondrial genome (77% AT-rich) may contribute for the observed codon usage pattern by providing a high proportion of AT-rich codons. Special features include a Serine start codon for cytochrome oxidase subunit I (COI) and incomplete stop codons for CO II, NADH 5 and NADH 4 genes. In addition to its general importance as a livestock ectoparasite, C. hominivorax mtDNA is particularly interesting as a source of sequence information useful for general dipteran molecular approaches. The contribution of screwworm mtDNA data will be discussed in terms of improving primer selection for Calliphoridae species, optimizing PCR-RFLP essays and providing phylogenetic informative sequence data for understanding dipteran evolution, especially from a Calyptratae perspective.

Index terms: Cochliomyia hominivorax, myiasis, mtDNA, molecular evolution.

[2272] BEMISIA TABACI POPULATIONS IN BRAZIL: GENETIC **DIVERSITY REVEALED BY RAPD MARKERS.**

L. H. C. Lima¹, L. Campos¹, M. C. Moretzsohn¹, D. Návia¹ & M. R. V. Oliveira¹, ¹Embrapa Recursos Genéticos e Biotecnologia, P. O. Box 02372, Brasília, DF 70.849-970, Brazil. E-mail: luzia@embrapa.cenargen.br

Bemisia tabaci is probably, one of the most damaging whitefly pest in agricultural systems worldwide, vectoring over 60 different plant viruses. In the last years, biological differences among Bemisia tabaci populations have led to the suggestion that some members of this taxon are separate species or are representative of a species complex. The taxonomic identity of B. tabaci is problematic as it is highly polymorphic with extreme plasticity in key with morphological characters that vary according to the host. Up to 1990, in Brazil, *B. tabaci* was considered a secondary pest, although a very efficient vector of geminivirus in beans and soybeans. However, in 1991, a new biotype, known as the poinsettia strain or silverleaf whitefly or B. tabaci biotype B (= B argentifolii) was detected in Brazil causing phytotoxic disorder in cucurbits and attacking weeds. After molecular analysis of the brazilian'whitefly population, it was determined that two biotypes existed in our agroecosystems: B. tabaci being nominated as biotype BR and biotype B. The purpose of this study was to evaluate the genetic diversity of 100 samples collected in 10 different localities on 5 cultivated plants, cabbage, pumpkin, melon, cotton, and soybean. We used the random amplified polymorphic DNA (RAPD) technique in search for genetic markers which would enable the identification of genetic variants within Brazilian populations of B. tabaci. Results showed a high genetic variability of B. tabaci population. An average Jaccard similarity of 0.67 was observed between all individuals. Cluster analysis demonstrated that populations from the same region tend to group together. AMOVA showed that most of the total genetic variation is found within populations (55,3%).

The study of mitochondrial genomes have been subject of increasing research interests, especially due to the ease of recovering genetic and evolutionary

information useful for the investigation of both molecular and organismal evolution.

Complete sequenced mitochondrial DNA (mtDNA) are currently available in

GenBank for five dipteran species representing the Brachycera (Drosophila and

Ceratitis) and the Nematocera (Anopheles) sub-orders. Calliphoridae species address

approximately 50% of all calypterate sequences published, mainly reported as

molecular markers for species-specific identification and phylogenetic reconstruction.

Symposium and Poster Session

[2273] CLONING AND THE EXPRESSION OF A CIRCADIAN CLOCK GENE PERIOD IN THE GERMAN COCKROACH, BLATTELLA GERMANICA

K. H. Lin¹, R. F. Liou² & H. J. Lee¹, 'Dept of Entomology, National Taiwan University, Taipei 106, Taiwan, E-mail m480@ccms.ntu.edu.tw., ²Dept of Plant Pathology, National Taiwan University, Taipei 106, Taiwan.

The circadian expression of *period* gene (*per*) is an important indicator of a functional endogenous clock. We use the RT-PCR and RACE strategies to clone the *per* homolog in the German cockroach, *Blattella germanica*. The cDNA of *per* homolog from *B. germanica* encodes a protein which shows 72% identity with the *per* protein of the American cockroach, *Periplaneta americana*. Comparing the peptide sequences among *B. germanica*, *P. americana*, and *Drosophila melanogaster*, we found that stretches of high identity were in the amino terminus and the PAS domain region. Unlike the *per* protein sequence of *P. americana*, the *per* homolog protein of *B. germanica* shows high identity with the *per* protein of *D. melanogaster* in the carboxyl terminus. With the RNase Protection Assays(RPA) method, the expression of *per* mRNA in the male adult was shown in circadian rhythm which is coinside with the locomotor circadian thythm. Although the female adult German cockroach doesn't show circadian thythm in locomotion, we could use RPA to examine whether the female's endogenous clock works properly or not. Index term: *Blattella germanica*, circadian thythm. *Per*.

[2274] MOLECULAR ANALYSIS OF THE EVOLUTIONARY DYNAMICS OF THE AFRICAN QUEEN BUTTERFLY DANAUS CHRYSIPPUS

<u>G. Lushai¹</u>, J.A. Allen¹, N. Maclean¹, D. Goulson¹ & D.A.S. Smith², ¹Sch. Biological Sciences, Univ. of Southampton, Bassett Crescent East, Southampton, SO16 7PX, UK, E-mail gl1@soton.ac.uk; ²Natural History Museum, Eton College, Windsor, Berkshire, SL4 6EW, UK.

The African queen butterfly, Danaus anosia chrysippus is a tropical butterfly with six subspecies currently recognised. Five of these are spread through tropical Asia, Australasia and Oceania and are allopatric and monomorphic. Under this scenario, all African forms are referred to as a single subspecies, *argyptius*, which is supposedly monomorphic for different forms in each of five geographical areas. In central and east Africa the situation is more complex, with the five regional forms (and others) coexisting sympatrically. The traditional view is that selection drives populations to monomorphism over much of the range of the single African subspecies and maintains polymorphism in east and central Africa. We propose that Danaus is a complex of five monomorphic subspecies which overlap sympatrically in northern and central eastern Africa. Using suitable mitochondrial (12s rRNA) and nuclear markers, i.e. the distal end of the 18s ribosomal gene, we have revealed that one of the supposed geographical races (dorippus) is probably a sister species. This finding is relevant to the dynamics of the species complex in northern and central parts of Africa. We have also studied the phylogenetics of the three sub-genera of Danaus together with most of the genera in the Danainae to determine more fully the status of the proposed sister species and to challenge the existing phylogeny of this family. Further findings support the hypothesis that a geographically extensive 'hybrid zone' is in operation over much of the African continent.

Index terms: Danainae, lepidoptera, sympatric, phylogenetics, hybrid zone

[2275] THE ORIGIN AND MOLECULAR EVOLUTION OF MOSQUITO NON-LTR RETROTRANSPOSONS BELONGING TO THE CR1 AND JOCKEY CLADES

C.A. Malcolm¹, J.L. Crainey¹ & C.F. Garvey^{1,2}, 1. Queen Mary & Westfield College, Univ. of London, Sch. of Biol. Sciences, Mile End Road, London E1 4NS, UK. 2. Current address: MRC-LMB Hill's Road, Cambridge CB2 2QH.

Phylogenies of non-LTR retrotransposable elements (retroposons), based on protein sequences inferred from the reverse transcriptase domain in ORF2, identify at least eleven distinct clades. This study focused on two sister clades: CR1 and Jockey. CR1 contains retroposons from blood fluke, nematode, turtle, chicken, puffer fish and also includes Q and T1 from Anopheles gambiae. Jockey, in contrast, contains only insect host species and includes the Juan elements from Culex pipiens and Aedes aegypti. To look for evidence of horizontal transfer and pre-requisite to an evaluation of retroposon contribution to mosquito evolution, a systematic survey was made by PCR, cloning and extensive database searches on mosquitoes from four genera, for retroposons belonging to the CR1 and Jockey clades. Previously, Anopheles stephensi was shown to contain multiple, highly divergent, families of retroposons falling into both clades, suggesting an ancient origin and a high probability that related retroposons are ubiquitous in mosquitoes. This has now been confirmed. Q/II and Juan related elements were found in multiple distinct families within all species analysed. Within the Jockey clade, a second lineage of mosquito retroposons more closely related to Chironomid NCR1Cth was discovered. A new retroposon closely related to Q/T1 was found in Drosophila melanogaster, thus ending the position of mosquitoes as the only insect hosts in the CR1 clade. It has been proposed that retroposons are not capable of horizontal transfer (Malik et al 1999, Mol Biol Evol 16:793-805). The make-up of the CR1 clade provided scope for the antithesis. Our discovery of two new families of retroposons in *Caenorhabiditus elegans* belonging to the CR1 clade and sharing the distinctive structured 3' untranslated regions of the Q/T/elements offered even more scope. However, overall, the current data for insects can easily be explained by vertical evolution; any horizontal transfer to insects within the CRI clade, has to date back prior to the divergence of the mosquito and Drosophila lineages. The origin of the Jockey clade predates the divergence of Lepidoptera and Diptera.

[2276] THE PRESENCE OF THE TRANSPOSABLE ELEMENTS R1 AND R2 IS ASSOCIATED TO MITOTIC CROSSING OVER IN SEVERAL APHID SPECIES

M. Mandrioli, N. Tarozzi, D. Bizzaro, G.C. Manicardi, <u>R. Crema</u>, A.M. Pagliai & U. Bianchi, Dipartimento di Biologia Animale, Università di Modena, Via Campi, 41100 Modena, Italy. E-mail: mandriol@unimo.it

The analysis of metaphase chromosomes obtained from parthenogenetic females of the aphid Megoura viciae, Acyrthosiphon pisum, Myzus persicae and Schizaphis graminum, after silver and chromomycin A3 (CMA3) staining as well as after fluorescent in situ hybridization (FISH) with a 28S rDNA probe evidenced the presence of inter- and intra-individual heteromorphism in NORs size which are localized in a telomeric region of the two X chromosomes. Since silver staining is a marker for ribosomal gene activity, the heteromorphism shown with AgNO3 could be considered as a consequence of different transcriptional activities between NORs and not as an indicator of variation in ribosomal gene numbers. The presence of such an heteromorphism even after CMA3 staining and FISH argues against this hypothesis and strongly indicate the existence of an heteromorphism in gene number. Moreover intra-individual differences in NORs size suggests that events of mitotic crossing over could be responsible for such an unequal distribution of the rDNA genes between the two X chromosomes. A comparison between slides obtained from aphids belonging to the four species analysed, evidenced that NOR heteromorphism was particularly strong in A. pisum and progressively lower in M. vicine, M. persicae and S. graminum. Molecular analysis of 28S rDNA carried out in order to go in depth in understanding the mechanism involved in the origin of NOR heteromorphism evidenced that all the aphid species analysed possess two different and independent retro-transposons called R1 and R2 in view of their specific and highly conserved localization into the rDNA array. Dot blot experiments, performed in order to quantify the number of R1 and R2 into the four aphid species, revealed that the number of R1 and R2 was particularly high in A. pisum and progressively lower in M. viciae, M. persicae and S. graminum. This data are in agreement with the observed frequency of NOR heteromorphism and suggest us that the number of R1 and R2 elements could be related to the frequency of NOR heteromorphism. In view of such data we suggest that R1 and R2 could be responsible for the mitotic crossing over implicated in the origin of such an heterotorphism. The implication of transposable elements in the origin of mitotic crossing over has been already described in other organisms but it is particularly important in aphids in view of their peculiar strategy of reproduction. Transposons could in fact represent a source of genetic recombination during parthenogenetic generations, when it is generally believed that no recombination occurs.

[2277] MITOCHONDRIAL DNA ANALYSIS IN SPECIES OF DREYFUSIA IN ITALY

B. Mantovani¹, V. Francardi², A. Binazzi ²& A. Leccese ², ¹Univ. of Bologna, Dept. of Exper. Evol. Biology, via Selmi n.3, 40126, Bologna, I, E-mail Barman@alma.unibo.it; 2 Exper. Inst. of Agric. Zoology, Forest Entomology Section, via di Lanciola 12A, Cascine del Riccio, 50125 Firenze, I, E-mail isza@fi.flashnet.it, ahinazzi@dada.it.

The genetic differentiation of five entities of the genus Dreyfusia Börner living on Abies in Italy has been evaluated through the molecular characterization of mitochondrial DNA genes. The aim of these molecular analyses was to better define the taxonomic position of these Dreyfusia taxa. Further, their real capability in colonizing firs was investigated: they are, in fact, able to reach high population levels, wherever host trees are stressed or decaying, so that they become pests to their host firs. The analysed species are the endemic D. piceae (Ratzeburg) with its "aggressive form", widespread in our country, and the exotic D. nordmannianae (Eckstein), D. merkeri Eichhorn, and D. prelli Grosmann whose recording areas are more reduced. Mt genes 16S (506 pb), cytocrome b (435 pb) and ND4 (426 pb) of each of the above mentioned species were amplified and sequenced. Main results are: an overall low degree of genetic differentiation among analyzed taxa, especially for 16S sequences; the absence of genetic divergence between the so far analysed specimens of *D. piceae*; an high affinity between *D. nordmannianae* and *D. merkeri* and a closer relationship between D. prelli and D. piceae. On the other hand the traditional morphometric analysis evidences divergent characters between D. piceae and D. piceae "aggressive form", as well as among the other species, even if it recognizes the same affinities between D. nordmannianae and D. merkeri, one side, and between D. prelli and D. piceae, the other. Mt DNA analysis is the first attempt to the molecular characterization of Dreyfusia species; other genetic analyses, such as RAPD, are going to be carried out to get more information about the degree of differentiation among the analysed entities of Dreyfusia.

Index terms: adelgidae, taxonomic positions.

[2278] USING PRIMERS DESIGNED FOR AMPLIFICATION OF FLIES'S MITOCHONDRIAL DNA TO AMPLIFY MITOCHONDRIAL DNA FROM TERMITES, WITH PHYLOGENETIC PURPOSE

V.G. Martins^{1,2} & M. Bacci Jr.², ¹Departamento de Fonoaudiologia, Univ. Estadual Paulista-UNESP, Ave. Hygino Muzzi Filho, 737, Marília, São Paulo, 17.525-900, Brazil, E-mail martv@uol.com.br; ²Centro de Estudos de Insetos Sociais, UNESP, Rio Claro, São Paulo, Ave. 24-A, 1515, 13.500-900, Brazil.

The C1-J-2792 (George) and TK-N-3772 (Eva) primers (Bogdanowicz et. al., 1993) designed early to amplify a mitochondrial DNA fragment from flies of approximately 1kb were used to amplify the same segment for Termites species from the Neotropical region. Those primers amplifies part of the Citocrome oxidase I (COI), the whole transfer RNA for Leucina (tRNALeu) and Citocrome oxidase I (COII) genes. So, amplifications by PCR were performed for eight species from three of the four Neotropical Isoptera families occurring in Brazil. Three of the studied species belong to Kalotermitidae, one to Rhinotermitidae and four to the Termitidae. Electrophoresis on agarosis gel of PCR products proved that the desired 1kb pairs of DNA fragment was amplified. Those DNA fragments were sequenced in a Perkin Elmer 377 Sequencer for three of the species. Early analyses performed for these sequences showed that some characters used for molecular phylogenetic studies were present in our DNA fragments and allowed us to infer that both primers will be useful for phylogenetic studies that are our main goal. These results are in accordance to previous studies for two species of the Termitidae (Cornitermes bequaerti and C. cumulans) which had the same segment amplified and sequenced, including pseudogenes for three populations of C. bequaerti, according to Martins et al. (Mol. Biol. and Evol. submitted).

[2279] ODYSSEUS, A NOVEL TRANSPOSON INVOLVED IN THE GENERATION OF CHROMOSOMAL INVERSIONS IN THE MALARIA MOSQUITO ANOPHELES ARABIENSIS

K.D. Mathiopoulos¹, F Santolamazza², A della Torre², V Petrarca^{2,3} & M Coluzzi², ¹Dept of Biology, Univ of Patras, Greece, e-mail: kmath@upatras.gr; ²Inst of Parasitology, Pasteur-Cenci Bolognetti Foundation; ³Dept of Genetics & Molecular Biology. Univ "La Sapienza", Rome, Italy.

