The noctuid moth species Helicoverpa armigera and Helicoverpa punctigera (heliothis) are major agricultural pests in Australia. Attributes contributing to their pest status include high mobility, high fecundity, polyphagy and a facultative diapause. Moths of both species undertake long distance migratory flights between regions as well as long- and short-range non-migratory flights within regions. These movements affect pest management in a variety of ways. For example, spring migration from non-cropping regions is a major source of moths early in the season, and also dilutes insecticide resistance genes selected for within the cropping regions. Movements within regions quickly spread problems of resistance or large numbers of moths among properties and between crops of different types. Moth movement is of particular interest to area-wide management because many area-wide management strategies make assumptions on movement patterns. For example, strict management of heliothis in early spring crops will significantly reduce pressure on summer crops only if the majority of summer moths are produced locally rather than by migration from other regions. Also, trap crops will be effective only if moths originating some distance from the trap crops move around enough to encounter them. Moth flight behaviour has been studied with techniques such as radar, aerial trapping, mark-recapture, natural markers and flight mills. These techniques provide information on movement processes that can be used to predict the effects of movement on the distribution and abundance of the insects. Empirical analysis of abundance data provides a means to validate such predictions and to estimate some movement parameters. Commercial crop scouting records are a low-cost source of such data for cotton growing regions in Australia. Regular (roughly twice weekly) counts of the egg and larva lifestages can be obtained for areas large enough for use in studies of regional movement. In this study we tested hypotheses on the movement of moths into and within a cropping region by applying spatial and non-spatial statistics to such scouting data. The study region was a 15×15-km mixed cropping area in the subtropical Darling Downs region of eastern Australia. We illustrate the types of hypotheses that can be tested with this kind of analysis, and discuss the suitability of commercial scouting records for such analysis. Index terms: Helicoverpa, movement, spatial ecology.

[0752] USING THE INTERNET TO SERVE ENTOMOLOGY TEACHING, RESEARCH AND EXTENSION AT IOWA STATE UNIVERSITY

J. K. VanDyk¹, ¹Dept. of Entomology, Iowa State Univ., 411 Science II, Ames, IA 50011-3222, USA, E-mail jvandyk@iastate.edu.

The Department of Entomology at Iowa State University is using the Internet to serve the department in various innovative ways. Distance education courses allow students from diverse geographic areas to participate and learn through instruction, interaction, and simulation. The production of photographically accurate virtual insects aids in instruction. The Entomology Index of Internet Resources serves as a directory and search engine for the discipline of entomology, allowing researchers to quickly locate information on the Internet. Search engine technology being developed within the department organizes integrated pest management information. Several newsletters for agricultural workers, gardeners and homeowners are published in print and via the web using databases and a content management system, emphasizing fast delivery of information to the end user. The website for the general public (http://www.ent.iastate.edu) receives more than one million hits each month. An interactive camera promotes selected insects within the Iowa State University Insect Zoo, serving as marketing for our school outreach program. Videoconferencing and digital cameras are used to identify insects from remote sites within Iowa. The end result is that technology is being used effectively in many ways that serve the mission of the Department of Entomology at Iowa State University. Index terms:Iowa,teaching,extension,WWW,internet

[0753] INTERNATIONAL INFORMATION SYSTEM ABOUT BIOLOGICAL CONTROL OF PESTS THROUGH THE INTERNET

<u>L. A. N. de Sá ¹</u>, D. Canhos ² & N. C. Gattaz¹, ¹Embrapa Meio Ambiente, C.P. 69, 13820-000, Jaguariúna, São Paulo, Brasil, E-mail Ians@cnpma.embrapa.br ; ²Fundação Tropical de Pesquisa e Tecnologia "André Tosello", 13087-010 Campinas, São Paulo, Brasil.

In Brazil, the use of biological control of pests has grown as a means of using less aggressive practices to the environment and maintaining species diversity. As a result of a cooperation between Embrapa Meio Ambiente and the Fundação André Tosello, an international information system on Biological Control was established in 1994, with a view of facilitating the interaction and integration of the scientific community worldwide. The System permits an informal and immediate contact of a great number of people dealing with different activities related to biological control through the internet. A discussion list, open to all interested, was set up to permit the exchange of information and experience among scientists. The list (biocontrol-l@bdt.org br) has 530 subscribers and also has a "read only" version set up as a database on the internet that is freely available (http://www.bdt.org.br/listas/biocontrol-I/). A side from the discussion list, which was the starting point of the information system, a number of databases were structured to further promote the exchange of information. The System, freely available on the internet (http://www.bdt.org.br/biocontrol), has the following information: Directory of Institutions that work with Biological Control of Insects, Who is Who in Biodiversity in Brazil, Who is Who in Risk Analysis of the use of Biocontrol Agents, Who is Who in Entomology, Legislation Relative to Biological Control (GATT: Agreement on the Application Sanitary and Phytosanitary Measures, Legislation of Argentina, Brazil, Chile), COSAVE (Plant Health Committee), Publications on Biological Control available at Embrapa Meio Ambiente and other biological control links. This system has contributed to the dissemination and exchange of information about biological control and shall be further developed in accordance with future demands.

[0755] DESIGNING EFFECTIVE MULTIMEDIA TEACHING PACKAGES FOR ENTOMOLOGY

D. J. Robinson, Dept. of Biological Sciences, Open University, Milton Keynes, MK7 6AA, U.K. Email d.j.robinson@open.ac.uk.

Educational multimedia is a relatively new field and fully evaluated examples of good design are not yet widely recorded in the literature. However, there are a number of rules that can guide the designer of teaching and learning packages and arguably the key rule to the design of effective multimedia teaching packages is to provide a substantial level of interactivity. In designing teaching and learning material for distance education in biology, it has been necessary to simulate on the computer, some of the exercises that students would undertake in laboratory or field situations. No simulation can recreate the real experience perfectly, but a simulation can teach a range of skills necessary for the entomologist in the laboratory or field. As part of the investigation of a section of woodland, students are required to collect data on insects that could form food for predators. By analysis of the energy content derived from the food, the students can build up a picture of the ecological relationships between the animals in the food chain and quantify the energy levels between one trophic level and the next. In addition to teaching ecological methods, the students learn about the use of field guides, insect life cycles and the distribution of insects within a woodland, at different seasons. The entire exercise is carried out by students learning in their own homes, using a computer. They receive the exercise on a CDROM that has been sent to them through the post. The taxonomy of the insects is also taught using a CDROM. A hierarchical browser is provided, which allows students to see the relationships between different groups and the characters that are used to distinguish between taxa. The browser is well illustrated with still pictures, video and sound. While these CDROMs were produced for use in distance education, they have a wider utility for biological education since the skills they teach are generally applicable and they have interactivity as the basis of their design.