The Anopheles gambiae complex is comprised of six sibling species, each one characterized by the presence of fixed paracentric inversions on their chromosomes. Two of these, An. gambiae s.s. and An. arabiensis, are the most important vectors of human malaria and are subdivided into discrete subpopulations, each carrying a unique set of polymorphic chromosomal inversions. Some of these inversion polymorphisms are associated with differences in seasonality of breeding, adaptation to natural vs. human-disturbed habitats, microhabitat selection, and host preference. The origin of inversions in nature is uncertain. There is indirect cytological evidence that hobo may be implicated in the generation of certain endemic inversions of natural D. melanogaster populations. However, direct molecular support for this event in natural populations has been elusive. We have cloned the breakpoints of the naturally occurring polymorphic inversion 2Rd' of the malaria vector Anopheles arabiensis. A cDNA clone that cytologically mapped on the proximal breakpoint was the starting material for the isolation of a cosmid clone that spanned the breakpoint. Analysis of the surrounding sequences demonstrated that adjacent to the distal breakpoint lies a transposable element that we called *Odysseus*. This element is distributed on all five chromosomal arms of the An. gambiae complex. Analysis of its cytological distribution in different An. gambiae strains indicates a relative recent activity of Odysseus. It seems specific to An. gambiae since an Odysseus probe does activity of Odysseus. It seems specific to An. gamonae since an Odysseus probe does not hybridize with DNA from the North American An. freeborni, the East Asian An. stephensi, or with Acdes aegypti mosquitoes. We have analyzed several additional copies of Odysseus from different insertion sites in the chromosomes in order to define the full-length transposable element as well as to obtain data on its variability. Analysis of the insertion site also sheds light on the mechanism of transposition and the mechanism by which Odysseus may have generated the 2Rd' inversion. It is theorized that Odysseus creates inversions by ectopic recombination between two copies of the transposon that are in opposite orientation.

[2280] IDENTIFICATION OF TEPHRITID FRUIT FLIES USING rRNA GENES

L. Mckenzie, <u>F. Driver</u>, L. Dransfield & J. Curran, CSIRO, Entomology, P. O. Box 1700, Canberra, ACT 2601, Australia, E-mail feliced@ento.csiro.au.

Surveillance and early detection of exotic pest incursions is vital to protecting Australian agriculture and Australia's unique environment. To assist in the identification of exotic and endemic fruit flies, we have designed a kit to provide a rapid molecular diagnostic system for larval and adult fruit flies that is suitable for non-specialist laboratories. Based on our initial analyses, restriction fragment length polymorphisms (RFLP) within the internal transcribed spacer (ITS) regions of the ribosomal RNA genes were used as the molecular markers. To date we have screened 79 species of fruit fly belonging to four genera; Bactrocera, Dacus, Certatitis, and Anastrepha. In addition we have developed sets of species-group specific PCR-primers to rapidly target unidentified specimens to a major taxonomic cluster. These techniques have been successfully applied to distinguish the majority of species of interest to Australia, however not all species clusters can be resolved by RFLP analysis of the ITS region. In some cases highly specific PCR-primers may be useful. An analysis of sequence data from rRNA gene regions reflects the complexity of some endemic and exotic species groups in Australia and raises issues about phylogenetic relationships.

Index terms: Tephritid fruit flies, Bactrocera, Dacus, Ceratitis, Anastrepha, rDNA

[2281] THE MEDITERRANEAN FRUIT FLY IN THE US: POPULATION STRUCTURE INFERRED FROM MITOCHONDRIAL DNA AND MICROSATELLITE ANALYSES

M. D. Meixner^{1,3}, J. G. Silva², B. A. McPheron² & W. S. Sheppard¹, 1) Dept. of Entomology, Washington State Univ., Pullman, WA 99164, USA, 2) Dept. of Entomology, Pennsylvania State Univ., College Park, PA16802, USA, 3) Inst. fuer Zoologie, Martin-Luther-Univ. Halle-Wittenberg, 06120 Halle, Germany

The Mediterranean fruit fly, Ceratitis capitata, is one of the most widespread and economically important agricultural pests worldwide. From a presumably sub-Saharan origin, it colonized the Mediterranean region, South and Central America, Australia and Hawaii within the past 150 years, reaching the continental US for the first time in 1929 and again in subsequent years. Because of their high economic impact, introductions of Mediterranean fruit fly result in costly measures for monitoring and eradication and also impose restrictions on export of fruits produced in infested regions. We report here the genetic structure of medfly populations from areas with established populations and recent introductions using mitochondrial DNA and microsatellites as genetic markers.

MtDNA of C. capitata samples was analyzed using PCR-RFLP for determining haplotype profiles with the enzymes XbaI, EcoRV and MnII. To improve the resolution of questions surrounding the introduction and eradication of medfly populations in the US, we also analyzed variation at two microsatellite loci, MF 106 and MF 113. Over 400 flies caught on monitoring traps from 1992 to 1998 in both California and Florida were analyzed. Composite genotypes obtained with analysis of mtDNA and microsatellites indicate several independent introductions of medflies into California between 1992 and 1998. While the majority of specimens displayed a single mtDNA haplotype (AAA), variation of microsatellite alleles among these flies suggests at least one additional introduction in 1993 into southern California. In contrast to earlier infestations, a few specimens caught in southern California in 1993 and again in 1998 showed both mtDNA and microsatellite patterns consistent with a Hawaiian origin. Flies displaying the AAB haplotype sampled in 1992 both in northern and southern California shared alleles absent in AAA flies while lacking others commonly found in AAA specimens, thus supporting the hypothesis of an independent introduction of these flies from a different source. In recent outbreaks in Florida, two different mtDNA haplotypes (AAB and AAC) were found in 1997, while AAB only was detected in 1998. Microsatellite analysis of the AAB specimens does not contradict the hypothesis that they persisted through the winter and later spread by human-mediated dispersal.

Index terms: Ceratitis capitata, mtDNA, PCR-RFLP, microsatellites.

[2282] A PARTHENOGENETIC NEW SPECIES OF THE GRYLLACRIDID GENUS APOTETAMENUS

A. Mesa & M. M. Levada, Dept. de Biologia, Instituto de Biociências, Univ. Estadual Paulista (UNESP), Av. 24A 1515, 13506900, Rio Claro, SP, BRAZIL. Email: alejomesa@linkway.com.br

Orthopteran insects are normally bisexual. Facultative parthenogenesis sometime occurs in cave crickets but reproduction by true parthenogenesis is definitely rare. In the case here reported the species was reproduced in the lab for several generations without the presence of males and the opposite sex was never collected in nature. The number of chromosomes in the species is 2n=11 (an unusual odd number for females) and the chromosomes are different from each other in such a way that no pairs can be formed. Two theories are advanced to explain that karyotype: 1) That the species is an haploid. 2) That the species is an hybrid between an 11 (male) – 12 (female) species and another 9 (male) – 10 (female), resulting from the union of a 5+X and a 4+X gamete. The putative parental species have not been yet collected. Index terms: Gryllacridoidea, Henicidae, parthenogenesis, chromosomes.

[2283] A X-AUTOSOME TANDEM FUSION IN AN UNDESCRIBED SPECIES OF THE FAMILY PODOSCIRTIDAE

A. Mesa & P. C. García, Dept. de Biologia, Instituto de Biociências, Univ. Estadual Paulista (UNESP), Av. 24A 1515, 13506900, Rio Claro, SP, BRAZIL. E-mail: alejomesa@linkway.com.br

In ortopteran insects, changes from XO to neo XY sex chromosome mechanisms take place in the majority of cases by means of X-autosome centric fusions. A single case of incorporation of an autosome to the X by means of tandem translocation has been reported in the literature for an eumastacid. The consequence of that incorporation results in the change of a reductional meiotic first division of the sex chromosomes to an equational one and viceversa for the second division. Illustrations of male and female of the undescribed species drawing of the male concealed genitalia sclerites and photograph of the meiotic process are provided. Index terms: Sex chromosomes, tandem fusion, cricket,

[2284] DOES AN X-AUTOSOME CENTRIC FUSION IN ACRIDOIDEA CONDEMN THE SPECIES TO EXTINTION?

A. Mesa, C. Fontanetti & P. C. García, Dept. de Biologia, Instituto de Biociências, Univ. Estadual Paulista (UNESP), Av. 24A 1515, 13506900, Rio Claro, SP, BRAZIL. E-mail: alejomesa@linkway.com.br

Neotropical actidids show an unusual high percentage of species with neo XY chromosomes sex determining mechanisms. Approximately 10% of nearly 500 species studied have this kind of X-autosome fusion. Once this mechanism is established it start a slow and gradative process that change the structure and behavior of the neo XY pair during first prophase male meiosis. During this period the ex-autosome pair gradually reduce the extension of pairing and the crossing-over to the tip chromosome end while Y becomes more and more condensed. At the beginning of the process, the ex homologous fused with X (neo XR arm) and Y remain euchromatic but towards its end, both X and Y appears wholly heterochromatic. Among fifty neo XY species analyzed, five are in the beginning of the process, with XR and Y pairing and showing crossing over along their entire length. Another five species are at the end of the process with neo X and Y including XR entirely heterochromatic, while the remaining 40 species show several intermediate stages. Species at the end of the process show a peculiar chromosome structure during first prophase, with bivalents pressing unusually large loops. The following assumptions follow: 1) The whole process needs to be relatively short in time since in many cases, species with old neo XY mechanisms coexist with XO species within the same genus. 2) If the process ends with the whole heterochromatinization of the neo XY pair, an accumulation of species with old mechanisms should be observed while this is not the case. 3) If species with old neo XY mechanisms survive during a long period of time and speciate, whole taxa as genera, tribus and subfamilies should be present in acridids with all their species showing old neo XY mechanisms. Since the second and third inferences are not observed, the only reasonably conclusion is that the species with old neo XY mechanism do not survive and are extinct. The meiotic structure changes observed in the bivalents during male first prophase could be a symptom of meiotic disorders that will finally conduce the species to a deficit in the generation of male gametes starting the consequent species decay. The early condensation of XR arm in male first meiotic prophase compromising the genetic control of a normal meiotic process could be the origin of troubles that conduces the species to extinction. Index terms: grasshopper, sex chromosomes, neoX-Y mechanism

[2285] NON MENDELIAN BEHAVIOR IN MALE MEIOSIS ASYNAPTICAL MULTIPLE SEX CHROMOSOMES IN CRICKETS

A. Mesa & P. C. García, Dept. de Biologia, Instituto de Biociências, Univ. Estadual Paulista (UNESP), Av. 24A 1515, 13506900, Rio Claro, SP, BRAZIL. E-mail: alejomesa@linkway.com.br

The majority of ortopteran species have XO males and XX female's sex determining mechanisms. Some species have however changed this simple and primitive condition to another more complex by mean of one or several centric or tandem fusions with autosomes. The male first prophase pairing of X's and Y's and the correct arrangement of them at first metaphase, assures that they go to opposites poles during first anaphase. The absence of such pairing should however liberate the sex chromosomes to behave freely in a Mendelian way joining each of them randomly to the poles. A single case was mentioned in the literature where the absence of pairing is the rule, in the cricket *Eneoptera surinamensis*. The unpaired sex chromosomes behave however in a non-mendelian way going always X1 and X2 to a pole and Y to the opposite pole. Four new cases with complex sex mechanisms in cricket species are reported in the present paper. They are as follows: 1) A similar case to E. surinamensis occurs in a still unidentified species of Mogoplistidae. 2) Another Mogoplistidae species have two X's and not Y and the unpaired X's go independently to the same pole during first anaphase. 3) In an undescribed species belonging to the family Podoscirtidae the mechanism is X_1X_2Y in males with Y and X_1 pairing normally and the unpaired X_2 going always to the same pole than X. 4) The most unusual case occurs in another undescribed species of Podoscirtidae, with four Xs and one Y. the Y chromosome pairs with X1, but X2, X3 and X4 remain unpaired during the whole male prophase but then go to the same pole than X1 during first anaphase. Studies aiming to solve the reasons of such unusual not Mendelian chromosome behavior are cogitated.

Index terms: Grylloidea, cytogenetic, multiple sex mechanism.

[2286]MARKER-ASSISTED SELECTION AS A STRATEGY FOR SELECTING INSECT RESISTANT BREEDING LINES WITH IMPROVED EFFICIENCY

<u>S. Mohankumar</u>^{1,2}, P.Shanmugasundaram² & M. A. Saghai Maroof¹, ¹ CSES Dept., Virginia Tech, Blacksburg, VA24061,USA, ²Center for Plant Molecular Biology, TamilNadu Agricultural Univ., Coimbatore-641003,INDIA. Enail:smk65@hotmail.com

Host plant resistance is the most desirable means of pest management resulting in positive environmental and economic benefits in crop production. Breeding of high yielding insect resistant varieties is one of the top priority areas of research in national and international crop breeding programs. Selection of plants based on DNA markers holds promise for accelerating the rate of development of crop plants resistant or tolerant to insects. DNA marker- based technology is being increasingly used to overcome some difficulties of plant breeding based on phenotypic characters (field and greenhouse screening). The greater number of DNA markers, independent of plant physiology and coincidence of crop and insect seasons made the breeders to merge pedigree analysis with DNA markers. Molecular breeding approaches facilitate the early and efficient selection for resistance genes even in areas where the insect is not known to occur. It is most appropriate for intersubspecific and interspecific transfer of insect resistance that have been difficult to improve using conventional methods. It also paves the way for selecting the target gene based on DNA marker with a predictable rate of accuracy. Marker-assisted selection will also be useful for pyramiding resistance genes into a single line from all resistance sources. Molecular marker-assisted selection techniques have been discussed widely in the current breeding approaches but there are few practical examples of utilization. When compared to genes for resistance to diseases, there are relatively few reports describing the mapping of insect resistance loci in crop plants. Molecular markers have been used to identify insect resistance loci in rice, barley, wheat, maize, cowpea, mungbean, soybean, potato, tomato and apple. In this presentation, the basic requirements to develop molecular markers and their potential application for selecting insect resistant crop varieties will be addressed. Data from phenotypic and genotypic evaluations of rice mapping populations screened for reaction to brown planthopper, white-backed planthopper, stemborer and leaffolder will be presented. Index terms: DNA markers, mapping populations, rice pests

[2287] MOLECULAR CHARACTERIZATION OF RICE BROWN PLANTHOPPER POPULATION

S. Mohankumar^{1,2}, N.SenthilKumar¹, J. Souframanien¹, P. Nagarajan¹, P. Shanmugasundaram¹, S. Sadasivam¹ & M. B. Cohen³, ^{1,2} CSES DEPT., VIRGINIA TECH, BLACKSBURG, VA24061, USA, ²Center for Plant Molecular Biology, TamilNadu Agricultural Univ., Coimbatore- 641 003, India, ³International Rice Research Institute, Philippines.

Brown plant hopper, Nilaparvata lugens (Stal.) is a persistent pest in rice fields throughout tropical Asia. Since 1970, IRRI has been maintaining green house colonies of three brown plant hopper biotypes, which differ in ability to survive on and injure various rice cultivars containing single genes for resistance. These biotypes are still used today for screening germplasm for resistance to the brown plant hopper. Indian brown planthopper population differed from the above biotypes and designated as biotype 4. The present study aims to characterize Indian BPH population in comparison with other biotypes through molecular markers. Genetic fingerprints of four biotypes were developed using random amplified polymorphic DNA-polymerase chain reaction (RAPD-PCR). Variation within biotype 4 was also analysed using seven populations collected from diverse agro-climatic zones. About one hundred random primers (OPERON) were screened and polymorphic primers were recorded. Each gel was scored for the presence (1) and absence (0) of a specific band, was worked out. A data matrix was generated to calculate genetic similarity index, analysed using NTSYS program and a dendrogram was constructed by using UPGMA. Two clusters were observed and first cluster consists of the biotype 1,2,3 and the second cluster with biotype 4 alone. The biotype 2 and 3 are closely related within the first cluster. Among the seven populations of biotype 4, the population collected from Raipur, Madhyapradesh is distinctly separated from others. Index terms: Rice, Nilaparvata lugens, biotypes, RAPD-PCR

[2288] ISOLATION, CLONING, AND CHARACTERIZATION OF G PROTEIN-COUPLED RECEPTOR GENES, FROM THE AFRICAN MIGRATORY LOCUST, *LOCUSTA MIGRATORIA*

<u>G. Molaei¹</u>, W.G. Bendena² & A. B. Lange¹, ¹Dept. of Zoology, Univ. of Toronto at Mississauga, 3359 Mississauga Rd., Mississauga, ON., L5L 1C6, Canada. ²Dept. of Biology, Queen's Univ., Kingston, ON., K7L 3N6, Canada.

G protein-coupled receptors (GPCRs) are involved in the transduction of specific extracellular signals across the lipid bilayer of the cell and the linkage of those signals to an intracellular second messenger pathway. This family of receptors responds to a wide range of chemical messengers, including biogenic amines, amino acids and peptides. An extensive amount of research has been carried out on the stimulatory and inhibitory effects of different peptides on visceral muscle contraction of the oviducts of the African migratory locust, *Locusta migratoria*. Molecular cloning studies are very valuable in characterizing the receptors for these peptides and in elucidating the related signaling pathways. In the search for GPCR genes, mRNA was isolated from the midgut and oviduct tissues and was converted to complimentary DNA using oligo (dT). Two primers corresponding to DNA sequences within the conserved regions of transmembrane domains of GPCRs were employed to amplify midgut and oviduct specific GPCR cDNAs by the Polymerase Chain Reaction (PCR). Cloning of the PCR products and further sequencing revealed that at least seven partial cDNAs demonstrate strong sequence homology with known GPCRs. To obtain the complete sequence of our positive PCR generated cDNA, a lambdaphage L. migratoria cDNA library was screened by PCR. This was accomplished by designing specific sense and antisense primers to the partial cDNA sequences and the lambda phage arms. The PCR generated fragments were subcloned into a pCR 2.1(Invitrogen) cloning vector. Experimentation is underway to complete the sequence and characterize these clones. The full-length cDNA clones will be employed to conduct expression studies using a suitable expression system and to perform *in situ* hybridization to localize the expression of the receptors, thereby identifying target tissues. Binding assays, and pharmacological studies will be performed to confirm the second messenger systems utilized by the various receptor types.