[0757] REAL ENTOMOLOGY ON COMPUTER: USING MULTIMEDIA TO TEACH PRACTICAL SKILLS

M. J. Hall, Dept. of Biological Sciences, Open Univ., Milton Keynes, MK7 6AA, UK, Email: m.j.hall@open.ac.uk.

The Holly Leaf Miner is a multimedia tutorial on CD-ROM which forms part of the UK's Open University distance-learning course for first-level undergraduate students, \$103 Discovering Science. One of the inherent problems of teaching science to distancelearning students is the difficulty of teaching practical skills. Holly Leaf Miner addresses this issue by introducing some simple practical skills while at the same time providing students with some basis information about insects and their ecology. Students studying the CD-ROM first learn, by means of a series of interactive exercises, about the life-cycle of the holly leaf miner (Phytomyza ilicis) and some the parasitoid wasps that prey on it (using Chrysocharis gemma and Sphegigaster pallicornis as examples). They then go out into the field to collect holly leaves that have been mined by holly leaf miner. This section introduces them to sampling techniques. Guided by the CD-ROM, they then inspect the leaves, dissecting them if necessary, count the proportion of miners that emerged successfully and identify the mortality factors affecting those that did not. This section introduces them to the use of a hand-lens and dissecting equipment, the problems of dealing with biological materials, and the concept of using an identification key. Next, they carry out a k-factor analysis on the data they have collected, and interpret the results in terms of the importance of the various mortality factors for their population. They also compare their own data with similar data collected from a particular holly bush near the Open University over several years. This enables them to consider the reasons for variation in mortality factors between different populations and between different years and interpret the Open University data set in terms of key and regulating mortality factors. The final section looks at the importance of mortality factors in biological control, using data on the whitefly Trialeurodes vaporariorum and the parasitic wasp Encarsia formosa. Index terms: Phytomyza ilicis, Chrysocharis gemma, Sphegigaster pallicornis, distance learning, mortality factor

[0756] THE INTERNET-BASED MULTIMEDIA TAXONOMIC DATABASES AS TOOLS IN ENTOMOLOGICAL EDUCATION

P. Naskrecki, Dept. of Ecology and Evolutionary Biology, University of Connecticut, Storrs, CT 06269, USA, E-mail piotr@neca.com.

The development and explosive growth of the Internet have presented teachers with many new and exciting tools for teaching entomology at levels ranging from primary to graduate. The resources available through the web technology can be as simple as teaching curricula for particular courses, and as complex as complete biological databases of insect taxa. The Internet provides the students not only with the information they need but also an easy way to publish their own findings. The interactive nature of the web encourages further exploration of topics and helps establish contacts between the students of entomology and specialists in particular areas. Taxonomic databases are particularly helpful in initiating student interest in entomology. The very first step in nearly every insect-related project is to identify the study organisms and find what is already known about them. This also used to be the most time consuming and tedious process, resulting in many students getting discouraged at the very beginning of their path. Complete taxonomic databases give a great starting point, regardless of whether the proposed project relates to behavior, distribution, or taxonomy of iasects. In the best case scenarios, such databases allow one to easily generate lists of species of particular taxa and geographic regions, or find relationships between host and parasite species, and locate food plant information. Taxonomic databases available now vary in quality and scope, but there is a clear tendency for making such databases more inclusive, easier to use, and geared towards a user with little entomological background. For example, the Orthoptera Species File Online, a web database of the orthopteroid insects of the world is one of the most complete taxonomic databases currently available, and has been extensively used by students and teachers worldwide for nearly 3 years. It provides users with complete literature references for all species of the Otthoptera, nearly 10,000 images of species, and sound recordings. It has been used in teaching in grade schools, high schools, and graduate research.

Index terms: insect identification, literature references, taxonomy, teaching

[0758] USING INSECTS IN THE CLASSROOM: A DISTANCE LEARNING COURSE

J. G. Stoffolano Jr., Department of Entomology, University of Massachusetts Amheist, MA 01003-2410, Phone 413-545-1046, Fax 413-545-2115, stoff@ent.umass.edu`

The effectiveness of distance learning is greatly influenced by the instructional medium used and the subject matter. Information about insects and their popularity amongst children are unmatched. Insects continue to increase in popularity throughout the world as vehicles to teach science process skills to preK-12 students. In addition to their universal polularity, they are ideal subjects for use in a multimedia distance learning course. They are visually captivating in color, shape and movement. Also, many excellent websites already exist for developing online-lesson based activities. This course capitalizes on the above qualities of insects, the enthusiasm children have for insects, and uses three different delivery systems for helping students most effectively learn how to use insects in their classrooms. Each week there are three different learning activities: (1) Participants view a 60 minute video which contains science content about insects, as well as a visiting guest(s) who discusses a pedagogial topic in the context of insects in the classroom; (2) Based on each video, students take an on-line, web-based quiz using the OWL program developed by the Univ. of Massachusetts. They also engage in an one hour online computer based portion of the course. The online workbook contains questions and activities based on the video, the resource materials, class handouts, and requires the students to use the internet, websites and course listserv; (3) The third portion of the course consists of live, interactive videoinstruction using the PictTel system. A brief discussion of the three different modes of deliver and a demonstration of various intructional materials will be presented.

[0761] AN INTERACTIVE INFORMATION RETRIEVAL AND REFERRAL SYSTEM FOR WORLDWIDE ELECTRONIC IPM INFORMATION

W. I. Bajwa & Marcos Kogan, Integrated Plant Protection Center (IPPC), Oregon State University, Corvallis, OR 97331-8530, USA.

The volume and variety of online IPM research and extension information are growing at an exponential rate. This information is poorly organized at present, as it is also for most other specialized fields. The World Wide Web is growing faster than the ability of Internet indices (Yahoo, Excite, Northern Light, Infoseek, HotBot, etc.) to organize access to the information it contains. Database of IPM Resources (DIR), an internet-based information system, was developed as a user friendly interface to online IPM information. DIR is a database of "metadata" that functions as an information system, linking IPM researchers and practitioners through a central network, which can be used by anyone seeking crop protection information. The basic goals of this system are: (a) to assist in IPM information dissemination, (b) raise public awareness about new and emerging techniques for agricultural, forest, livestock and medically-important pests, and (c) provide support for decision-making in IPM. The overall goal of (his system is to promote global IPM development and adoption through rapid access to useful information developed by specialists from all across the globe. The design and schema of this database allow a user to retrieve desired information with minimum efforts in as little time as possible. DIR presents Internet IPM resources in a logical, structured, and searchable way that greatly reduces the frustration and disappointment often encountered when using general search engines on the web. This system is presently a compendium of 2,000 documents, i.e., unique URLs developed specifically for DIR. DIR has three main components including informational databases & knowledgebases, directories of Internet IPM resources, and search engines. Currently, DIR contains four informational databases, seven bibliographic databases, five knowledgebases, and a database with more than 5,500 documented Internet resources and their hyperlinks searchable through its simple and advanced search engines. DIR covers a wide array of crops, pests, control tactics, organizations, technical/scientific societies, educational and research institutions, and related topics in a format that is searchable, highly customized, and user-friendly. DIR is available at www.IPMnet.org/DIR/ and ippc.orst.edu/DIR/.

[0760] DESIGN AND ANALYSIS OF TIME-MORTALITY BIOASSAYS AND WEB-BASED PROGRAM DISTRIBUTION

J. E. Throne¹, ¹USDA-ARS Grain Marketing and Production Research Center, 1515 College Ave., Manhattan, KS 66502, USA, E-mail throne@usgmrl.ksu.edu.

The design of bioassays to determine the time to death of insects treated with a conventional insecticide or a biopesticide is discussed. Methods for analyzing data from time-mortality assays are reviewed, including the advantages and disadvantages of both non-parametric and parametric methods. Non-parametric methods reviewed include the Kaplan-Meier method. Parametric methods include the logit model developed by Bliss and programmed in ViStat, and an adaptation of the probit analysis method which is suitable for analyzing time-mortality data. The reasons why conventional probit analysis should not be used for time-mortality data are discussed. Examples of data analyzed using the different analysis methods are presented. Advantages of web-based distribution of time-mortality programs are discussed.

Index terms: bioassays, probit analysis, time-mortality data

[0762] PEST MANAGEMENT INFORMATION IN AUSTRALIA

R. W. Sutherst, G.F. Maywald & B. Russell, CSIRO Entomology, Long Pocket Laboratories, 120 Meiers Rd, Indooroopilly, Queensland, Australia 4068. Email R.Sutherst@ento.csiro.au

IPM is an information-dependent practice that increasingly demands rapid access to current information that is applicable under the vastly different environmental conditions around Australia. These demands are driving a range of data storage, organisation, interpretation and dissemination activities. Australia has led innovation in a number of fields that exploit computers to enhance the value of IPM information. DELTA (Description Language for Taxonomy) and Platypus (an databasing system for nomenclature information) were developed and are now being integrated under the name of BioLink. Meanwhile, a parallel effort has been in progress firstly, to digitise information from collection records. INTKEY and LUCID were produced to provide simple, easy tools to generate taxonomic keys. More recently, the databasing initiative has been extended to build seamless links between different specimen collections around Australia and the world, using the internet, to make them machine-readable from any site. These software tools and databases provide a valuable resource for IPM in Australia and their value has been enhanced by the parallel development of interpretative tools. In the 1970s innovative applications were developed in population modelling for IPM, aimed at mostly at aphids and cattle ticks. CLIMEX was developed to model the responses of species to climate for use in quarantine risk assessment, biological control, climate change species to climate for use in qualatione first assessment, biological for population modelling impact assessment, and bio-geography. In the 1990s, the demand for population modelling led to the development of the DYMEX modelling toolkit. DYMEX is designed to be userfriendly for biologists, by employing a Windows-based interface to dialogue boxes, to avoid them having to write computer code. It has since been found to be particularly valuable as a tool with which to build prototype models rapidly in a workshop environment. This has enabled the development of national networks of researchers, managers and academics with the objective of developing national approaches to Australia's key insects, diseases and weeds. Users are invited to pool their modules into a library for distribution to other users in order to avoid wasteful duplication. In addition, computers now play a key role in teaching, with IPM trainces being exposed to many of the above computer-based approaches. Most recent efforts to expedite delivery of IPM information to users are aimed at integrating some of these technologies, linking all information relevant to IPM in a WWW portal, 'IPM Australia' and delivering information from databases and models over the WWW. A number of the above programs have enjoyed widespread, international adoption and will be illustrated. Index keywords: BioLink, CLIMEX, DYMEX, IPM Australia.

[0763] THE EXOTIC FOREST PEST INFORMATION SYSTEM FOR NORTH AMERICA

<u>R. A. Hnack</u>¹ & J. G. O'Brien², ¹ US Dept. Agriculture, Forest Service, North Central Research Station, 1407 S. Harrison Rd., East Lansing, MI 48823, USA; E-mail: rhaack @fs.fed.us; ² US Dept. Agriculture, Forest Service, Forest Health Protection, 1992 Folwell Ave., St. Paul, MN 55108, USA; E-mail: jobrien @fs.fed.us