[2289] SEX-BIASED PARASITISM IN INSECTS

<u>S.L. Moore¹</u>, R.S. Hails² & K. Wilson¹, 1 Institute of Biological Sciences, University of Stirling, Stirling FK9 4LA, UK, e-mail: s.l.moore@stir.ac.uk: 2 Institute of Virology and Environmental Microbiology, Mansfield Road, Oxford OX1 3SR, UK;

Male-biased parasitism has been observed in a number of vertebrate taxa, including mammals and birds. One hypothesis to explain the greater susceptibility of males to parasites is the innuncocompetence haudicap (ICH) hypothesis, which proposes that the male immune system is suppressed by the sex-steroid, testosterone. In order to determine if this hypothesis could be a universal explanation for male-biased parasitism, I reviewed the evidence for a similar bias in the invertebrates, which do not produce sex hormones. Currently there are very few data on sex-differences in parasitism rates in invertebrates. However, significant sex-biases in parasitism have been reported and I will use meta-analysis methods to determine if there is a consistent trend across all of the studies.

Index terms: sex-biased parasitism, immunocompetence handicap (ICH) hypothesis, meta-analysis

[2291] DIAPAUSE HORMONE AND PHEROMONE BIOSYNTHESIS ACTIVATING NEUROPEPTIDE (DH-PBAN) GENE EXPRESSION IN THE EMBRYO OF THE SILK WORM, BOMBYX MORI

A. Morita, F. Niimi & O. Yamashita, Grad. Sch. Bioagric. Sci., Nagoya Univ., Chikusa, Nagoya, 464-8601 Japan. E-mail: amorita@agr.nagoya-u.ac.jp

The scenario leading to embryonic diapause of the silkworm, Bombyx mori, starts at the embryonic stage of maternal generation, when the environment serves as the initial signal to develop neuroendocrine system for diapause hormone synthesis. In this study, we focused on the maternal embryos to examine when the neuroendocrine system is established functionally to recognize the environmental stimuli for regulation. From the results of the quantitative RT-PCR, the diapause hormonepheromone biosynthesis activating neuropeptide (DH-PBAN) gene expression is shown to start in the late embryonic stage regardless environmental conditions. By using anti-FXPRLamide antibody, immunoreactive somata were observed in the subesophageal ganglion of both embryos at 15 and 25°C. Furthermore, when the caudal part of the embryo incubated at 15 or 25°C was implanted into pupae, all recipients laid nondiapause eggs. Thus, that the DH-PBAN gene expresses and its products are translated and secreted in the late embryonic stage. Therefore, we concluded that in the late embryonic stage, the neuroendocrine system for diapause hormone-synthesis and -secretion is completed, but this system functions independently of environmental conditions.

Index term: Bombyx mori, diapause hormone, embryo of the maternal generation

[2290] STUDY OF HYBRID ZONE AMONG DROSOPHILA SERIDO AND DROSOPHILA SP D, SPECIES OF THE CLUSTER BUZZATH

A.C.Morales¹; M.H.Manfrin¹ & F.M.Sene², ¹Deptorde Biologia, FFCLRP, Univ. de São Paulo. Av. dos Bandeirantes, 3900. CEP 14040-901, Ribeirão Preto, SP, Brazil. Email: morales@rgm.fmrp.usp.br.² Depto. de Genética da FMRP, Univ. de São Paulo. Av. dos Bandeirantes 3900. CEP 14049-901, Ribeirão Preto, SP, Brazil. Financial Support: FAPESP, CNPq, FINEP, CAPES and USP.

The buzzatii "cluster", endemic of South America, is composed by seven cactus breeding species: Drosophila buzzaiii, D. borborema, D. koepferae, D. seriema, D. serido, Drosophila. sp B e Drosophila sp D, distributed in different vegetation formations of South America. Drosophila/cacti associations make that differentiation processes inside of this group are related with the successive expansions and retractions of the South American xerophytic vegetation due to paleoclimatic fluctuations, that provoked an asynchronism of historical connections among the populations. A hybrid zone among Drosophila sp D and D. serido was described in the coast of the Santa Catarina and Rio Grande do Sul, Brazil. The objective this work was characterize through isoenzymes the populations of Florianopolis, SC (D. serido), Santiago, RS (Drosophila sp D) and the contact area populations of Arroio Teixeira, RS; Cornélio, RS; Osório, RS and Tramandaí, RS. The technique used was starch gel (14%), horizontal electrophoresis. Thirteen loci were used for the characterization of the genetic structure of these populations: alcohol dehydrogenase (ADH-1 and ADH-2), esterase (EST-1 and EST-2), 1-glicerophosphate dehydrogenase (a-GPDH), hexokinase (Hk-2 and Hk-3), isocitrate dehydrogenase (IDH), leucine aminopeptidase (LAP), malate dehydrogenase (MDH), malic enzyme (ME), peptidase (PEP), phosphoglucomutase (PGM). The distance estimative and the construction of phylogenetics trees were accomplished through the method of Neighbor-Joining using the DISPAN software. The phylogenetic relationships obtained show two main branches: one composed by the Santa Catarina (D. serido), the Arroio Teixeira and Osório populations (hybrid zone), and another branch composed by the Santiago (D. sp D), Cornélio and Tramandal populations (hybrid composed by the balance (D, sp D), content and Hamman populations (D, sp D) was located. The data obtained at the moment, do not support the hypothesis of the structure of the hybrid zone described for the area, however should be considered that enzymes in many cases are under selection, which might do not diagnose historical events of populations. Some populations are in Hardy-Weinberg equilibrium, others are not.

Index terms: allozyme, genetic structure, contact area.

[2292] GENETICS ACROSS THE SPECIES BOUNDARY: HOST PLANT PREFERENCE AND COLOUR PATTERN IN HELICONIUS CYDNO AND H. MELPOMENE

<u>R.E. Naisbit</u> & J.I.B. Mallet, Galton Laboratory, Department of Biology, University College London, 4 Stephenson Way, London NW1 2HE, UK. E-mail r.naisbit@ucl.ac.uk

Sympatric species that are able to hybridise offer an opportunity to study the genetic basis of traits which currently maintain species distinctness, and which may have contributed to speciation. The butterflies *Heliconius cydno* and *H. melpomene* are sympatric across much of Central and Andean South America and retain the ability to hybridise, although hybrids are thought to form less tan 0.1% of wild populations. They occupy different Müllerian minicry rings and have diverged in host plant and habitat use, all of which will act to reduce gene flow between the two. In Panama, *H. melpomene* specializes on *Passiflora menispermifolia* in secondary growth, while *H. cydno* oviposits on most of the available *Passiflora* species in the understory. These preferences are retained in the insectary and are autosomally inherited, with dominance of the preference of *H. melpomene*. Oviposition differences will act as a barrier to gene flow between the two species, since caterpillars pupate close to the host plant and males patrol the plants and mate with newly emerged females. Colour pattern differences are controlled by several loci of major effect, together with many modifier loci. This divergence will contribute to assortative mating since initial attraction is on the basis of colour, and also lead to selection against the nonmimetic colour pattern of hybrids by preductry birds.

Index terms: speciation, Müllerian mimicry, assortative mating.

[2293] MULTIPLE PARTIAL BARRIERS TO GENE FLOW BETWEEN HELICONIUS CYDNO AND H. MELPOMENE

R.E. Naisbit, C.D. Jiggins & J.L.B. Mallet, Galton Laboratory, Department of Biology, University College London, 4 Stephenson Way, London NW1 2HE, UK. Email r.naisbit@ucl.ac.uk

A growing number of studies have shown that closely related sympatric species are separated by multiple, incomplete barriers to gene flow. These are often a direct result of ecological divergence, generating assortative mating in conjunction with some form of selection against hybrids. This will have consequences for the way we view the species boundary, and how we study speciation. The butterflies *Heliconius* cydno and *H. melpomene* retain the ability to hybridise, but in their sympatric range across much of Central and Andean South America hybrids are thought to form less than 0.1% of wild populations. Speciation has accompanied shifts in both Müllerian mimicry ring and habitat use. Barriers to gene flow between the two currently take the form of assortative mating, differentiation in habitat use, sterility of female hybrids, and selection by predators acting against the novel colouration of hybrids. We present data from mate choice experiments which show very strong assortative mating between the two species, and weaker discrimination against F1 hybrids. Oviposition sites and adult capture data show habitat segregation along a transect from open habitat to closed forest, reducing but not eliminating the possibility of encounter and hybridisation. Data will also be presented on sterility of female hybrids (following Haldane's Rule), with complete sterility in the FI generation and segregation of the trait in backcross broods.

Index terms: speciation, assortative mating, Haldane's Rule, habitat segregation.

[2294] A MOLECULAR VIEW OF TRYPSIN SYNTHESIS IN AEDES AEGYPTI

F.G. Noriega^{1,2}, K.Edgar^{1,2} & M.A. Wells^{1,2}, ¹Dept. of Biochemistry, Univ. of Arizona, BSW 440, Tucson, AZ 857, USA, E-mail fnoriega@u.arizona.edu; ² Center for Insect Science, Univ. of AZ.

Ingestion of a blood meal induces two phases of trypsin synthesis in the mideut of Aedes aegypti females. The first phase, which encompasses the first 4-6 hours following a blood meal, is characterized by the presence of small amounts of early trypsin. The second phase, which occurs between 8 and 36 hours after blood feeding, is characterized by the presence of large amounts of late trypsin. A specific form of regulation of trypsin synthesis characterizes each phase: early trypsin synthesis is regulated at the translational level, while late trypsin synthesis is regulated at the transcriptional level. The enzymatic activity of early trypsin plays a unique and critical role in the regulation of late trypsin synthesis. Early trypsin acts like a "sensor". It carries out limited proteolysis of the ingested proteins and, somehow, the products of this limited proteolysis induce synthesis of late trypsin, which is the protease responsible for the majority of the endoproteolytic cleavage of the meal proteins. Transcription of the early trypsin gene starts a few hours after adult emergence and is under control of juvenile hormone. However, the early trypsin mRNA is stored in the midgut epithelium and remains untranslated until a blood meal is taken. The exact mechanism responsible for initiating translation is presently unknown, but an increase in the size of the amino acid pool in the midgut is sufficient to activate translation of early trypsin mRNA. The transcription of the late trypsin gene is regulated by uncharacterized proteolysis products generated by the action of early trypsin on the blood meal proteins. Once transcription has been activated, the rate of transcription of the late trypsin gene is proportional to the amount of protein present in the meal. In addition, the amount of late trypsin protein translation is controlled by the amount of amino acid released during digestion. Regulation at both transcriptional and translational levels allows the midgut to adjust the amount of late trypsin with remarkable flexibility in response to a particular meal.

[2295] A HOMOLOGUE OF THE DROSOPHILA MELANOGASTER SEX-DETERMINING GENE DOUBLESEX IS TRANSCRIBED INTO SEX-SPECIFIC ISOFORMES IN THE SILK WORM, BOMBYX MORI

F. Ohbayashi¹, M. G. Suzuki¹, K. Mita², K. Okano³, T. Sugasaki^{1,4} & T. Shimada¹, ¹Dept. of Agric. Environ. Biol., Univ. of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113-8657, Japan. E-mail aa77005@mail.ecc.u-tokyo.ac.jp; ²Natl. Inst. of Radiol. Sci., Anagawa 4-9-1, Inage-ku, Chiba City, Japan; ³Lab of Mol. Entomol. and Baculovirol., RIKEN, Hirosawa 2-1 Wako, Saitama, Japan; ⁴Kitamoto High School, Kitamoto, Saitama, Japan

The doublesex (dsx) gene is known as the final gene of the sex-determining cascade in Drosophila melanoguster. We have isolated a homologue of dsx from a pheromone gland and testis CDNA library of silkworm, Bombyx mori, which has an epistatic feminizing gene located on the W chromosome, by using the expressed sequence tags (EST) database. RT-PCR analysis indicated that the size of the amplified products of Bombyx mori dsx (Bmdsx) showed sexual differences in all the examined tissues. Northern blot hybridization revealed that transcriptional level of Bmdsx is higher in ganads and pheromone gland and the Bmdsx probe detected a band with a sexspecific size difference. The female-specific Bmdsx mRNA isoform was approximately 10.6kb in length and the male-specific one was approximately 10.4kb. The male-specific cDNA was skipped over the sequence between 713 and 961nt of the female-specific cDNA. As the result of RNase protection assay it was confirmed that this sequence was male-specifically removed from the *Bmdsx* pre-mRNA. A Southern blot analysis and bacterial artificial chromosome (BAC) library hybridization showed that the Bmdsx is present at single copy in the genome. Linkage analysis by using hybrid resulting from the backcross between Bombyx mori and Bombyx mandarina revealed that the Bmdsx is located on the 25th chromosome of Bombyx mori. These results strongly suggested that the Bmdsx gene is alternatively spliced to yield male- and female-specific mRNA isoforms. These sex-specific isoforms encoded polypeptides with a common amino terminal sequence but sexspecific carboxyl termini. The largest ORF of female cDNA is 795nt and encode 265 amino acids. On the other hand, the largest ORF of male cDNA is 801nt and encode 267 amino acids. The level of identity of the sex-specific DSX proteins of Bombyx mori with Drosophila melanogaster DSX proteins, across the region corresponding to the DNA binding domain (DM domain), is 80%. These results suggest the possibility that the dsx homologue in Bombyx mori would also regulate sexual differentiation like the Drosophila ds. gene.

Index terms: Bombyx mori, doublesex, sex determination, alternative splicing

[2296] MORPHOLOGICAL AND MOLECULAR IDENTIFICATION OF WHITEFLIES SPECIES IN BRAZIL

M.R.V. Oliveira', L. Campos', K.R. Vilarinho', W.N.M. Lago' & L.H.C. Lima¹, Embrapa Recursos Genéticos e Biotecnologia, P. O. Box 02372, Brasília, DF 70.849-970, Brazil. E-mail: vilarin@cenargen.embrapa.br.

Whiteflies have been described in Brazil for more than 100 years but never caused severe problems in agricultural ecosystems, excepted for *Bemisia tabaci* as a vector of phytovirus, in beans and soybeans crops. This situation changed 1992 onwards when *B. tabaci* outbreaks as a pest was described in São Paulo State. During the past three years we have received 223 samples of whiteflies from investigators all over Brazil and from Paraguay. These represents collections made in 47 different host plants, among them, melon, cotton, squash, watermelon, tomato, soybean and weeds. Morphological characters of the pupal case were examined by sterescopic microscopy. For *B. tabaci* biotypes, DNA was extracted from individuals and subjected to RAPD-PCR (randomly amplified polymorphic DNA polymerase chain reaction) analysis. RAPD-PCR, using fresh or alcohol preserved material, enables the B biotype to be distinguished from a tange of other biotypes a well as other species. The most common whiteflies found among the samples analyzed were: papaya and coffee (*Tetraleurodes sp.*), cashew (*Aleurodicus cociss*), green cabbage (*Trialeurodes abutiloneus*), citrus (*Aleurothrixus floccosus*) and *Brosinum gaudichadii* (*Aleurodicus dugesii*). *B. tabaci* biotype BR was found in 15,92% samples and biotype B, in 70,40%. The results also showed that for the first time, biotype B of *B. tabaci* is found feeding on cassava crops in Brazil. Index terms: Whitefly, *Bernisia tabaci*, genetic diversity, RAPD.