The Exotic Forest Pest Information System for North America is a project sponsored by the North American Forestry Commission, comprised of members from Canada, Mexico, and the United States. This Internet-accessible database identifies insects, mites and pathogens with potential to become established and cause damage to forest resources in any of the three North American countries. Emphasis is placed on organisms not yet present in North America. Each record in the database consists of a brief pest risk assessment and a pest information section. For each organism, the risk assessment section qualifies risk by probability of establishment, economic impact, and environmental impact. The pest information section provides details on host plants, geographic distribution, methods for detection and identification, means of spread, control measures, general biology, and a bibliography. It is anticipated that this information will prove useful in assessing and managing future pest organisms in both North America and worldwide. The web site and pest records will be available in English, French, and Spanish. The directors of the project are actively seeking authors to write new pest records for the database, as well as qualified people to review current and future records. A new record can be submitted in any of the three official languages: English, French, or Spanish. Once approved and edited in the language in which it was first submitted, each record will then be translated to the other two languages by project members. The original authors and their affiliations are listed for each record. For further information, or to participate in the development of this information system, visit the web site at: http://www.exoticforestpests.org

Index terms: database, exotic pest, quarantine pest, risk assessment

[0765] COLLABORATIVE SEARCH TOOLS FOR INTEGRATED PEST MANAGEMENT

J. K. VanDyk¹, ¹Dept. of Entomology, Iowa State Univ., 411 Science II, Ames, IA 50011-3222, USA, E-mail jvandyk@iastate.edu.

Integrated pest management information on the internet is not available in a single, organized categorical hierarchy. Instead, it exists on many different webservers . The National IPM network of the United States has developed a categorical search engine that organizes information across disparate servers. A central browsable directory is created from meta information located in web documents. Contributors may submit web pages for inclusion and supply meta information for existing web pages. Each page is indexed using traditional search engine methodology and categorized if appropriate meta information is present. The result is a search engine and categorical directory that can use any class of meta information (author, state, pest) as a criterion or filter. In this way, subject-specific information from the internet can be organized. The software and interfaces for accomplishing this task will be demonstrated.

[0766] HYBRID KEYS AND SYNTHETIC DATASETS: NEW DEVELOPMENTS IN INTERACTIVE KEYS WITH LUCID VERSION 2.0

D. K. Yeates^{1,3} & K. Thiele^{2,3}, ¹Dept of Zoology and Entomology, The University of Queensland, Brisbane, 4072 AUSTRALIA, E-mail d.yeates@mailbox.uq.edu.au; ²Australian National Herbarium, G.P.O. Box 1600, ACT 2601, AUSTRALIA; ³Centre for Pest Information Technology & Transfer, The University of Queensland, Brisbane Qld 4072 AUSTRALIA.

Two types of identification key used in systematics are route keys ("dichotomous" keys) and random-access ("interactive") keys. The two key types have very different logical structures, with the strengths of one often the weaknesses of the other. Route keys are inflexible, and users can face unanswerable couplets. Random-access keys solve these problems, but they cannot handle character contingency, a problem especially at higher taxonomic levels. In addition, route keys can be constructed while the key developer only knows a small proportion of the full matrix of characters necessary for the development of a random access dataset. Random-access keys will not supersede route keys, and there is much potential for hybrid structures that combine the strengths of both approaches and avoid their weaknesses. The strengths of a synthetic approach to dataset construction, with the inclusion of molecular, morphological and behavioural characters will also be discussed and demonstrated with an example from the dacine Tephritidae. Index terms: Tephritidae, random access keys, synthetic

datasets.

[0769] THE GLOBAL BIODIVERSITY INFORMATION FACILITY (GBIF): WHAT IT IS, WHAT IT WILL DO AND HOW IT WILL BE ESTABLISHED

E. S. Nielsen, CSIRO Entomology, GPO Box 1700, Canberra ACI 2601, Australia (ebbe.nielsen@ento.csiro.au).

An international mechanism is needed to make biodiversity data and information accessible worldwide. The existence of such a mechanism will produce many social and economic benefits. For example, the Convention on Biological Diversity (CBD) obligates nations to implement provisions relating to conservation, use, and equitable sharing of biodiversity. A scientific information resource that could facilitate fulfillment of these obligations is greatly needed. Such a resource will also be a central element in sustainable development. The Subgroup on Biodiversity Informatics of the Working Group on Biological Informatics of the Megascience Forum of the Organization for Cooperation and Development has in 1999 recommended that the governments of OECD countries establish and support a distributed system of interlinked and interoperable modules (databases, software and networking tools, search engines, analytical algorithms, etc.) that together will form a Global Biodiversity Information Facility (GBIF). This Facility was endorsed by OECD Science Ministers in June 1999. They stated that GBIF should be a body in its own right with open-ended membership. It will work in close cooperation with established programmes and organisations that compile, maintain and use biological resources. GBIF is currently being established by an Interim Steering Committee representing the governments of some 15 countries as well as the CBD. GBIF will be open to all countries and peoples, will enable users to navigate and put to use vast quantities of biodiversity information, thereby (1) advancing scientific research in areas such as agriculture, biomedicine, biotechnology, environmental management, pest control, health, education, and conservation, among others; (2) serving the economic and quality-of-life interests of society; and (3) providing a basis from which our knowledge of the natural world can grow rapidly and in a manner that avoids duplication of effort and expenditure. The presentation will detail the development of the GBIF concept, the timetable and principles for its implementation, GBIF characteristics, contents, work programs and organization. The OECD report is available under reports at http://www.oecd.org/dsti/sti/s_t/ms/index.htm and the Ministerial concusions at: http://www.oecd.org/news_and_events/release/nw99http 68a.htm.Index terms: biodiversity informatics, biological informatics

[0768] TECHNOLOGICAL OPPORTUNITIES AND CHALLENGES IN BUILDING A GLOBAL BIOLOGICAL INFORMATION INFRASTRUCTURE

H.Saarenmaa, European Enviroment Agency, Kongens Nytorv 6, 1050 Copenhagen, Denmark; E-mail: hannu.saarenmaa@eea.eu.int.