[2297] GENETIC VARIABILITY OF CACOPHONY GENE IN LUTZOMYIA LONGIPALPIS POPULATIONS

<u>S. G. Oliveira</u>¹, N. A. Souza², C. P. Kyriacou³ & A. A. Peixoto¹, ¹Department of Biochemistry and Molecular Biology, Inst. Oswaldo Cruz, Aven. Brasil 4365,21045-900, Brazil, E-mail: sigomes@gene.dbbm.fiocruz.br; ² Department of Entomology, Inst. Oswaldo Cruz; ³Department of Genetics, Univ. of Leicester

Lutzomyia longipalpis is a phlebotomine that is considered as the major vector of visceral leishmaniasis in New World. Several studies confirm its widely distribution in Brazil and suggest that L. longipalpis could be a complex of cryptic species. In this work we utilized a DNA fragment of L. longipalpis correspondent to cacophony (cac) gene of Drosophila melanogaster to analyse the genetic variability in this complex of species, cac (Dmca1A) gene is a mutantion that encodes the al subunit of a voltage sensitive calcium channel in Drosophila melanogaster. This gene promoves variations in courtship song produced by vibrations of wings of males. The ritm of this love song depends of length of IPI (inter pulses intervals) and the number of the cycles. The love song produced by cac mutants have increased IPI and the number of cycles in each pulse. In some species of Drosophila these variations reflects disturbious in choice of male by females to mating, due it cac could have a important role in speciation process. The sexual behaviour of L. longipalpis suggests that the same process could be happen in this complex cryptic species. At this moment were analysed 57 individuals of three populations: Natal/ RN, Gruta da Lapinha/MG and Jacobina/BA. To obtain and amplify this fragment we utilized specific primers of L. logipalpis using PCR technics. The DNA fragments obtained were cloned and each one was sequenced automaticaly. The sequences were alinged and polimorfism observed in the intron of these DNA fragments were analysed. The polimorfism in intron finded were increased in Natal and Lapinha populations than Jacobina population. Inumerous alleles were find in three populations, some of they were frequents in Natal and Lapinha populations, but some other were finded only in one population. Some of these results suggest that could be happend introgression process in these populations. Others studies are been realized to confirm this suggestion. Index terms: Lutzomyia longipalpis, cacophony, genetic, polimorfism

[2298] ANALYSIS OF GENETIC STRUCTURE CHANGES WITH POPULATION DENSITY IN PANONYCHUS CITRI IN A SMALL HABITAT USING AN ESTERASE LOCUS

Mh. Osakabe¹ & S. Komazaki², ¹Dept. of Plant Protection, National Agriculture Research Center, 3-1-1 Kannondai, Tsukuba, Ibaraki 305-8666, Japan, E-mail mhosaka@narc.affrc.go.jp; ²Persimmon and Grape Research Center, National Inst. of Fruit Tree Science, Toyota, Hiroshima 729-2494, Japan, E-mail koma@akt.affrc.go.jp.

Several instances of proof of restricted dispersion ability have been reported in spider mites. If the dispersion rate is very low, the size of their breeding colonies is small, causing a genetic differentiation among trees or branches. The resulting genetic structure is assumed to affect preservation and dispersion of an acaricide-resistance gene. In the early stages of acaricide resistance development, a few individuals generally survive in parts of the orchard after spraying. In this study, to learn the genetic structure in a small habitat, the spatial distribution of *Panonychus citri* and the change of the inbreeding coefficient with population density on citrus seedlings were analyzed using an esterase locus as a genetic marker. Genotype frequencies in F₁ females after mating in various population densities suggested that P. citri mated randomly. Adult P. citri females were introduced to small sour orange seedlings, and the spatial distribution of eggs laid on leaves and the offspring were observed. Introduced adult females laid most eggs on the leaves on which they were set and most of the offspring grew on the leaves where they hatched. In the next experiment, females with different homo genotypes were separately introduced on leaves at the top and the bottom of the three sour orange seedlings. The inbreeding coefficient of the developing population was kept high for at least a month in all seedlings although it gradually decreased with the population increase. A linear relationship was found between the density of adult females and the inbreeding coefficient. From these results, the genetic structure in a small habitat can be explained as follows. The relatively aggregated egg production, the low dispersion rate in the immature stage, the precopulatory mate-guarding behavior of the male and ineffectiveness of the second mating may increase the frequency of sibmating. These traits force a delay in hybridization among the breeding colonies at low density. With an increase in population density, distances among the colonies established by different immigrants or survivors are closer. This increases the opportunity for an adult male to meet quiescent females of different colonies. Consequently, the inbreeding coefficient will gradually decrease with coefficient population development and probably converge at Symposium and Poster Session

[2299] STRUCTURE AND EVOLUTION OF THE WING ARTICULATION AND PLEURITES OF THE PSYLLOIDEA (HEMIPTERA, STERNORRHYNCHA)

<u>D. Ouvrard</u>, Mus. nat. d'Hist. nat. Lab. d'Entomologie & ESA 8043 CNRS. 45 rue Buffon. 75005 Paris. FRANCE. E-mail: ouvrard@cimrs1.mnhn.fr.

The characters of the thorax have been rarely used for the taxonomy of the Psylloidea. Reasons for this are probably linked to the jumping aptitude of these insects which has led to the particular development of the metathoracic internal furcae on one hand and of the meron of the coxa on the other hand. This has led to the apparent disappearance of some structures (pleural suture, wing process) and to a difficulty in interpreting (in terms of homology) thoracic sclerites. This lack of discernible homology has led psyllid systematists to focus on head, wing and genitalia characters, or only on the prothoracic pleurites. The dissections of 25 genera representative of the current taxonomic arrangement in psyllids and several species with striking thorax features (Apsylla cistellata, Trichochermes magna, Rhegmoza tinctoria, Diclidophlebia eastopi, Notophyllura cataphracta) have led to a topographical and connective definition of the mesopleurites, to the evolutionary hypothesis concerning the metathoracic pleural suture, to the understanding of the endopleurites in relation with the sternal apophyses, and to the description of peculiar features in the arrangement of the sclerites of the forewing base articulation. As previously claimed by other authors, the propleurites show interesting variations, but the exact primary homology of the antero-ventral angle of the proepisternum varies with the taxa: it is a real trochantin in some species, but a precoxal bridge (i. e. the catepisternum + basisternum) in other species. The metathoracic pleural suture in not the secondary structure designated by several authors, but clearly the incomplete suture indicated by the fossa of the deep pleural apophysis. An internal apodeme at the ventral part of the mesepisternum is reported for the first time, and its serial homologous apodeme is also found in the metathorax, and used as an important landmark. Finally, the metathoracic pleural suture appears to be pressed to the ventral edge of the metepimeron, as it has been shown in the mesothorax of some species. when the meron of the mesocoxa is also developed (Caillardia inedita). The study of the wing articulation shows special trends in the evolution of sternorrhynchal third axillary sclerite in relation to the proximal medial plate (what consequences for the flight of these insects ?). These new interpretations and the discovery of new internal apodemes are useful to assess the primary homology of structures for phylogenetic studies in progress. A glossary of terms used standardizes the nomenclature within the Hemiptera non-Heteroptera taking into account the most recent specialized work and older major works on the thorax of insects.

Index terms: forewing base structure, insect flight, pleurites, pleural suture, thorax, morphology, phylogeny

[2300] SEX CHROMOSOME VARIATION AMONG MUSCOIDEA FLIES

P.P. Parise-Maltempi¹, R.M.P.Avancini² & <u>G. Tirone¹</u>, ¹Dept. of Cell Biology, ²Dept. of Parasitology, Inst. of Biology/ State Univ. of Campinas P. O. Box 6109 Cep 13083-970 Campinas, São Paulo, Brazil.

The chromosome modal number in Muscoidea Diptera is 2n=12: five pairs of autosomes and one sex chromosome pair. Nevertheless, some species with 2n=10 chromosomes have been described, all of them from the Muscidae family. We analyzed the karyotype of some species of Muscidae, Calliphoridae and Sarcophagidae, for the presence or absence of heteromorphic chromosomes. Besides, once there is a relation between NOR(s) and heterochromatin with sex chromosomes, we also investigated these regions through FISH for NOR and C banding for heterochromatin localization. Sex chromosomes are present in the Muscidae species: Ophyra chalcogaster, Synthesiomyia nudiseta and Musca domestica; in the Calliphoridae flies: Chrysomya putoria and C. megacephala; and in the Sarcophagidae Pattonella intermutans. Muscina stabulans and Haematobia irritans are exceptions among Muscidae, since they lack sex chromosomes. There is a considerable variation on the length of sex chromosomes among the different species. Sex chromosomes are very short in O. chalcogaster, medium-size in M. domestica and Chrysomya species and very long in S. nudiseta and P. intermutans. NOR is located on pair II of M. stabulans and M. domestica, on pair III of S. nudiseta, on pair IV of P. intermutans and on sex chromosomes of C. putoria and C. megacephala. Usually in Diptera NORs are associated with sex chromosomes, therefore NORs located in autosomes may suggest an intermediary step in the chromosome evolution of that group where some sequences of the genome, such as NOR(s), could be moved from sex to autosome chromosomes, avoiding serious damage to the genome if parts of sex chromosomes are lost. The Muscidae species apparently are in a more advanced stage in the evolution of sex chromosome. Moreover, in all the Muscidae investigated that presented sex chromosomes these chromosomes are heterochromatic and NOR(s) are located in the autosomes. Pattonella intermutans has long sex chromosomes, that are totally heterochromatic and NOR is also located in the autosomes. The Calliphoridae species studied in this work, seem to be in an intermediate stage, with NOR located in the sex chromosomes, which are not totally heterochromatic.

Index terms: Panonychus citri, citrus, esterase, inbreeding

[2301] MOLECULAR PHYLOGENY, CHROMOSOMES, AND HOST PLANT AFFILIATION IN CHRYSOLINA AND OREINA (COLEOPTERA, CHRYSOMELIDAE)

E. Petitpierre, C.F. Garín, B. De Astorza, C. Juan & I. Garnería, Lab. Genètica, Dept. Biologia, UIB, 07071 Palma de Mallorca (Spain), e-mail: dbaepv@clust.uib.es.

A segment of 510 bp length of rDNA from mitochondrial genome has been sequenced in forty-one species of Chrysolina and five of Oreina, belonging to twenty-four and three current subgenera, respectively. A maximum parsimony tree was built where some subgenera or groupings of them are clearly established by supported nodes. Thus, among the Lamiaceae feeders having 2n = 24 chromosomes, at least four clades are shown: 1) Maenadochrysa + C. (Colaphosoma) sturmi, 2) Taeniochrysa + Chrysolinopsis + Rhyssoloma, 3) Fastuolina + Chrysomorpha, 4) Methastriella + Melasomoptera + Erythrochrysa. A quite polyphagous clade feeding on Lamiaceae, Plantaginaceae, Asteraceae and Ranunculaceae, joins Chrysolina s.str. + C. (Colaphoptera) rufa, the latter feeding on Lamiaceae and Asteraceae, and sharing also 2n = 23 chromosomes. The *Chalcoidea*, Asteraceae feeders with 2n = 40chromosomes, are a highly supported clade as well as the Hypericia + Sphaeromela, on Clusiaceae and with 2n = 38 and 32 chromosomes, respectively. The Stichoptera are also clustered despite their distinct choices, on Scrophulariaceae or Lamiaceae, and their chromosomal heterogeneity, while the Threnosoma agree with their feeding on Apiaceae and with their 2n = 47 chromosomes. Finally, five Oreina appear in two allied branches: Chrysochloa and Oreina s.str. + Protorina. The separation of Chrysolina respect to Oreina needs additional analyses by using more conserved genetic markers. Conversely, Chrysolina-Oreina diverges strikingly from other enera of Chrysomelinae.

Index terms: 16S rDNA, genetic interrelationships, trophic selection

[2303] THE ECOLOGO-KARYOTYPICAL APPROACH TO THE ANALYSIS OF SIBLING-SPECIES GENUS CHIRONOMUS MEIG. (CHIRONOMIDAE, DIPTERA)

N.V. Polukonova, Saratov Medical Univ. Russia, 410710, Saratov, Bolshaja Kzachja St., 112

The ecologo-karyotypical approach to the analysis of chromosomal polymorphism of sibling species allows to reveal the common tendencies in the formation of karyofunds of evolutionary young species and to trace the influence of external environment on karyotypical structure of hydrobionts taxocenosises. The study represent of simpatrical living sibling species seems to be most convenient. The natural populations of *Chironomus* gr. *plumosus* species of Volga river basin reservoirs of the Saratov region (Lower Volga) were investigated. On analysis the following ecologo-karyotypic parameters were taken into account, which, in our opinion, could reflect karyotype connection with external environment: 1 - quantity of heterozygotic inversions in a species, 2 - chromosome arms with inversions (only common for all species of taxocenosis), 3 - chromosome segments, included in heterosygotic inversions (only common for all species of taxocenosis), 4 - segments chromosome where break off forming inversions (only common for all species of taxocenosis). The analysis we carried out, has revealed certain, optimale for the given ecological conditions the set of the inverted chromosome segments, which is maintained by selection as selectively favourable. General set of such segments for different species of group plumosus once again indicates their evolutionary youth. On the other hand, it is obvious, that a set of the inverted segments, number of heterozygotic inversions and chromosomal arms with inversions can vary in this or that direction depending on conditions of a definite reservoir.

Index terms: karyotype, polytenic chromosomes, heterotopic insects, midges.

[2302] CHROMOSOMAL AND MORPHOLOGICAL DIVERGENCE SPECIES OF A GENUS CHIRONOMUS MEIG. (CHIRONOMUDAE, DIPTERA)

<u>N.V. Polukonova</u>, Saratov Medical State Univ. Russia, Saratov, 410710, Saratov, Bolshaja Kazachja St., 112

Researches of closely related species of a genus Chironomus Meig. have shown, that during chironomids evolutionary divergence distinction between species revealed with the help of the karyotypic analysis, it is not necessary correlated with distinctions between them to morphological signs. So, C. curabilis, C. nuditarsis and C. behningi with chromosomal figure of disks close to C. plumosus, do not belong to group *plumosus* following morphological signs of larva - absence of serration in the anterior edge of a ventromental plate, and in *C. behningi* also by the presence of 4-5 bladed premandibule (instead of 2-bladed). However, C. behningi has in the G arm identical chromosomal sequence with C. usenicus (sibling species C. plumosus). Identity in the sequence of disks in a G arm in different species is rare case in Chironomus genus. The species of thummi cytocomplex (AB, CD, EF and G) form groups of closely related species inside it. But these groups can include species of others cytocomplexes, for example, *C. nudiventris* of group *lumosus*, from the cytocomplex *staegeri*, with 2n = 6 (AB, CD, GEF). There are representatives from listed cytocomplexes in others subgenus's - Baeotendipes (C. valkanovi from a staegeri-complex), Lobochironomus (C. globulus from a thummi-complex) etc. Species subgenus Camptochironomus - C. tentans and C. pallidivittatus, belong to a genus Chironomus following morphology larva, but they have "their own" cytocomplex camptochironomus (AB, CF, DE and G). Species Chironomus of North - C. fraternus and C. fundatus - C. wulkeri, clearly different karyologically, can have weak morphological differences (Filinkova, 1995 in Russian). Dendrogramms of species similarity in group's plumosus and obtusidens, formed on morphological and karyotypical signs do not correspond in a sequence of species and their relative The discrepancies between morphological and cytogenetical arrangement. differentiation are found out and in other groups of animals (Yegorov, 1983; Giljova, 1990 all in Russian). Apparently, the karyotype structural transformations do not contribute significantly to evolutionary transformation of external morphological signs, and the processes of chromosomal and morphological differentiation, at least, at early stages of evolutionary divergence, go independently.

Index terms: evolution, kariosystematic, karyotype, heterotopic insects, midges.

[2304] PATTERNS OF RDNA LOCALIZATION IN TIGER BEETLES (COLEOPTERA: CICINDELIDAE)

<u>S. J. R. Proenca</u>¹, A. R. M. Serrano¹ & J. Galián², ¹Depto Zoologia e Antropologia and Centro de Biologia Ambiental, Fac. Ciências, Univ. Lisboa, Campo Grande, Bloco C2 - 3º Piso, 1700 Lisboa, Portugal, E-mail soniajr@fcu.um.es; ²Depto Biologia Animal, Fac. Veterinaria, Univ. Múrcia, 30071 Múrcia, Spain.

Tiger beetles are Coleoptera belonging to the family Cicindelidae, which are characterised by the presence of multiple sex chromosomes of the type XnY (males) XnXn (females) that form a non-chiasmatic multivalent during meiosis. With the exception of the chromosome number and sex chromosome mechanism, little is known about their nuclear genome organisation. The localization pattern of conserved genes such as ribosomal DNA is of particular interest in phylogenetic and evolutionary studies. The ribosomal clusters were localized on meiotic and mitotic chromosomes and in interphase nuclei of nine Paleartic taxa belonging to the genus Cicindela (s.l.) by fluorescence in situ hybridization (FISH), using a PCR-amplified 18S rDNA fragment as a probe. The Cicindela species studied (C. hispanica, C. maura, C. deserticoloides, C. circumdata, C. trisignata, C. littoralis littoralis, C. littoralis nemoralis, C. flexuosa and C. paludosa) show variation regarding to the number of chromosomes with ribosomal genes, which varies from 2 to 4, as well as their localization within the genome. Polymorphism between populations and between subspecies has also been observed. Four new patterns of rDNA localization can be added to the one previously described corresponding to two fluorescent signals in two of the heterosomes (XY). These four patterns are: 1) two fluorescent signals located in an autosomal pair; 2) three fluorescent signals located in an autosomal pair and in one of the heterosomes (X); 3) three fluorescent signals located in three of the heterosomes (XXY) and 4) four fluorescent signals in an autosomal pair and in two of the heterosomes (apparently XY). These results show that ribosomal cistrons have changed their localization between autosomes, from autosomes to heterosomes, from heterosomes to autosomes and between heterosomes during the evolution of the genus Cicindela, showing a dynamic rather than a conservative pattern. The polarity of these changes is discussed. A mechanism that involves transposable elements that jump from one localization in the genome to another, in some cases leaving copies in the original localization is proposed to explain these dynamics.