An overview is given how newest information technologies can help to manage biological information. The possibilities have increased dramatically just over one or two past years. It is important to see the difference between infrastructure, meant to provide shared building blocks, and applications that are just to solve a specific problem. Many of the new possibilities especially enable the building of infrastructure. Several global processes such as the CHM and GBIF are heavily dependent on these new infrastructure technologies. XML (eXtended Markup Language) is a successor to HTML that unifies data management and presentation under document content management. It enables information interchange with both human and computer-readable packages. Using XSL (eXtended Style Sheets) the information can be viewed from various angles. Data Type Definitions (DTD) and XML schemas for biological information should be standardized urgently. Examples of content that should rely on XML from this on include species homepages and observation data. Digitizing of type specimens should be a priority of all collections. It is nowadays very easy and inexpensive with digital cameras and video capture devices. Once digitized, specimen data is safe, does not lose color, and can be accessed world-wide instantly, if so desired. Electronic publishing of descriptions has become practically feasible with the 4th ICZN. A work issued after 1999 in numerous identical and durable copies may be regarded as published even if not printed on paper, provided that identical copies deposited in at least 5 named and publicly accessible libraries are provided. Analogously to Internet's Domain Name System, a stable addressing system for scientific names of organisms could be designed using stable numeric identifiers derived from IPv6. This would be used to overcome the volatility of the Linnéan names, which are not suitable for keys. Using such global IDs for both taxa and names, biological information could be addressable from web services worldwide by broadcasting. Building global directories of expertise, technology transfer, and information resources is now feasible using Directory Services and the Lightweight Directory Access Protocol (LDAP). An information architecture building on the above concepts and glued together by distributed objects is outlined. It should be conceivable as it does not require standardization of local data. Mapping of local data to a global ontology can be done using XML and stable IDs.

Index terms: taxonomy, informatics, standardization, XML, digitizing

[0770] THE TREE OF LIFE PROJECT: A MULTI-AUTHORED, DISTRIBUTED INTERNET PROJECT CONTAINING INFORMATION ABOUT PHYLOGENY AND BIODIVERSITY

D. R. Maddison, Dept. of Entomology, Univ. of Arizona, Tucson, AZ 85721, USA, Email tree@ag.arizona.edu.

The Tree of Life Project (http://phylogeny.arizona.edu/tree/phylogeny.html) is a collaborative effort among biologists providing a collection of information, available over the Internet, about the evolutionary history and diversity of life on Earth. It consists of a series of web pages, each illustrating and discussing an individual species or a group of species, linked together in the form of the evolutionary tree of life. Along with pictures and introductory information of interest to the general public and students of all levels, Tree of Life pages feature specialized sections (on morphology, phylogeny, biogeography, etc.) addressing the needs of researchers in the field. There are currently over 300 biologists (http://phylogeny.arizona.edu/tree/home.pages/participants.html) in 21 countries contributing to the project. The Tree of Life Project is designed to provide comprehensive, authoritative, and up-to-date information on every species of organism, living and extinct, as well as proposals of their origin and relationships (a goal that will never be fully achieved), and to facilitate communication and initiate collaboration between researchers working on the same or related groups of organisms. The current operation and plans for the future of the Tree of Life Project will be described. The next step in the project will be conversion from a static collection of web pages into a database-driven system. This conversion will allow information to be assembled dynamically and in customizable ways, and will provide for greater communication with other biological databases. Index terms: Evolutionary tree, World Wide Web

[0771] ENTOMOLOGY IN COSTA RICA INBio

<u>A. Solís,</u> Instituto Nacional de Biodiversidad, Santo Domingo, Apartado Postal 22 3100, Heredia, Costa Rica. E-mail: asolis@inbio.ac.cr

Since the creation of INBio in 1989, all our activities in the Entomological Department were planned and designed on the way, take into consideration many of the possibilities and advantages offered by the Informatics nowadays. Beginning with the basic objective: "Decrease the information scarcity about the insects, and make this information available to the people of Costa Rica and the rest of the world, for a rational use, and for the conservation and development", we have generated a number of procedures and computerized applications for the capture, storage, management, and publication of the achieved information. The specimens are collected by parataxonomists in lots using various collecting methods, and the data of each lot is captured into INBio's database, where a code is created for each lot. Also, for each specimen a record is created in the database and is linked to its lot information using a distinct identifier represented in the specimen by the bar code label. Later, the specimens are separated by technicians, mostly to the family level, and are put accessible to the Taxasphere, and at that point with the expert's help, the specimens are divided to the lowest possible level. From the experts, we are able to obtain electronic taxonomic dictionaries in their fields of taxonomic expertise. In batch, the identification's information is gathered to each specimen record in the database. The Collection is adequately curated continuously, and each year is profiled in order to get the best accessibility level. We want to facilitate the job of the Taxonomists to the degree that they won't need to waste their valuable time getting the label information or doing some other things. The information of the collection is put accessible through the Web or by others electronic means. Additionally, from the databases, the expert can obtain some natural history information and distribution maps about collected specimens. And an image database is also available for storing or getting draws and pictures. Using all of these support things, the expert can do his traditional taxonomic work, or could generate Basic Information Units (UBIs). The UBIs system allows the integration of the species information including taxonomic history, diagnostic description, distribution, natural history data, maps, illustrations, etc, in order to make it available to all the people using the Web.

[0772] ISSUES OF QUALITY CONTROL IN LARGE DISTRIBUTED ENTOMOLOGICAL DATABASES

J. Soberon, National Commission of Biodiversity, Mexico. E-mail: jsoberon@xolo.conabio.gob.mx

In recent times an increasing amount labels in museum's specimens is being computerized and often made accessible through the Internet. This opens the door to the creation of large (in the orders of 104 to 106 records) databases that can be used (and are being used) for a number of applications, from basic science, in the exploration of evolutionary questions, to management issues, like the assessment of the potential damage of invasive species, to name just two examples. However, such large database of ahout 50,000 records of Papilionidae and Pieridae butterflies of Mexico, obtained from nearly twenty different museums, to explore some of the major problems of such databases and ways of identifying and correcting them. The thesis of the work is that probably all large, mixedorigin databases are fraught with problems, so great care should be used in using them. Nevertheless, techniques already exist to deal with some of those problems and to extract useful knowledge from the databases. [0773] AN INFORMATION INFRASTRUCTURE FOR GERMAN INSECT COLLECTIONS INCLUDING MULTIMEDIA AND GIS-TOOLS

K. H. Lampe & K. Riede, Zoologisches Forschungsinstitut und Museum Alexander Koenig (ZFMK), Adenauerallee 150-164, D-51113 Bonn, Germany, E-mail: k.lampe.zfmk@unibonn.de; k.riede.zfmk@uni-bonn.de;

The number of insect species on earth and their actual extinction rate is a matter of speculation for several years already, but exact numbers are still not available. This is mainly due to the lack of an efficient information infrastructure. Complete registers of valid taxa only exist for few insect groups, and much of the information stored within museum collections is not readily accessible, because most of it is not digitised. The German Ministry of Science and Education (BMBF) has launched the EDIS-project (Entomological Data and Information System) to digitise and harmonise the rich, but scattered entomological collections housed at various German institutions within one specimen-based collection database. This concept is illustrated for the DORSA-subproject, which will integrate Orthoptera collections within one "Virtual Museum", accessible by an internet-based user interface. As a taxonomic backbone we will use the "Orthopteran Species File" (OSF: Otte & Naskreeki 1997), which is among the few electronic catalogues of named organisms (global species register) already available on the WorldWide Web (http://viceroy.eeb.uconn.edu/Orthoptera). DORSA will integrate specimen-based sound recordings. These species-specific songs will be used as a knowledge base for the development of song recognition algorithms and bioacoustic "Rapid assessment tools". In addition, all localities will be geo-referenced, resulting in a huge dataset of point data, which can be exported into Geographical Information Systems (GIS). These distribution data can be overlaid with other GIS-maps (e.g. on rainforest extension). However, most GIStools are not able to tell the user which species occur in a delimited area in a user-friendly way. We present a customised Java-tool that allows geographic visualisation and retrieval of taxonomic data. This might be a first step to answer simple questions such as 'How many insects have been discovered in a certain area?' or - possibly even more important - 'How many species have been affected by habitat destruction within a certain area?'

Index terms: database, Orthoptera, global species register, bioacoustics, rapid assessment

[0774] INTERACTIVE IDENTIFICATION USING THE INTERNET

M. J. Dallwitz, T. A. Paine & E. J. Zurcher, CSIRO Division of Entomology, GPO Box 1700, Canberra ACT 2601, Australia. E-mail: md@ento.csiro.au.

Computer-based interactive keys have several advantages over conventional keys: a correct identification can be made in spite of errors by the user or in the data; characters can be used, and their values changed, in any order; numeric characters can be used directly, without being divided into ranges; the user can express uncertainty by entering more than one state value, or a range of numerical values; Other features important for efficient and reliable identification include: advice on the most suitable characters to use at any stage of an identification; locating errors which were circumvented by the errortolerance mechanism; notes on the interpretation of characters; illustrations of characters and taxa; finding the differences and similarities between taxa; finding diagnostic descriptions. Interactive identification can be made available over the Internet in the following ways. 1.A helper application for a Web browser. Example: Intkey, http://biodiversity.uno.edu/delta/ 2. A program (Java or JavaScript) running in a Web browser. Example: NaviKey, http://www.herbaria.harvard.edu/software/navikey/ Cooperating programs running in a Web browser and server. Example: DAP, http://www.botanik.biologie.uni-muenchen.de/botsamml/lias/lias.html 4. A program running on a Web server, and generating HTML pages. Example: PollyClave, http://prod.library.utoronto.ca/polyclave/index.html Programs of type 1 must first be installed, and most are available for only one operating system (usually MS-Windows). Programs of types 1 and 2 download the data matrix at the start of a session. The user cannot proceed until the downloading is completed, but afterwards response is fast, and there is no further load on the network and server, except when subsidiary files, such as images, are required. The programs can also be used off line. In programs of types 3 and 4, the data matrix is not downloaded. Each operation requires an Internet transaction, so responses tend to be slow, and a continuing load is placed on the network and server. The programs cannot be used off line. In programs of type 4, the user interface is familiar to Web users, but may become cumbersome for some operations, particularly with large data sets. Programs of types 2-4 are potentially independent of the user's operating system and browser, but in practice there may be problems. Currently available programs of types 2-4 lack many of the features required for efficient and reliable identification. Index terms: DELTA, Intkey, keys.

[0775] NEW APPROACHES TO CREATING GLOBAL SPECIES DATABASES IN ENTOMOLOGY

M.J. Scoble, ¹Dept. of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, E-mail: m.scoble@nhm.ac.uk.

Global species databases are, broadly speaking, computerised taxonomic catalogues. Databases have, however, the capacity to be more extensive than catalogues, and they are much more effectively searched. They can also be networked. It is increasingly evident that the kind of information inherent in traditional taxonomic catalogues is of value beyond the systematics community. In particular, it forms the basis for such products as life-lists, biodiversity surveys and inventories, which are needed to meet certain requirements under the Convention on Biological Diversity. The main difference between creating global species databases for insects and most other groups of organisms is that of the size of the task. In this paper I give an example of the steps in creating one such database (on geometrid moths) and the hardcopy catalogue that was derived from it. Although a great deal of effort was required to complete the database in a timely fashion, such large compilations are quite possible given appropriate facilities and the right people. Key features in the production of the work, both material and in terms of human effort, will be discussed. Some other insect databases will be cited. These examples have been created from just a subset of extensive archival sources in natural history museums. Attempts are now being made by the University of Essex and The Natural History Museum, London, to build a Versatile Interactive Archive Document System (VIADOCS). The project proposes a novel interactive method of archive conversion by extending a current commercial optical character recognition system for completing forms. A demonstration interactive conversion system utilizing a particular Lepidoptera index-card archive (on Pyraloidea) will be developed, and evaluated against current manual conversion methods, and in interactive use 'on demand' over the Internet. The aim of producing this system is to provide a means of making accessible extensive quantities of data trapped in typed and hand-written archives. All these efforts should be seen in the broader context of computerising biological data typically associated with biological collections.