Index terms: Cicindela, ribosomal genes, FISH.

[2305] CHARACTERIZATION OF GENOMIC GENE ENCODING KYNURENINE 3-MONOOXYGENASE IN THE SILKWORM BOMEYX MORI

G. X. Quan¹, L. Kim², T. Shimada², T. Kômoto¹, K. Yukuhiro¹, T. Kanda¹, K. Mita³, M. Kobayashi² & T. Tamura¹, ¹Dept. of Insect Genetics and Breeding, National Institute of Sericultural and Entomological Science, Owashi 1-2, Tsukuba, Ibaraki 305, JAPAN; ²Dept. of Agricult., University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, JAPAN; ³Nat. Inst. of Radiological Sciences, Anagawa4, Inage, Chiba 263, JAPAN.

To develop a efficient system for the transgenesis in the silkworm, it is important to use a visible dominant marker gene which possesses very high sensitivity and expresses at early developmental stage of the embryogenesis. In the silkworm, many white egg color mutants were known and preserve in NISES and Kyusyu University. One of the mutant called w1 is knows its egg color is white and caused by the deficiency of kynurenine 3-monooxigenase (KMO). The mutant cannot accumulate ommochrome pigments in the serosal membrane cells of the embryos. Recently, cDNA homologue of Drosophila KMO gene was cloned by Kim et al. (1998). We performed further analysis related to the genomic gene structure of the wild type and the w1 mutant. Southern blot analysis showed that the Bombyx KMO gene is present as a single copy gene in the silkworm genome. The clones covered the entire region of KMO gene was isolated from the BAC library. The sequencing of the whole region of the gene showed that the silkworm KMO gene consist of 10 exons and its total size is about 16kb. The DNA sequences associated with CREBP(cAMPresponse element binding protein) and CEBP (CAAT/enhancer binding protein) consensus were found in the 5'upstream region of the gene. The highly reiterated sequences were found at the introns. Especially, the large insertion was found in the third introns. Comparison of the DNA sequences of KMO genes between the Bombyx and Drosophila showed that the second to eighth exons of the silkworm gene correspond to the second exon of Drosophila KMO gene and the ninth to tenth exons were equivalent to the third exon of Drosophila. No consensus sequences were identified in 5'upstream regions between the two genes. Although the expression of KMO gene in the mutant was much lower than the wild, the comparison of the sequences of 5' upstream region appeared only minor difference in the mutant and wild type genes.

Index tems: lepidoptera, white egg, w1, ommochrome, transgenic.

[2306] CLONING FULL-LENGTH CDNAS ENCODING TWO NOVEL INSECT HYPERACTIVE ANTIFREEZE PROTEIN ISOFORMS FROM SPRUCE BUDWORM

<u>M. Rahavard</u>, Department of Anatomy, Univ. of Medical Sciences, P. O. Box 19735-183, Tehran, 19735, Iran, E-mail mRahavard@hotmail.com

Spruce budworm (Choristoneura fumiferana) employ antifreeze proteins (AFPs) and other cryoprotectants as part of their freezing avoidance overwinteing strategey. The second instar, 1mm larvae overwinter successfully in hibernaculae attached unprotected to the tips of conifer branches, exposed to frequent-30° C and lower. The pest destroys millions of hectares of North American forests in peridic outbraeks. AFPs bind to the microscopic seed ice crystal via surface adsorption-inhibition mechanism and inhibit ice crystal growth. This function is resulted in lowering body fluids freezing point, non-colligatively, bellow the melting point which is defined as thermal hysteresis (TH). On a molar basis the TH obtained from this insect is 10 to 30 times higher than that of the fishes'. Based on the 9kDa, hyperactive, antifreeze protein sequences, which previously obtained, oligonucleotide degenerate primers (sense and antisense) were designed for cloning AFP cDNA via polymerase chain reaction (PCR). As the template for the reaction, first strand cDNA was prepared via reverse transcription, using poly (A⁺)-enriched mRNA isolated from second instar larvae. The PCR, amplified a 120 -bp DNA fragment which subsequently was used as a hybridization probe for screening the second instar larval cDNA library. Sequencing of some of the isolated positive clones revealed full-length AFP cDNAs. Conceptual translation of the DNA sequences to their encoded proteins, produced two novel 107 and 108 amino acid AFP isofrms, which contained all previously obtained protein sequences confirming identity of the clones. Alignment of the two AFP isoforms showed 77.6 % identity. Results showed that at least two cDNAs are encoding the spruce budworm AFPs. In addition, preliminary Northern analysis showed that AFP cDNA hybridizes to three functional AFP mRNA transcripts. This also suggests that more than one gene or a close family of genes is encoding spruce budworm AFP isoforms. Potentially, spruce budworm AFP gene can be a preferred candidate to be over or/ under expressd in producing frost resistant or/suceptible transgenic plants and animals, respectively. Frost suceptible transgenic pests may help integrated pest control strategies. Other applications of the AFP in cryomedicine, cryopreservation of frozen food and in biotechnology in general may be also invaluble.

Indexterms: Choristoneura fumiferana, Antifreeze protein, cryprotection

Symposium and Poster Session

[2307] COMPARATIVE CYTOGENETICS IN ARGENTINE SPECIES OF PENTATOMINAE (PENTATOMIDAE, HETEROPTERA)

P.J. Rebagliati, L. M. Mola & A. G. Papeschi, Lab. de Citogenética y Evolución, Depto. de Ciencias Biológicas, FCEN, Universidad de Buenos Aires, C.P.A.: C1428BGA, Argentina. E-mail: gchu@bg.fcen.uba.ar.

Species of Pentatominae are generally phytophagous, feeding on a wide range of weeds and cultivated plants, and causing great economic losses. Cytogenetic analysis is one of the tools employed in the species characterization. The Pentatominae, as is the rule in Heteroptera, have holokinetic chromosomes and a particular meiotic development: bivalents present only one chiasma and arrange in a circle at metaphase plates; sex chromosomes are achiasmatic and lie at the center of the autosomal ring at these stages. The analysis of more than 200 species of the subfamily reveals a diploid chromosome number ranging from 2n=6 to 27, with a mode in 14 (86%) and a sex chromosome determining system XY/XX (male/female). Adult males of Loxa deducta, Macropygium reticulare, Piezodorus guildinii, Edessa meditabunda, Edessa rufomarginata, Proxys albopunctatus, Dinocoris prolineatus and Dichelops furcatus from different localities have been cytogenetically analyzed. Specimens were fixed in 3:1 (absolute ethanol: glacial acetic acid), gonads were dissected out and slides were performed by the squash method in iron propionic haematoxylin; DAPI banding was also carried out in both Edessa species. All the species present 2u=14, n=6+XY, except D. furcatus with 2n=12, n=5+XY, and meiosis proceeds as usual in Heteroptera. Despite the great constancy in chromosome number, the species show differences in karyotype and meiotic behaviour. D. furcatus shows a reduced chromosome number due to an autosomal fusioa, while E. meditabunda, E. rufomarginata, P. albopunctatus and L. deducta have a large autosomal bivalent which can present two chiasmata. Sex chromosomes are also diagnostic: in P. albopunctatus and P. guildinii the X and Y are strikingly unequal in size; in E. meditabunda and E. rufomarginata the smaller sex chromosome is DAPI negative and iso-DAPI, respectively, from metaphase I onwards. Besides, the larger sex chromosome of *E. meditabunda* is frequently part of the ring of autoscmes at metaphase I. Finally, *L. deducta, M. reticulare* and *D. prolineatus* show a highly irregular meiosis in one testis lobe ("hariequin lobe"), a feature already described in only 23 species of Pentatominae belonging to 3 different tribes, Pentatomini, Halyini and Discocephalini.

Index terms: Edessa meditabunda, Dinocoris prolineatus, Dichelops furcatus, Macropigium reticulare, meiosis.

[2308] MOLECULAR GENETIC MAPPING IN THE HESSIAN FLY

S. D. Rider Jr.¹, W. Sun¹, F. H. Valicente¹ & J. J. Stuart¹, ¹Dept.of Entomology, Purdue Univ., West Lafayette, IN,47907, USA. Email: jeff_stuart@entm.purdue.edu

The Hessian fly, Mayetiola destructor (Say), is one of the most destructive insect pests of wheat in the United States and is the most important pest of wheat worldwide. The most effective method of control of the Hessian fly to date depends on the development and deployment of wheats that carry genes that provide resistance to this pest. Over time, Hessian fly populations evolve into new virulent biotypes' against which these genes are not effective. Our objectives are to understand the mechanism of virulence by mapping and cloning the genes conditioning avirulence/virulence in this insect. Bulked segregant analysis was used to identify molecular genetic markers associated with Hessian fly genes conditioning avirulence to the H5, H6, H9, H7/H8 and H13 wheat resistance genes. An AFLPbased genetic linkage map of the Hessian fly genome was created to facilitate the acquisition of flanking markers for each avirulence gene. The map shown was generated using 84 polymorphic loci and a backcross mating design. The map covers approximately 580 Kosambi centimorgans which translates to an average of less than 170 kb per centimorgan of recombination. In conjunction with a large insert BAC or cosmid library, positional cloning of avirulence loci is feasible. We are also focusing on the locus controlling sex determination in the Hessian fly. Fine-scale mapping and positional cloning one avirulence gene, vH13, has been initiated.

Index terms: host plant resistance, Cecidomyiidae, avirulence, bulked segregant analysis.

[2309] CYTOGENETIC HETEROGENEITY IN COMMON ARGENTINE HAPLOGINE SPIDERS

S. G. Rodríguez Gil¹, L.M. Mola¹, A. G. Papeschi¹ & C. L. Scioscia^{1,2}, ¹Lab. de Citogenética y Evolución, Depto. de Ciencias Biológicas, FCEN. Univ. de Buenos Aires, CPA: C1423BGA, Argentina, E-mail Errol Indicador não definido.. ²Museo Argentino de Ciencias Naturales "B. Rivadavia", Buenos Aires, Argentina.

During the last decade phylogenetic knowledge of the higher systematics of Araneae has increased. Cladistic evidence suggests that although classical Haploginae were originally defined on the basis of a plesiomorphy, they form a monophyletic group. This paper had its origin as an attempt to bring cytogenetic data that can be used as new evidences for a better understanding of the relationships in this conflictive group. Araneae comprises 108 families and more than 3000 described genera; just a little more than 100 genera and 300 species have been cytogenetically analized and only 7% of the species are haploginae. Most spiders present monocentric chromosomes (acro or telocentric), a diploid chromosome number ranging from 2n=22 to 28, chiasmatic meiosis and a sex chromosome determining system X1X20/X1X1X2X2 (male/female). Spermatogenesis of Dysdera crocota (Dysderidae), Ariadna bocsenbergii (Segestriidae), Pholcus phalangioides (Pholcidae), Kukulkania hibernalis (Filistatidae) and Scytodes maculata (Scytodidae) has been analyzed in immature and adults. Specimens were fixed in 3:1 (absolute ethanol: glacial acetic acid), testes were dissected out and slides were performed by the squash method in iron propionic haematoxylin. The chromosomes of D. crocota (2n=11, n=5+X0) lack a primary constriction (holokinetic chromosomes), and meiosis is achiasmatic; the sex univalent chromatids separate at anaphase 1 (post-reductional division); A. boesenbergii (2n=9, n=4+X0) also presents holokinetic chromosomes. P. phalangioides (2n=24, n=11+X1X20) possess monocentric chromosomes of very small size, making difficult their morphological characterization; K. hibernalis $(2n=24, n=11+X_1X_20)$ and S. maculata (2n=13, n=6+X0) have metacentric autosomes. In all these 4 species meiosis is chiasmatic and the sex chromosomes divide pre-reductionally: both X_1 and X_2 , or both chromatids of the unique X, migrate together to one pole at anaphase I. Cytogenetic studies in species of Segestriidae and Dysderidae reveal a low diploid chromosome number, and the presence of holokinetic chromosomes, contrasting with the generality of spiders; ail the species of Pholeidae characterize by the presence of very small sized chromosomes. Finally, S. maculata and K. hibernalis are the only species cytogenetically analyzed until present in Scytodidae and Filistatidze, and they show an uncommon chromosome morphology (metacentric chromosomes). Cytogenetic data in haplogine spiders far from being homogeneous show strong differences from generality, a fact also encountered in many other characters in the group.

[2310] MITOCHONDRIAL DNA "A+T RICH" REGION AS A GENETIC MARKER IN AEDES AEGYPTI POPULATION STUDIES

J. C. Rondan Dueiias¹, G. Panzetta-Duttari² & <u>C. N. Gardenal</u>¹, ¹Cátedra de Química Biológica, Facultad de Ciencias Médicas; ²Departamento de Bioquímica Clínica, Facultad de Ciencias Químicas, Universidad Nacional de Córdoba, Casilla de Correo 35, Sucursal. 16, 5016 Córdoba, Argentina. E-mail: ngardenal@biomed.fcm.unc.edu.ar;

Because of its maternal inheritance, non recombinant nature and high levels of polymorphism, nutochondrial (mt) DNA has been extensively used as genetic marker in animal population genetics. Among the few noncoding segments of mt DNA, the control region comprising the replication origin is usually long and hypervariable, being potentially suitable for studies at the intraspecific level. In insects, this fragment is called A+T rich region, because of its particularly high content of adenine and thymine. The usefulness of this region, because of its particularly man content of adcanne and thymine. The usefulness of this region as a tool for the study of population structure has not been investigated in mosquitees. We present here a survey of length and restriction fragment diversity in the A+T rich region in natural populations of *Aedes aegypti*, the main urban vector of yellow lever and dengue. Samples were obtained from five cities of Argentina (Orán, Salta, Posadas, Córdoba, Villa María and Buenos Aires) and from San Juan de Puerto Rico. DNA of 8 to 16 individual adult mosquitoes from each locality was extracted by standard phenol-chloroform procedure. Universal primers were used for amplification by the polymerase chain reaction (PCR). Aliquots of amplification products were digested with 7 restrictases, according to the manufacturer's protocols. The PCR product varied in length (2.1, 2.3 and 2.5 kb) among individuals and populations, and was used as one of the variables to define haplotypes. Four out of the seven restrictases employed (Ssp I, Dra I, Apo I and Pac I) originated patterns revealing intrapopulation restriction fragment length polymorphism (RFLP). A total of nine different haplotypes could be defined in Argentina; haplotype 2 had the highest frequency and was present in four out of five populations . The sample from Salta was the most polymorphic, showing 6 haplotypes. In individuals from Puerto Rico, three different haplotypes were observed, none of them found in Argentina. Our results demonstrate that the A+T rich region of Ae. aegypti offers good levels of polymorphism to allow intrapopulation discrimination, being a suitable genetic marker for the study of population structure.

Index terms: mosquitoes, population structure, RFLP, haplotypes.

[2311] GENETIC VARIATION OF EUROPEAN CORN BORER (OSTRINIA NUBILALIS) POPULATIONS IN NEBRASKA DETECTED BY RANDOM AMPLIFIED POLYMORPHIC DNA (RAPD)

L. A. Saldanha¹, S. Skoda², S. S. Quisenberry³ & J. E. Foster¹, ¹Dept. of Entomology, 202 Plant Industry Building, University of Nebraska-Lincoln, Nebraska, USA 68583-0816, ²USDA-ARS Midwest Livestock Insects Research Laboratory, Department of Entomology University of Nebraska, Lincoln, USA 68583-0938, ³Montana State University, College of Agriculture 202 Linfield Hall, Bozeman, MT 59717-2860

The European corn borer, Ostrinia nubilalis (Lepidoptera: Crambidae) an introduced pest of maize (Zea mays), is common to maize growing areas throughout North America. European corn borer is a polyphagous species that causes about US\$ 1 billion damage annually. It exists in three morphologically similar ecotypes. Despite the importance of this pest, limited information is available concerning the nature and extent of genetic diversity of the European corn borer in the United States. Because there is a need to understand the genetic structure of the European corn borer, we used random amplified polymorphic DNA-Polymerase chain reaction (RAPD-PCR) to examine ecotype variation in European corn borer from five sites in Nebraska. After initially screening 120 RAPD primers we selected 10 for further studies. RAPD-PCR of European corn borer DNA, resulted in the amplification of a series of DNA fragments of varying length. We use only fragments that were consistently present and reliable. The results showed that the European corn borer from Nebraska constituted a broad genetic group. We found the genetic population structure to consist of 35.5% univoltine, 44.5% bivoltine, and 20% multivoltine ecotypes. More research along these lines will give a better understanding of the ecotype distribution of European corn borer and may be useful in developing pest control strategies.