[0777] BIOSYSTEMATIC DATABASE OF WORLD DIPTERA: THE FIRST GLOBAL MASTER SPECIES DATABASE IN ENTOMOLOGY

F. C. Thompson¹ & N. L. Evenhuis², ¹Systematic Entomology Lab., ARS, USDA, Washington, D.C. 20560-0169, USA, e-mail: cthompso@sel.barc.usda.gov; ²Bishop Museum, 1525 Bernice St., Honolulu, Hawai'i 96817-0916 USA, e-mail: neale@bishopmuseum.org

The BioSystematic Database of World Diptera (BDWD) is a cooperative effort of the World's leading dipterists to provide a comprehensive index to the names of flies (Order Diptera). The database is disseminated annually on CD-ROM (on the Diptera Data Dissemination Disk) and is available on the World-Wide-Web with quarterly updates at USDA Systematic Entomology Laboratory Diptera the vita (http://www.sel.barc.usda.gov/Diptera).All the nomenclatural details (name, author, year, page, type, current status, valid name, valid author, family) are included. For valid names, abbreviated distributional data are provided. While the database is still being constructed, all name records are available. Those that have been checked by specialists and have been peer-reviewed are identified and dated. Currently the fruit flies and a number of small families have been completed. Altogether, there are more than 160,000 names, including all family-(4,324) and genus-group names (21,000) and about two-thirds of the speciesgroup names (130,000). The reference file includes little more than 7,000 citations. Ultimately the database will contain more than 250,000 names and 25,000 references. Currently more than 100,000 different kinds of flies are known to Science with some 2,000 new ones being described annually. The BDWD has participated with the Species 2000 program and Integrated Taxonomic Information System (ITIS) since their initiation. Likewise, the BDWD will contribute to the Global Biodiversity Information Facility, Electronic Catalog of Names of Known Organisms. The BDWD is endorsed by the Council for the International Congresses of Dipterology, a scientific member of the International Union of Biological Sciences. The BDWD is sponsored by the Systematic Entomology Laboratory, Plant Sciences Institute, Beltsville Agricultural Research Center, Agricultural Research Service, USDA, Washington, D.C. and the Bishop Museum, Honolulu, Hawai'i.

[0776] DEVELOPING AND SHARING DATA GLOBALLY: THE 'GLOBAL BUTTERFLY INFORMATION SYSTEM' – GLOBIS

<u>G. Lamas</u>¹, E. S. Nielsen², R. K. Robbins³, C. L. Häuser⁴ & R. de Jong⁵, ¹Museo Nacional de Historia Natural, Universidad Nacional Mayor de San Marcos, Apartado 14-0434, Lima-14, Peru; ²CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia; ³Department of Entomology NHB-127, National Museum for Natural History, Smithsonian Institution, Washington, DC 20560, USA; ⁴Staatliches Museum für Naturkunde, Rosenstein 1, D-70191 Stuttgart, Germany; ⁵Department of Entomology, National Museum of Natural History, PO Box 9517, 2300 RA Leiden, The Netherlands.

Butterflies are beautiful, they make up 1% of all named species of organisms (more than twice the number of birds), and are naturally abundant in a wide variety of ecosystems throughout the world. Despite their obvious aesthetic appeal and well-established value for assessing and understanding biodiversity, there is no universal standard system for knowing what butterflies exist, how to identify them, where they naturally occur, or how to find out what is (and what is not) known about them. GloBIS (Global Butterfly Information System) is a proposal for an internationally-operated, web-based, multimillion dollar program to rectify this deficiency. A collaborative project planned by butterfly specialists from major museums and entomological institutes, GloBIS will give equitable access worldwide to a vast store of information about butterflies never assembled or available before. The core of GloBIS will be a complete list of all scientific names ever applied to butterfly species and groups of species, for the entire world. Linked to that list will be distribution maps and distribution data; images of adult butterflies (both preserved and living), their early stages, morphological details, and habitats; interactive identification keys; hostplant and parasitoid databases; and a bibliographical database.

[0778] BEETLES AND BEETLE LARVAE OF THE WORLD: INTERACTIVE IDENTIFICATION AND INFORMATION SYSTEMS FOR FAMILIES AND SUBFAMILIES

J. F. Lawrence & <u>R. G. Oberprieler</u>, CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, AUSTRALIA. E-mail Rolf.Oberprieler@ento.csiro.au.

Two recently released CD-ROM products (CSIRO Entomology, November 1999) are presented: 'Beetles of the World: A Key and Information System for Families and Subfamilies' and 'Beetle Larvae of the World: Interactive Identification and Information Retrieval for Families and Subfamilies', by J.F. Lawrence, A.M. Hastings, M.J. Dallwitz, T.A. Paine & E.J. Zurcher. These MS-Windows-based products are the first comprehensive interactive identification systems for all families and most subfamilies of beetles. Beetles of the World spans 945 taxa representing all 172 recognized beetle families and most subfamilies, and uses 312 anatomical characters accompanied by clarifying notes plus 17 text characters dealing with classification, distribution, biology and key literature for each taxon. All taxa are illustrated, using more than 2500 colour and black-and-white images, and 75% of the characters are elucidated by means of explanatory images. A Beetle Browser (an illustrated tool for finding the names of major beetle body parts) and a glossary of terms are included. Beetle Larvae of the World (an update of the 1993 MS-DOS version) covers 390 taxa representing 148 families and many subfamilies, and uses 170 anatomical characters plus 9 text characters dealing with classification, distribution, biology and key literature. 40% of the taxa and 60% of the characters are illustrated by means of enhanced drawings in colour. These interactive systems can be used to: identify a beetle or beetle larva from any part of the world to family, usually to subfamily and occasionally to tribe and genus level; for a particular taxon obtain information on distribution and biology, the current valid family name, a printed full description or diagnosis and a list of references; generate a list of beetle groups having a particular attribute or occurring in certain geographical regions; and restrict an identification to one of these areas. The identification process can be automated (allowing the program to suggest the most suitable discriminating characters) or started from any selected character, or set of characters in any sequence, and it allows for uncertainties and errors in character coding and for no matches being found. Copious notes and images facilitate character coding, and identification is easy and efficient. These identification systems are essential tools for researchers, museum curators, teachers, environmentalists, agriculturalists, quarantine inspectors, naturalists and beetle lovers in general Index terms: classification tools, diagnostic characters, key references