Index terms: DNA polymorphism, population genetics, PCR, randomly amplified polymorphic DNA, molecular markers

[2312] REPRODUCTIVE ISOLATION AND GENETIC DIFFERENTIATION IN JAPANESE SPECIES OF ADOXOPHYES (LEPIDOPTERA: TORTORICIDAE)

<u>Y, Sato</u>, Lab. of Entomology, National Research Institute of Vegetables, Ornamental Plants and Tea. 2769, Kanaya, Shizuoka 428-8501, Japan, E-mail lucifer@tea.affrc.go.jp

The smaller tea tortrix, Adoxophyes honmai and its sibling species, A. dubia are important pests of tea plants, and the summer fruits tortrix, A. orana has been known to attack various fruit trees in Japan. These three Japanese Adoxophyes species have been recognized based on larval host, adult pheromone, or some morphological differences, but no consistent genetic differences have been reported. To clarify their genetic relationships, I surveyed mitochondrial DNA (mtDNA) and allozyme variations of these species. Most specimens were sequenced over an 832-bp segment of the ND5 region. At the molecular level, these three species were very similar; especially A. honmai and A. dubia were most closely related species. The crossbreeds between A. honmai and A. dubia didn't lose their fertility alone. Viable and fertile interspecific hybrids can be obtained in the laboratory, thus permitting a genetic study of some of these traits. However, these results don't confirm the allozyme survey, which found that A. dubia was the most genetically distinct species. These closely related tortrcid moths have been found in sympatry in southern part of Japan, and habitat isolations among these species by their host plant preference are incomplete. Therefore, I also examined the degree of reproductive isolation among these species. The sexual isolation was confirmed by mating choice experiments in the laboratory. Most mating of A. honmai were conspecific. A.dubia and A. orana also showed a tendency to the conspecific matings, although the mating activity of these species was restrained under the experimental conditions. The presence of other Adoxophyes females seemed to suppress the mating activity of A. dubia and A. orana. Observations at 22°C, under a 14:10 LD-cycle mating times of A.dubia revealed two hours earlier than these of A. honmai and A. orana. These data suggest that the Japanese Adoxophyes species differ by 1) ecological preferences, 2) some morphological features, 3) the relative amounts of the two main components of the female pheromonal blend, 4) the temporal pattern of sexual behavior, and 5) the genetic differentiations

Index terms:. Adoxophyes, A. dubia, A. orana, reproductive isolation, mt-DNA

Symposium and Poster Session

[2313] MITOCHONDRIAL DNA COI SEQUENCES DIFFERENTIATE TWO CLOSELY-RELATED SPECIES, ANOPHELES DUNHAMI AND ANOPHELES NUNEZTOVARI (DIPTERA: CULICIDAE)

Y. M. Scarpassa¹ & J. E. Conn², ¹ Lab. de Vetores da Malária, Inst. Nac. Pesquisas Amazônia, Avenida André Araujo, 1756, Manaus, Amazonas, 69011-970, Brazil. ² Dept. Biology, Univ. of Vermont, Burlington, VT, USA 05405-0086

The known geographic distribution of Anopheles dunhami Causey is restricted, including only Tefé (type locality) and Tabatinga, on the Solimões River, in Amazonas State, Brazil. This species was a synonym of Anopheles nuñeztovari Gabaldón, and in recent publications A. dunhami was resurrected as a distinct species; and Anopheles trinkae Faran regarded as the senior synonym of A. dunhami based on isomorphic genitalia. Currently, A. dunhami, A. nuñeztovari and A. trinkae are considered as separate species based on differences in egg ultrastructure, accessory gland volume, the ITS2 region of ribosomal DNA, RAPD sequences and polytene chromosomes. In the present study, we determined one new locality for A. dunhami, Coari, which is situated on the Solimões River, in Amazonas State. Anopheles dunhami from Coari was identified using 873 base pairs of DNA from the mitochondrial cytochrome oxidase subunit I (COI) and the results were compared with the sequences of A. dunhami from Tefé, the sequences of 16 populations of the sister-taxon A. nuñeztovari from South America, and the sequences of the outgroup, Anopheles darlingi Root. The uncorrected pairwise divergence between the two populations of A. dunhami ranged from 0.6% to 0.9%, while the divergences between A. dunhami and A. nuñeztovari were 1.6% to 3.2%. Among the sequences of A. dunhami, the matrix presented 9 variable sites (1.0%) and 0 (0%) informative sites, while the data matrix showed 10 (1.1%) phylogenetically informative sites between the two species. The strict consensus tree, using maximum parsimony, supported A. dunhami and A. nuñeztovari, morphologically indistinguishable as wild-caught females, as distinct species with 85% bootstrap support (1000 replications). These results demonstrate the utility of mtDNA COI sequences to separate the human malaria vector A. nuñeztovari and A. dunhami, especially in areas where they are sympatric. This research was supported by INPA/PPI-3190 and NIH AI 40116 to

[2314] INVASION GENETICS OF THE PEA LEAFMINER LIRIOMYZA HUIDOBRENSIS (DIPTERA: AGROMYZIDAE): CRYPTIC SPECIES AND GEOGRAPHIC ORIGINS OF PEST POPULATIONS

<u>S. J. Scheffer^L</u>, ¹Systematic Entomology Laboratory, USDA-ARS, Bld 005, Rm. 137, BARC-W, 10300 Baltimore Ave., Beltsville, MD, USA, sscheffe@sel.barc.usda.gov.

Liriomyza huidobrensis is currently a major worldwide pest of many vegetable and flower crops. Originally known from the western United States and South America, this polyphagous leafmining fly has recently been introduced into many locations around the world, giving rise to new outbreak populations that are currently causing substantial economic losses. Phylogenetic relationships among populations of the L. huidobrensis were investigated using mitochondrial cytochrome oxidase sequence data. Results show that L. huidobrensis contains two well-defined monophyletic groups, one comprised of specimens from California and Hawaii and one comprised of specimens from South and Central America. The differentiation between the two clades within L. huidobrensis is equivalent to that seen between other agromyzid species, suggesting that L. huidobrensis as currently defined contains two cryptic species. This finding is consistent with reports of field observations of differences in pest status and insecticide resistance between L. huidobrensis populations from these different regions. Introduced populations, sampled to date, of L. huidobrensis present in other regions of the world all belong to the South and Central American clade. The potential of nuclear DNA markers to further identify geographic origins of introduced pest populations will be addressed. Until additional studies are complete, no changes has been addressed with the proposed. However, researchers and quarantine officials may wish to consider the findings of the present study in designing research, pest management, and quarantine programs for L. huidobrensis.

Index terms: phylogeography, molecular systematics.

[2315] FROM SEVEN CRYPTIC SPECIES OF THE CULICOIDES IMICOLA COMPLEX (DIPTERA: CERATOPOGONIDAE)

F. Sebastiani¹, **R.** Meiswinke¹², **P.** Mellor³, **L.** M. Gomulski¹ & <u>G. Gasperi¹</u>, 1Dept. of Animal Biology, Univ. of Pavia, 27100 Pavia, Italy; 20nderstepoort Veterinary Inst., Onderstepoort, Republic of South Africa; 3Inst. for Animal Health, Pirbright Laboratory, Pirbright, UK

The Culicoides imicola complex is represented by seven morphological described species (Meiswinkel, Onderstepoort J. Vet. Res., 1989; 1991; 1992; 1995). The taxonomic rank of species assigned on morphological basis has been already validated by the use of the molecular technique AP-PCR (Sebastiani et al., VII Congr. Europ. Soc. Evol. Biol., 1999). In the Old World C. imicola ss and C. Congr. Europ. Soc. Evol. Biol., 1999). In the Old World C. Imicola ss and C. bolitinos represent the only verified vectors of African Horse Sickness Virus (AHSV) and Blue Tongue Virus (BTV) (Meiswinkel, et al. 1994 - Vectors: Culicoides spp. In Infectious Diseases of Livestock, with special reference to southern Africa, pp. 68-89 [J. A. W. Coetzer, G. R. Thomson & R. C. Tustin. Eds.] Cape Town, Oxford Univ. Press). The morphological discrimination between the seven cryptic species is very difficult but essential for preventive and epidemiological studies of virus transmission. For this purpose we have developed an approach based on diagnostic PCR and restriction enzyme analyses. The second internal transcribed spacer (ITS2) of the ribosomal DNA was considered to discriminate the seven cryptic species of the Culicoides imicola complex from Southern Africa. After amplification and sequencing of ITS2 of all seven C. inicola species, the length of the ITS2 was in the range of 350 and 395bp among species. The variation in the length of the ITS2 is due to indels in simple repeats and in species-specific sequences. Differences in the presence of restriction sites may be useful for the identification of the species of the C. imicola complex. Besides, primers can be constructed for species-specific PCR amplification of midges DNA based on differences in their nucleotide sequences. Index terms: Culicoides inticola, species complex, ITS2 polymorphism, PCR assays.

[2316] SPECIES DIAGNOSTIC DIFFERENCES IN RIBOSOMAL DNA INTERNAL TRANSCRIBED SPACER 2 FROM SEVEN CRYPTIC SPECIES OF TILE CULICOIDES IMICOLA COMPLEX (DIPTERA: CERATOPOGONIDAE)

F. Sebastinni, **R. Meiswinke**², **P. Mellor**³, **L. M. Gomulski**¹ & **G. Gasperi**¹, ¹Dept. of Animal Biology, Univ. of Pavia, 27100 Pavia, Italy; ²Onderstepoort Veterinary Inst., Onderstepoort, Republic of South Africa; ³Inst. for Animal Health, Pirbright Laboratory, Pirbright, UK

The Culicoides inicola complex is represented by seven morphological described species (Meiswinkel, Onderstepoort J. Vet. Res., 1989; 1991; 1992; 1995). The taxonomic rank of species assigned on morphological basis has been already validated by the use of the molecular technique AP-PCR (Sebastiani et al., VII Congr. Europ. Soc. Evol. Biol., 1999). In the Old World C. imicola ss and C. bolitinos represent the only verified vectors of African Horse Sickness Virus (AHSV) and Blue Tongue Virus (BTV) (Meiswinkel, et al. 1994 - Vectors: Culicoides spp. In Infectious Diseases of Livestock, with special reference to southern Africa, pp. 68-89 [J. A. W. Coetzer, G. R. Thomson & R. C. Tustin. Eds.] Cape Town, Oxford Univ. Press). The morphological discrimination between the seven cryptic species is very difficult but essential for preventive and epidemiological studies of virus transmission. For this purpose we have developed an approach based on diagnostic PCR and restriction enzyme analyses. The second internal transcribed spacer (ITS2) of the ribosomal DNA was considered to discriminate the seven cryptic species of the Culicoides imicola complex from Southern Africa. After amplification and sequencing of ITS2 of all seven C. imicola species, the length of the ITS2 was in the range of 350 and 395bp among species. The variation in the length of the ITS2 is due to indels in simple repeats and in species-specific sequences. Differences in the presence of restriction sites may be useful for the identification of the species of the C. imicola complex. Besides, primers can be constructed for species-specific PCR amplification of midges DNA based on differences in their nucleotide sequences

Index terms: Culicoides imicola, species complex, ITS2 polymorphism, PCR assays.

[2317] CHARACTERIZATION OF CRYPTIC SPECIES OF THE ANASTREPHA FRATERCULUS COMPLEX

D. Selivon, Depto. de Biologia, Univ. São Paulo, C.P.11461, São Paulo, SP, 04522-970, Brazil, E-mail dselivon@usp.br.

Since the 40's it is known that the nominal species Anastrepha fraterculus presents a large variability in the wing pattern. In the last decades analysis of isolate biological attributes, as karyotype, isozymes, mt DNA, lead to the suggestion that the species could indeed harbour a complex of cryptic species, the "A. fraterculus complex". However, no limits among the species were determined. Recently, using combined studies of several characteristics (chromosomes, isozymes, morphometric parameters and crossing), followed by analysis of eggshell morphology and embryonic developmental patterns, two species were found and provisorily named Anastrepha sp 1 aff. fraterculus and A. sp 2 aff. fraterculus (appearing in previous publications as A. fraterculus type 1 and type 2 or sp 1 and sp 2). Here we describe characteristics of individuals of A. fraterculus collected in two localities, one in the southeast coast of Brazil, and the other in the coast of Ecuador. In both, the karyotypes present 12 chromosomes similarly to Anastrepha sp 1 and sp 2. However, conspicuous differences were found in the sex chromosomes mainly in relation to the presence and size of blocks of heterochromatin (C-bands). Differences in the ornamentation of the eggshell allow discrimination of the four populations. The mesonotum and wing patterns are somewhat variable within populations but the differences among populations are larger, specially in individuals from the brazilian coast where the distinctive yellowish stripes of the mesonotum are not found. In this population, the proximal portion of the wings is clearly distinctive from the other ones. The results so far obtained indicates that the southeastern brazilian and the ecuadorian populations can be distinguished one from the other as well as they can be differentiate from the described Anastrepha sp 1 and sp2. Although more studies are necessary with the two populations here described, the data suggest that they may represent two other biological entities in the "Anastrepha fraterculus complex" Index terms: fruit flies, chromosomes, eggshell, morphology

[2318] RESTORATION OF CIRCADIAN BEHAVIORAL RHYTHM OF DROSOPHILA DOUBLE-TIME MUTANTS BY GENE TRANFER

<u>M. Shimoda¹</u>, M. W. Young² & L. Saez², ¹Dept. of Insect Genetics, Inst. of Sericul. Entomol. Sci. Ohwashi1-2, Tsukuba, Ibaraki 305-8634, Japan; ²Lab. of Genetics, and NSF Science and Technology Center for Biological Timing, The Rockefeller Univ., 1230 York Avenue, New York, NY 10021, USA

double-time (dbt) is a casein kinase gene involved in cell survival and circadian rhythms in the fruitfly, *Drosophila melanogaster*. Mutant alleles of *dbt* shorten or lengthen the period of circadian rhythms and the null allele causes lethality during early development. The effect of the expression of *dbt* on the lethality and locomotor activity rhythm of *dbt* mutants were studied. Using a *gal4-UAS* gene expression system, *dbt* expression from the *armadillo* promoter averted lethality caused by the

strongly hypomorphic mutant dbt . Many rescued flies showed abnormal wing

revVIII angle and lost the flight activity. dbt flies carrying a full-length dbt transgene showed ~24 hrs locomotor activity rhythm, indicating that a functional Drosophila clock can be restored entirely in the null mutation through dbt expression. Furthermore, dbt over-expression never shortened the locomotor rhythm of both dbt mutants and wild-type fly below the normal period (~24hrs), indicating that the DBT activity was saturated in wild-type flies. The ability of the kinase domain of dbt and the mammalian homologue of dbt, casein kinase I epsilon (hckle), to rescue the lethality and locomotor activity rhythm caused by dbt mutant was also tested. Under the same condition in which full length dbt rescued the null allele, neither the kinase domain of dbt nor the heterologous kinase could rescue the dbt mutant phenotype. These observations suggest that CKIe can not replace dbt activity in flies and that the C-terminal region of dbt appears to be indispensable for their regulatory activity. Index terms: circadian clock, locomotor activity, casein kinase I, dbt [2319] BIOCHEMICAL CHARACTERIZATION AND GENOMIC ORGANIZATION OF H. CUNEA LECTIN

<u>S. W. Shin</u>, D. S. Park & H.-Y. Park, Insect Resources Laboratory, Korea Research Institute of Bioscience and Biotechnology, 52 Eoun-dong, Yusong, Taejon, 305-600, Korea, E-mail hypark@mail.kribb.re.kr.

We previously identified a novel lectin cDNA from the fall webworm (Shin et al., 1998), which encodes two carbohydrate recognition domains (CRD-N and CRD-C) and is up-regulated following bacterial challenge. The lipopolysaccharide binding activities of the recombinant CRD-N and CRD-C (rCRD-N and rCRD-C) were investigated by enzyme-linked immunosorbent assay. The lipopolysaccharide binding of rCRD-N and rCRD-C was pH-dependent: at pH below 6.0, they show higher binding ability to lipopolysaccharide. The binding of the recombinant CRD-N was inhibited by both D-mannose and N-acetyl-D-glucosamine, whereas the binding of both rCRD-C was inhibited only by D-mannose. The binding of both rCRD-C was inhibited only by D-mannose. The binding of both rCRD-N and rCRD-C to *E. coli* was mainly mediated through the O-specific chain. The result of Southern analysis suggested the existence of several genes similar to *H. cunea* lectin in the genome. Several different genonic clones of H. cunea lectin were isolated and sequenced. The characteristics of these clones will be discussed. Index terms: carbohydrate recognition domain, CRD-N, CRD-C

[2320] CYTOGENETICS OF SOME SPECIES OF PARASITIC WASPS OF THE FAMILIES PTEROMALIDAE AND EULOPHIDAE

J. C. Silva-Junior¹, S. G. Pompolo¹ & L. A. O. Campos¹, ¹ Depto. de Biologia Geral, Universidade Federal de Viçosa - UFV, 36571-000. Viçosa - MG, Brasil. Email: juvenaljr@bol.com.br

The parasitoid insects are organisms that develop on or inside a host that represents the food source necessary to complete their development and represent a intermediary life style between predators and parasites. Several cytogenetic studies of parasitic wasps have been performed on the last years. However, a few of them provide information about localization of constitutive heterochromatin regions or NORs. The aim of this work was to characterize cytogenetically five species of Eulophidae (Emersonella sp., Palmistichus eloeisis, Melittobia hawaiiensis, Melittobia australica e Trichospilus diatraeae) and two species of Pteromalidae (Spalangia endius and Muscidifurax uniraptor), determining the number and the morphology of the chromosomes, distribution of constitutive heterochromatin, NOR-bands and localization of AT- or CG-rich regions. Data were obtained using techniques of standard staining, C-band, NOR-band and the fluorochromes DAPI/CMA3. From the total species of Eulophidae, four showed 2n=12 chromosomes. The only exception was T. diatracae with 2n=14 chromosomes. Among the Pteromalidae, M. uniraptor showed 2n=10 and S. endius, 2n=12. C-banding data demonstrated that the majority of species showed small heterochromatics blocks randomly dispersed in the chromosomes. The only exception was S. endius which showed a distinct pattern of pericentromeric heterochromatic blocks. In all species, NORs were only found in one chromosome pair and two regions in the interphasic nucleus. The results obtained with fluorochromes pointed small DAPI bands in P. eloeisis and CMA₃ in M. hawaiiensis. In M. hawaiiensis there was a correspondence between NOR and CMA3 bands. S. endius showed coincident bands of DAPI, CMA3 and C-band. The results obtained with giernsa pointed a great uniformity of size, type of chromosome and number of karyotypes in all studied species. Considering the modal theory of karyotype evolution, we could propose that Eulophidae present six as a modal number, so the chromosomic number 2n=14 observed in T. diatraeae could be resulted of a fission in a metacentric pair in the ancestral karyotype, resulting in two new acrocentric pairs. In the Pteromalidae the modal number is five, so the karyotype of S. endius could be resulted of a centric fission in a metacentric pair. Index terms: chromosomes, karyotype evolution, hymenoptera, parasitoid

[2321] THE 4-KDA PROTEASE INHIBITOR FAMILY IN THE DESERT LOCUST SCHISTOCERCA GREGARIA: MOLECULAR CLONING AND ANALYSIS OF TISSUE- AND STAGE-DEPENDENT EXPRESSION

G. Simonet, I. Claeys, R. Maes, T. Janssen, A. De Loof & <u>J. Vanden Broeck</u> Lab. for Developmental Physiology and Molecular Biology, Zoological Institute K.U.Leuven, Naamsestraat 59, B-3000 Leuven, Belgium

Serine proteases and their corresponding inhibitors play a crucial role in the regulation of a large variety of physiological processes, such as food digestion, blood clotting, embryogenesis, tissue reorganization, defense mechanisms and immune responses. Based on their structural characteristics, serine protease inhibitors were initially classified in twelve distinct families (Laskowski and Kato, 1980). Recently, members of a novel peptide family (the 4-kDa protease inhibitor family) were discovered in invertebrates. Boigegrain et al. (1992) and Nakakura et al. (1992) independently reported the identification of two serine protease inhibitors (PMP-D2 and PMP-C) from the migratory locust, Locusta migratoria. Kromer et al. (1994) showed that both peptides were derived from a single precursor polypeptide. A third related peptide (HI) was identified by Kellenberger et al. (1995) and by means of NMR spectroscopy the solution structures of PMP-D₂ and PMP-C were analyzed (Mer et al. 1994, 1996). More recently, five additional members, designated as SGPI-1-5, were isolated (Hamdaoui et al., 1998) from another locust species, namely Schistocerca gregaria. Although they were initially isolated from the ovaries, further studies revealed the presence of these peptides in different tissues (fat body and gonads). In addition, the cDNAs encoding the precursors for SGPI-1-3 have been cloned and stage- and hormone-dependence of gene expression has been studied in different locust tissues (Vanden Broeck et al., 1998). Based on the available sequence data we have also determined the complete cDNA sequence of the precursors for SGPI-4 and SGPI-5. Interestingly, these two precursors contain three additional peptides that display significant sequence similarities to the other 4-kDa Furthermore, northern blot analysis revealed important tissue-dependent inhibitors. differences in the expression of both precursors.

[2322] FROM GENE OF HONEYBEE (APIS MELLIFERA) TO MOLECULAR PROPERTIES AND FUNCTION OF MAJOR PROTEINS OF ROYAL JELLY

J. Simuth, B. Malecova, K. Bilikova, S. Albert, J. Klaudiny, J. Schmitzova & II. Lehrach, Laboratory for Genetic Engineering, Institute of Chemistry, Slovak Academy of Sciences, Dubravska 9, SK-842 38 Bratislava, Slovak Republic; ¹Max-Planck-Institute for Molecular Genetics, Ihnestrasse 72, D-14195 Berlin, Germany

We started a targeted study of RJ proteins at molecular level by characterisation of the main RJ protein, designated as MRJP1 (1). Sequential characterisation of the MRJP1 gene and its regulation region by the methods used in mapping of human genome showed that it was composed from 5 introns and 6 exons. It was found (2) that MRJP1 was expressed in the brain of an adult honeybee at the sites where the learning and memory centres are located. The MRJP1 was characterised as a member of protein family of major proteins of RJ (MRJP1, MRJP2, MRJP3, MRJP4, MRJP5) represent about 82% of total protein of RJ (3). The obtained sequential data of MRJP3s showed that their C-terminal fragment is composed of multiple, repeating five-membered sequential repeat XQNXX. With this finding is connected also the polymorphous nature of MRJP3s found by DNA analysis of individual honeybees using PCR (4). Also MRJP5 posses repeat region containing 58 repeats of DRF motif (5). This length polymorphism at the level of the nutritional proteins brings a new view on qualitative evaluation of RJ as a substance composed of secretions of various honeybees with different genetical background. It points also to genetical determination of variability in a honeybee colony from the point of view of production of RJ proteins and larval nutrition by individual honeybees. The MRJP family is related to yellow proteins of D. mellanogaster and has no relatives in other non-insect metazoan species. One characteristic feature of RJPs, apparently absent in the Yellow proteins is the presence of repetitive region at their C-terminal (5). The bioactivity of RJ-proteins is not fully evaluated. We prepared these proteins in recombined forms for studies of their structures and their testing as ingredients of larval diet and functional food.

[2323] THE USE OF PHENOBARBITAL IN STUDIES OF *AEDES AEGYPTI* RESISTANCE TO INSECTICIDES

R. C. Sousa & H. E. M. C. Bicudo, IBILCE/UNESP. Rua Cristóvão Colombo, 2265, CEP. 15054-000, São José do Rio Preto-SP-Brasil.

Increased detoxification for resistance to organophosphorous (OP) insecticides has been described in some insects. In Culex pipiens such a mechanism results from overproduction of esterase-A and -B due to gene amplification. A-esterases are organophosphate hydrolyzing serine containing enzymes, such as carboxylesterase, that also inactivates organophosphates. They protect cholinesterases by binding Ops themselves. Phenobarbital (PB) is considered an enzyme inductor able to lower organophosphorous toxicity. Pretreatment with phenobarbital increased the LD₅₀values of several organophosphorous insecticides by 1 to 12 fold for rats and by 1 to 3-fold for mice. PB increased carboxylesterase activity in serum and liver of mice by about 50% and possibly the same amount of plasma cholinesterase activities. The mentioned results suggested the present study on PB effects in changes of esterase patterns of Aedes aegypti, followed by the study of its effect on resistance increase. Two kinds of treatment were performed: (1) a continuous treatment in which Aedes aegypti eggs were put to eclode in 0.10% PB and remained in that medium till adult stage and (2) a descontinuous treatment in which larvae, pupae and adults were treated during 30 hours in medium containing 0.15% of PB before freezing. The frozen fourth instar larvae, pupae and adults were individually used for sample preparations analyzed in polyacrilamyde gels. Esterase activity was visualized in gels by using the α and β naphtyl acetates as substrates. Gels from individuals submitted to continuous and descontinuous treatments compared to the controls showed activity increase or decrease of different bands. These changes of pattern were indicated by the staining degree and thickness of the bands and were supported by profile graphs obtained using an image analysis program. The use of inhibitors in gel preparations allowed to classify biochemically the esterase bands, indicating that the band that exhibited the greatest degree of activity increase is a cholinesterase and the two bands that showed activity decrease are carboxylesterases. As mentioned, cholinesterases as also carboxylesterases are involved in resistance and thus the results already obtained are very promising for the continuing studies. (FAPESP) Index terms: esterases, disease vector, population control

[2324] SEX-SPECIFIC ALTERNATIVE SPLICING OF THE LEPIDOPTERAN HOMOLOGS OF THE DROSOPHILA MELANOGASTER SEX DETERMINING GENE DOUBLESEX

M. G. Suzuki¹, F. Ohbayashi¹, T. Kamiya¹, K. Mita², Y. Koike^{1,2} & T. Shimada¹, ¹Dept. of Agricultural and Environmental Biology, Univ. of Tokyo, Yayoi, Bunkyoku, Tokyo 113-8657, Japan, E-mail gakyo@ss.ab.a.u-tokyo.ac.jp; ²Natl. Inst. of Radiological Science, Anagawa 4-9-1, Inage-ku, Chiba City, Chiba 263-8555, Japan.

A homologue of the bifunctional sex-determining gene, doublesex (dsx), has been identified in the silkworm, Bombyx mori, and has been found to be expressed in a sex-specific manner. We revealed that this homologue, Bmdsx, was transcribed to produce a common primary transcript that is alternatively spliced to yield male- and female specific mRNAs. These sex-specific mRNAs shared a common 5' end. Unlike the dsx gene, sex-specific exon was only one (exon 3, female-specific), and the remaining exons were shared between both sexes. However, in female, the exon 4 was transcribed as a 3' UTR because female-specific stop codon was found in the exon 3, resulting that the amino acid sequence encoded by the exon 4 was malespecific while this exon was transcribed in both sexes. Thus, sex-specific mRNAs encoded polypeptides with a common amino-terminal sequence but sex-specific carboxyl termini. The female-specific acceptor, which is a weak acceptor in dsx, was appeared to be a normal acceptor in Bmdsx because that had the same number of pyrimidines in comparison with the other splice acceptor sites in Bmdsx. This suggests that a splicing enhancer like TRA and TRA-2, which activates a weak dsx female-specific acceptor to promote processing of the dsx pre-mRNA into the femalespecific form, is not required to induce female-specific splicing of Bmdsx pre-mRNA. This idea was supported by the fact that no TRA/TRA-2 binding site could be identified in the female-specific exon of the Bmdsx gene. These results suggest that the sex-specific alternative splicing of the Bmdsx pre-mRNA is regulated by the different mechanisms from those observed in the case of the dsx gene. The dsx homologous genes were also found in the other lepidopteran insects, Bombyx mandarina, Antheraea pernyi, Samia cynthia ricini, and were appeared to be expressed in a sex-specific manner. The level of identity of the sex-specific DSX proteins of these insects with D. melanogaster DSX proteins, across the region corresponding to the DNA binding domain and the oligomerization domain, is greater than 50%. These results suggest the possibility that the dsx homologue in lepidopteran insects would also be transcribed into sex-specific mRNA isoforms and regulate sexual differentiation like the Drosophila dsx gene.

[2325] COSTS AND BENEFITS OF MULTIPLE MATING IN A BEETLE

T. J. B. Taylor¹ & R. H. Smith², ¹²Univ. of Leicester, Univ. Road, Leicester, UK, LEI 7RH. E-mail: tjt3@le.ac.uk

Two geographical strains of Callosobruchus maculatus beetles with contrasting life histories were compared. Female Callosobruchus maculatus beetles were manipulated to experience four different mating treatments. Multiple mating in the Brazil strain increased fecundity but decreased longevity of females. Multiple mating by parents also reduced the longevity of their singly mated offspring. In contrast, multiple mating in the South India strain had no effect on longevity or fecundity of female parents or their singly mated offspring. These differences are interpreted in relation to the trade-off between longevity and fecundity in the two strains. Index terms: Callosobruchus maculatus, fecundity, longevity.

[2326] MOLECULAR PHYLOGENETIC INSIGHTS INTO THE ORIGIN OF TERMITE WORKERS

G.J. Thompson¹, O. Kitade², N. Lo³ & R.II. Crozier¹, ¹School of Tropical Biology, James Cook Univ.Townsville, QLD Australia 4811; ²Faculty of Science, Ibaraki Univ. 2-1-1 Bunkyo, Mito, Ibaraki, 310-8512 Japan; ³Department of Biochemistry, Univ. of Sydney, NSW Australia 2006.

Phylogenetic analysis based on sequence variation in mitochondrial large-subunit rRNA and COII genes was used to investigate the evolutionary relationships among termite families. Maximum likelihood and parsimony analyses of a combined nucleotide data set yielded a single well-supported topology, which is: (((((Termitidae, Rhinotermitidae), Serritermitidae), Kalotermitidae), (Hodotermitidae, Termopsidae)), Mastotermitidae). While some aspects of this topology are consistent with previous schemes, overall it differs from any published. Optimization of 'true' workers onto the tree suggests that this caste originated once, early in the history of the lineage and has been lost secondarily twice. This scenario differs from the more widely accepted notion that workers are derived and of polyphyletic origin, and that extant pseudergates, or 'false' workers, are their developmentally unspecialized ancestor caste. We found that worker gains and losses co-vary directly in number and direction with shifts in 'ecological life type'. A phylogenetically-corrected test for correlated evolution indicates that this pattern is of biological significance and suggests that the variable occurrence of a worker caste in termites has ecological determinants, apparently linked to differences in feeding and nesting habits. Isoptera, mitochondrial-DNA, social-evolution, concentrated-changes-test

[3227] LIFE CYCLE, MORPHOLOGICAL AND GENETIC VARIATION IN CLONES OF MYZUS PERSICAE (HOMOPTERA: APHIDIDAE)

J. A. Tsitsipis¹, J. T. Margaritopoulos¹, R. L. Blackman³, L. Sannino⁴, K. Zitoudi¹, T. E. Kephalogianni¹, Z. Mamuris² & S. Goudoudaki¹, ¹Lab. of Entomology and Agricultural Zoology, ³Lab. of Biology and Chemistry, Univ. of Thessaly, P. O. Box 38334, Pedion Areos, Volos, Greece, E-mail tsitsipi@mail.uth.gr, ³The Natural History Museum, Cromwell Road, London SW7 5BD, UK, ⁴Istit. Sperimentale per il Tabacco, Biology Central Section, P. O. Box 84018, Via Vitiello 66, Scafati, Italy.

During years 1995-1999 life cycle variation of 2,774 Myzus persicae clones, collected from primary and various secondary hosts from different regions of Greece and Southern Italy (Caserta) was studied. Morphological and genetic variation of 166 and 95 clones respectively was examined using canonical variate analysis and random amplified polymorphic DNA (RAPD) analysis. Four life cycle categories were found: holocyclic, androcyclic, anholocyclic and intermediates. Ninety four % of peach originating clones were holocyclic. In peach-growing regions of Greece proportion of holocyclic clones was above 40% reaching up to 100%. Further south proportion of holocyclic clones was above 40% reaching up to 100% reaching the form of holocyclic sound in Greece and Caserta (near Naples), where peach is not common, holocyclic clones ranged between 0 and 30%. Fifty seven % of examined anholocyclic clones produced males under short day conditions. Intermediate clones were sampled from all host-plants but at low frequencies (3.4% of total examined clones or 6.5% of non-holocyclic clones). Red clones were predominant in regions where aphids overwinter parthenogeneticaly on weeds or winter crops. However, almost all clones from primary host were green. Scores of first two canonical variates generally separated tobacco-feeding clones from those of other secondary host-plants. In tobacco areas tobacco-feeding form predominated on peach in spring populations and was sometimes found on other secondary hosts. By cluster analysis tobacco clones from Caserta showed a relatively large phenotypic distance from Greek clones. Clonal phenotypes were affected both by host plant on which clones were reared and by long-term parthenogenetic rearing. In spite of these effects, tobacco form was distinguishable from aphids originating from other hosts. Despite genetic variability found between samples no specific RAPD marker was detected discriminating the different populations. Aphids from peach and pepper, collected far from tobacco regions, showed a genetic divergence from the tobacco-feeding clones. Holocyclic clones from tobacco showed higher level of estimated heterozygosity than anholocyclic (anholocyclic, androcyclic, intermediate) ones.-Observed genetic variation could be associated with different colour of examined clones, since most of anholocyclic clones were red and almost all of holocyclic ones green. Index terms: Myzus persicae, tobacco, peach

[2328] A POPULATION GENETIC COMPARISON OF ISOLATED POPULATIONS OF THE PHYTOPHAGOUS FOREST BEE PHYLLOTRETA TETRASTIGMA (COLEOPTERA: CHRYSOMELIDAE) BEETLE

P. Verdyck^{1,2} & K. Desender¹, ¹Dept. Entomology, RBINSc, Vautierstr. 29, B-1000 Brussels, Belgium, E-mail: verdyck@kbinirsnb.be; ²Dept. of Biology, Univ. of Antwerp, RUCA, Groenenborgerlaan 171, B-2020 Antwerpen.

In Flanders the remaining natural habitats are very fragmented, and this is especially the case for forests. For nature conservation purposes we studied several woodland beetle species. As most of these species are poor dispersers, fragmentation can easily lead to genetic differentiation. Also reduction of habitat can lead to reduction in population size and loss of genetic variation. Here we focus on the relatively rare cruciferous flea beetle Phyllotreta tetrastigma, a species which is restricted to very wet forests, as both larvae and adults only live on the plants Cardamine amara and C. flexuosa. In total 1080 individuals from twelve localities were studied genetically by means of cellulose acetate gel electrophoresis. For several of these localities populations from different years were analysed. Genetic variability was detected at five loci (PGM-1, AAT-1, IDH-1, ME-3 and PEP-Z). All populations were in Hardy-Weinberg equilibrium at all loci. There is no linkage between the different loci. No genetic differences were detected between populations from the same locality but from different years. Although not significant there is a tendency towards more genetic diversity in larger populations. There is significant genetic differentiation between localities, but there is no geographical pattern, probably meaning that even populations that are relatively close to each other are already genetically isolated and differentiated.

Index terms: flea beetle, nature conservation, allozyme electrophoresis.

[2329] GENETIC PATTERNS IN PHYTOPHAGOUS BEETLES OF THE GALÁPAGOS ARCHIPELAGO

P. Verdyck^{1,2}, K. Desender¹ & Dhuyvetter, II.^{2, 1} Dept. Entomology, RBINSc, Vautierstr. 29, B-1000 Brussels, Belgium, E-mail: verdyck@kbinirsnb.be; ² Dept. of Biology, Univ. of Antwerp, RUCA, Groenenborgerlaan 171, B-2020 Antwerpen

The Galápagos islands lie in the Pacific Ocean about 1000 km from the South American coast and straddling the Equator. There are 13 large volcanic islands, 6 smaller ones and 107 islets and rocks, with a total land area of about 8000 square kilometes. 97% of their land area was designated national park, and the islands are also recognised internationally as a Man and the Biosphere Reserve and a Unesco World Heritage Site. The Galápagos are also known as a living laboratory for the study of evolution because they are home to many examples of radiated endemic groups (e.g. Darwin finches, giant tortoises, mockingbirds, Opuntia cacti, Lava lizards). Also the most biodiverse group of organisms, the insects, show several cases of radiated genera, but these have been studied to a much lesser extent. Here we compare results of population genetic and evolutionary studies on a variety of phytophagous beetle genera from the families Chrysomelidae, Oedemeridae and Curculionidae, and with special emphasis on the flea beetles beetles (Alticinae, Chrysomelidae). The techniques used are allozyme electrophoresis, RAPD's and mtDNA sequencing. One of the more striking results is the detection of a metapopulation structure with recurrent extinctions and recolonisations in the endemic chrysomelid beetle Nesaecrepida darwini.

[2330] A MOLECULAR PHYLOGENY OF COLEOPTERA FROM 18S rRNA SEQUENCES

A. P. Vogler^{1,2}, V. L. Shull¹, L Ribera^{1,2}, M. S. Caterino¹ & P. M. Hammond¹, ¹Department of Entomology, The Natural History Museum, Cromwell Road, London, SW7 5BD, ²Department of Biology, Imperial College at Silwood Park, Ascot, Berks SL5 7PY, UK

The Colcoptera (beetles) are traditionally separated into four suborders (Adephaga, Polyphaga, Myxophaga, Archestomata), of which the largest, Polyphaga, is further subdivided into five Series containing the nearly 150 families of the suborder. No formal phylogenetic analysis for the entirety of the coleopteran relationships has been attempted, mostly due to the lack of a consistent character set applicable to all major groups. We used full-length 18S ribosomal RNA sequences to infer relationships of major groups within the Coleoptera. A thorough taxon sampling included exemplar taxa for all suborders and superfamilies, including nearly all families and numerous of the larger subfamilies. In total, some 500 sequences were generated, of which approximately half were selected for formal cladistic analysis. Those excluded mostly exhibited extreme length variation in the expansions segments of the molecule, and/or they were highly divergent from their relatives. The main results support the monophyly of the two large suborders Adephaga and Polyphaga, they support a major split of the terrestrial Geadephaga and aquatic Hydradephaga, and polyphagan relationships broadly agree with accepted ideas. Both the Staphyliniformia and Cucujiformia are recovered as monophyletic. The monophyly of the remaining Series, however, appears questionable. The Elateriformia in particular, appears to be a polyphyletic mix of very basal (Scirtoidea) and derived lineages.

Index: sequence alignment; expansion segments; species richness; rate variation; cladistics.

[2331] THE EVOLUTION OF HOST PLANT USE IN MELITAEINE BUTTERFLIES: A PHYLOGENETIC ANALYSIS

<u>N. Wahlberg¹</u>. ¹Metapopulation Research Group, Dept. of Ecology and Systematics, Div. of Population Biology, FIN-00014 University of Helsinki, Finland, E-mail niklas.wahlberg@helsinki.fi

Plant chemistry is a major determinant of host plant use in phytophagous insects, often dictating the availability of possible host plants. I have investigated the evolutionary history of host plant use in Melitaeini butterflies (Lepidoptera: Nymphalidae). There are four species genera in the melitaeines, with a total of about 250 species. Many species are mono- or oligophagous on species of plant belonging to twelve families of plants. Of these Antirrhinaceae, Orobanchaceae, Acanthaceae and Asteraceae are the most important. Eleven of the plant families utilized by melitaeines contain iridoid compounds, on which many of the butterflies apparently specialize. Plant species in Asteraceae do not contain iridoids. Using a molecular phylogeny of 64 species, I have attempted to elucidate the patterns of evolution of host plant family use in the melitaeines and then studied the effect of host plant chemistry on this pattern. My results show that host plant chemistry has been the driving force behind the evolution of host plant utilization in the melitaeines. There have been possibly five independent colonizations of Asteraceae, the only major host plant anily without tridoids.

[2332] OCCURRENCE OF TWO DELTA-ENDOTOXIN GENES, THE CRY9DA AND A NOVEL ALLIED GENE, IN JAPANESE BACILLUS THURINGIENSIS ENVIRONMENTAL ISOLATES THAT PRODUCE SPHERICAL PARASPORAL INCLUSIONS WITH LEPIDOPTERA-SPECIFIC TOXICITY

N. Wasano¹, M. Ohba¹ & K. Miyamoto², ¹Division of Biorescurce and Bioenvironmental Sciences, Graduate School, Kyushu University, Fukuoka 812-8581, Japan, E-mail wasano@grt.kyushu-u.ac.jp; ²National Institute of Sericultural and Entomological Science, Tsukuba, 305-0851, Japan

Six Lepidoptera-specific Bacillus thuringiensis isolates, that belong to the four H serovars (sotto, fukuokaensis, canadensis, and galleriae) and produce spherical parasporal inclusions, were examined for assignment of the classes of the deltaendotoxin genes. Gene analysis was conducted by PCR technique using primers designed to probe the genes cry9Ca and cry9Da. The data revealed that the deltaendotoxin of the serovar canadensis isolate is encoded by the gene cry9Da, while those of the five other strains are encoded by an undescribed delta-endotoxin gene. DNA fragments from the five strains had an identical 1917-bp nucleotide sequence, covering the four conserved regions and a partial sequence of the block 5 region. The deduced amino acid sequence exibited a 70.6% homology to that of the corresponding region of the Cry9Ea delta-endotoxin protein active on the order Lepidoptera, and a 63.1% homology to the Cry9Ca protein highly toxic to the noctuid The results showed that Japanese isolates of B. thuringiensis lepidopterans. producing spherical parasporal inclusions with Lepidoptera-specific activity are categorized into two groups; one produces the class Cry9Da protein and the another a novel delta-endotoxin allied to the class Cry9. It also appeared that heterogeneous multiple H serovars are involved in each group.

Index terms: Novel cry gene, the class cry9, Lepidoptera specificity.

[2333] GENE EXPRESSION AND THE EVOLUTION OF INSECT POLYPHENISMS: INTRODUCTION

<u>D.E. Wheeler</u>¹, J.D. Evans², ¹Dept. of Entomology, Univ. of Arizona, Tucson, AZ 85721-0036, USA, E-mail: dewsants@ag.arizona.edu; ²Bee Research Lab, USDA-ARS BARC-E, Bldg. 476 Beltsville, MD 20705 E-mail: jevans@astr.arsusda.gov

Insects seem to have a special evolvability in regard to plasticities and polyphenisms. In many species, environmental variation during larval development leads to a continuum of variation in one or a few morphological traits. In polyphenic taxa, distinct sets of characters respond together, producing more profound differences between forms. Recent advances in molecular genetics, and their successful transfer from model to outlaw systems, portend rapid progress in understanding the developmental basis of a diversity of insect polyphenisms. Questions that can now be addressed include (1) the functional and evolutionary relationship between reactions norms and polyphenisms, (2) the developmental relationships between multiple morphs in complex systems such as aphids, (3) the relationship between mechanisms mediating allelic and polyphenic differences among the same characters, and (4) the role of hormones in coordinating the expression of alternative polyphenisms. Success of molecular genetics tools in tackling polyphenisms will have no greater impact than in our understanding of social insects. Previous studies aimed at the mechanisms behind social insect polyphenisms were slowed by the fact that no social insect species have been developed into a model genetic system. This barrier has fallen on several counts. First, new techniques for isolating differentially expressed genes, including cDNA subtraction and differential-display techniques, are being used to screen social insect genomes for genes involved with both regulatory and downstream steps on the route toward polyphenisms. Second, genome-wide studies of expression in other insects, including *Drosophila*, provide a rich source of potential homologues that can be screened in social insects. As one example, juvenile hormone-responsive genes isolated from Drosophila might be involved in similar ways in reproductive caste determination and development in social insects. Further, gene-expression studies of metamorphosis and other major developmental events in Drosophila will almost certainly clarify processes important for the evolution of phenotypic variation in polyphenic species. Finally, the honey bee, Apis mellifera, has emerged as a bona fide genetic organism, thanks to a fairly complete physical map, available DNA and cDNA gridded libraries, and an abundance of data on the genetic components of behavior and physiology. While this system lacks attributes that will push it into the realm of established genetic systems, including a demonstration of transgenesis or a viable tissue-culture protocol, honey bees show traits such as male haploidy and an efficient method for artificial insemination that make them unique among insects for studies of genetic mechanisms.

[2334] WEAK EXPRESSION OF EGFP IN TRANSGENIC AEDES AEGYPTI AND STOMOXYS CALCITRANS DESPITE THE PRESENCE OF MULTIPLE COPIES OF THE TRANSGENE

R.Wilson¹, M. J. Lehane², P. W. Atkinson³ & D. A. O'Brochts¹, ¹Center for Agricul. Biotech., Plant Sci. Bldg., Univ. of Maryland, MD 20742, USA. ²School of Biol. Sci., Univ. of Wales, Bangor, Gwynedd, LL57 2DG, UK. ³Dept. of Entomology, Univ. California, Riverside, CA 92521, USA.

Transgenic Aedes aegypti and Stomoxys calcitrans were created by embyonic injection of Hermes elements containing the EGFP gene, under the control of the actin5C promoter. Transgenic lines were identified by the presence of expressed EGFP in the G₁ progeny. All of the lines identified, one in Aedes and four in Stomoxys, exhibited an unexpectedly weak expression of EGFP. In the Stomoxys inset the expression of EGFP was limited to a few distinct, small spots of fluorescence, while the Aedes line EGFP expression was only visible in the pupae as a very weak, diffuse glow throughout the head and thoracic regions. No EGFP-specific fluorescence was detectable in either the larvae or adults of Aedes. All of the lines were shown to be transgenic by both PCR and Southern blot analysis of genomic DNA, and each contained at least two copies of the Hermes element. These results suggest that the actin5C promoter might not be ideal for use as a promoter for transgenic markers in these species.

[2335] EVOLUTIONARY TRENDS ON MALE GENITAL STRUCTURES OF CHALCOSIINAE (LEPIDOPTERA: ZYGAENIDAE)

S. II. Yen¹, D. L. Quicke^{1, 2}, & G. S. Robinson², ¹Dept. of Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY UK, E-mail s.yen@ic.ac.uk; ²Dept. of Entomology, British Museum (Natural History), Cromwell Rd., SW4 5BD, London, UK.

The evolutionary trends of male genital structures with the associated 8th abdominal segments of Chalcosiinae (Zygaenidae) are examined. In our preferred cladogram, two major lineages are recognized. The first lineage, comprising of Agalopini + Aglaopini + Cyclosiini + Heteropanini assemblage, has typical lepidopterous genital and abdominal structures without any modification. However, the second lineage, comprising of Chalcosiini sensu lato, has the valva (=clasper) and uncus greatly reduced or rudimentary and morphologically and functionally replaced by the 8th tergite and sternite. A complicated structure formed by fusion of an extension of the tegumen, interior apodemes and juxta is newly recognized in Chalcosiinae sensu lato. The homology of sclerites of the male genitalia, the possible sister-group, the monophyly, tribe and genus-level systematics of this subfamily are also discussed.

[2336] DENTIFICATION AND CHARACTERIZATION OF THE KS-1 GENE, WHICH IS EXPRESSED PREFERENTIALLY IN THE SMALL TYPE-KENYON CELLS OF THE HONEYBEE BRAIN.

D. Yoshino¹, M. Sawata¹, H. Takeuchi¹, A. Kamikouchi¹, K. Sekimizu¹, S. Natori² & <u>T. Kubo</u>^{1, 1}Grad. Sch. Pharm.Sci., Univ. Tokyo, Bunkyo-ku, Tokyo, 113-0033 Japan; and ²Natori Special Lab. RIKEN, Wako-shi, Saitama, 351-0198, Japan

The honeybee Apis mellifera L. is a social insect, and various exquisite social behaviors are performed by their colony members. To analyze the molecular basis of their social behaviors, we have searched for genes that are expressed selectively in the mushroom bodies, putative sensory integration centers of the honeybee brain. The honeybee mushroom bodies consist of two types of intrinsic neurons, large and small-types of Kenyon cells. By the differential display method, we first identified a gene (Ks-1) which was expressed selectively in the small type-Kenyon cells of the mushroom bodies. Possibly, the function of the Ks-1 gene product is specifically needed for the small type-Kenyon cells. To determine the nucleotide sequence of the full length Ks-1 cDNA, we performed cDNA walking and identified a consensus Ks-1 cDNA sequences of 17.3kbp in length. We also isolated a genomic clone and identified a putative transcription initiation site of the Ks-1 gene by the primer extension method. Unexpectedly, many termination codons appeared all over the nucleotide sequence of the Ks-1 cDNA and no ORF longer than 300bp was contained in the sequence, suggesting that the Ks-1 transcript encodes no proteins and functions as an untranslated RNA. The analysis of the biological function of the Ks-1 transcript would be an important cue to understand the molecular basis of the division of the function of the Ks-1 transcript encodes no proteins and functions.

[2337] TRACKING AUSTRALIAN FRUIT FLIES USING MICROSATELLITES

H. Yu¹, M. Frommer¹, <u>M.K. Robson¹</u>, B. Dominiak², A. Meats¹ & J.A. Sved¹, ¹ Fruit Fly Research Centre, School of Biological Sciences A12, The University of Sydney. 2006. AUSTRALIA¹² New South Wales Department of Agriculture, Locked Bag 21, Orange 2800. AUSTRALIA.

Microsatellites are variable repeated segments of DNA that are proving extremely useful in population analoyses. A six year survey of endemic regions of the major Australian fruit fly pest, *Bactrocera tryoni*, using microsatellites will be presented. The results indicate a surprising stability over time for the sub-regions of this fly. The major export fruit growing area of mainland Australia is within the Fruit Fly Exclusion Zone (FFEZ). This is an area of 180,000 square kilometres covering the borders of three states, New South Wales, Victoria and South Australia, and its management is covered by the 'TriState Agreement'. Any infestation occurring within the FFEZ results in suspension of exports from crops within a 30-80 km radius (and a lesser radius for domestic markets). In the past 3-4 years, exceptionally mild and wet weather has been associated with many severe breaches of the zone. The identification by the Fruit Fly Research Centre of characteristic patterns of microsatellites in the DNA of fruit flies trapped by the New South Wales Department of Agriculture has provided strong evidence that: (a) fruit flies causing infestation within the FFEZ come from the small towns surrounding the zone. (b) fly populations in these towns are distinct and do not receive a substantial number of immigrants from capital cities or the coast. This research by the Fruit Fly Research Centre has been supported by Woldworths Supermarkets through the Horticultural Research & Development Corporation.