[0779] A SOFTWARE ENGINEERING PERSPECTIVE ON DEVELOPING ELECTRONIC FIELD GUIDES: LESSONS FOR BIOINFORMATICS

R. A. Morris¹, M. Passell¹ & <u>R. D. Stevenson</u>², ¹Dept. of Math and Computer Science and ² Dept. of Biology, Univ. of Massachusetts, Boston, MA, USA. E-mail robert.stevenson@umb.edu

Consumers of bioinformatics software have specific needs that must be considered by software designers in order to build systems that will be used. For biologists interested in biodiversity data, experience has taught (1) that a single data model at the species level is inadequate, (2) that software should be extensible and flexible, and usable without the assistance of computer scientists, and (3) that to meet biologists' needs, data models should support data exchange and federation. With these needs in mind, we have begun to design and implement Electronic Field Guide software (http://www.cs.umb.edu/efg). An object-oriented database (OODB, here Object Store) specifies the diversity structure while edge-labeled directed acyclic graphs hold data. Taxonomic schemata are largely uncontroversial so taxa are represented by simple tree graphs. Keys use idiosyncratic and complex character lists with multiple paths to the correct species so they are implemented as acyclic graphs. Java servlets provide the middleware accessible by (to be) public protocols. Output is generated dynamically as HTML and Java applets. OODB tools are not widely accessible to biologists so data from EFG authors are imported through an ODBC/JDBC bridge. Java beans are constructed for each taxon in the import; attributes in import are object properties. These are unknown in advance. (Note that ODBC can not specify order of attributes nor of data when attributes are unknown in advance.) The point of attachment is a path in the data graph. (See semi-structured data literature, especially as described in Abetiboul et al. "Data on the Web", Morgan Kaufman.) Software will be available via the Free Software Foundation's General Public License. Our experiences serve as a foundation to discuss the use of XML for data exchange and federation with other biodiversity databases.

[0783] INSECT INFORMATICS: TO MEET THE CHALLENGE OF MODERN INFORMATION DISSEMINATION

<u>Y. L. Xia</u> & J. Baumgärtner, Dept. of Population Ecology and Ecosystem Science, International Centre of Insect Physiology and Ecology (ICIPE), P. O. Box 30772, Nairobi, Kenya, E-mail: yxia@icipe.org

The "Post-PC Era" is about to come with new opportunities and challenges. Users will access to web, personal, and business data from a variety of devices, relying on wired or wireless communication. There will be available a variety of inter-networkable information appliances with wide range of applicability. For example, voice recognition technology may overcome screen and keyboard limits of information appliances. Insect Informatics is a novel subject dealing with the generation, processing and dissemination of insect information through the use of modern information and communication technology. To meet the challenge of the "Post-PC Era", International Centre of Insect Physiology and Ecology (ICIPE) started the Insect Informatics Initiative in early 1998. Its aim was to integrate and strengthen the delivery of insect-related information via modern information and communication technology, while at the same time contributing to the building of capacity in information technology in Africa through regional partnerships, networking and training. ICIPE's Insect Informatics Initiative has identified the following R&D areas: 1) Methodology-oriented area: Web-based Intelligent Decision Support Information System, GIS, Early Warning/Expert System. 2) Information Dissemination-oriented area: Africa Regional IPM Information Network, Bio-Control Information System, Insect Biodiversity Information system, Multimedia Products on Insects. 3) Commodity-oriented area: Horticulture, Apiculture, Sericulture. 4) Pest-oriented area: Stemborer, Mosquito, Tsetsefly, Tick, Fruitfly, Whitefly, Grasshopper/locust. 5) System Development-oriented area: Virtual Biovillage (community-driven integrated health and resource management system). 6) Other areas: Genome Informatics for Insects, Insect Visual Study, Africa IPVM Virtual training. Highest priority is given to the development of web-based intelligent insect management information systems, which will serve as strategic planning and decision support tools for integrated crop and pest management. Index terms: Insect Informatics Initiative, Post-PC Era, IT, ICT, ICIPE

[0784] INVESTIGATING THE WINGBEAT SIGNALS OF MIGRATING INSECTS USING AN INSECT MONITORING RADAR

<u>V.A. Drake & I.T. Harman</u>, School of Physics, University College, The University of New South Wales, Australian Defence Force Academy, Canberra, ACT 2600, Australia.Email: ian.harman@adfa.edu.au.

In its primary mode of operation, an Insect Monitoring Radar (IMR) employs a rotating offset beam to produce a strongly modulated signal from which target trajectory, size, and shape can be extracted. Any weak modulation in the signal is usually overwhelmed by the larger effects produced by the rotating polarization and conical scan. A second mode of operation in which the beam is stationary has therefore been introduced, to allow the target-characterization capabilities of the IMR to be developed further. In this mode, the echo signals from individual insects show a slow variation arising from the target's transit across the beam and, superimposed, low-amplitude modulations due to wingbeating and, occasionally, breathing. Special software has been developed to automatically extract all the available information from digitisations of these echoes. Automatic observations employing the stationary-beam mode of the IMR are conducted hourly during routine operations and occupy 25% of observing time. Data is acquired from 8 altitude levels spanning 200-1300 m, with each sample gate using a narrow detection window to minimize the probability of acquiring overlapping echoes. A hardware filter passes frequency components in the range 0-128 Hz, which previous studies have indicated covers the wingbeats of moths, grasshoppers and birds. This filter improves the signal-tonoise ratio and eliminates aliasing from higher frequencies. Observations are made sequentially at three polarization angles 60° apart to minimize dependence on target orientation. The data presented derives from observations of moth and locust migrations made with an IMR installed at Bourke, New South Wales, in eastern inland Australia during the spring and summer of 1998-99. The estimated target parameters have been correlated with height of flight, time of night, and season. Index terms: IMR, moth, locust, Australia.

[0785] HOW MIGRATION AFFECTS ECOLOGICAL DIVERSIFICATION OF *APIS DORSATA* POPULATION. AN APPROACH BY SELF-ORGANIZING MAPS PROCESSING

G. Kastberger¹, **D.K. Sharma²**, **E. Hüttinger³ & G. Kranner⁴**, ¹ Department of Zoology, University of Graz, Austria; ² Department of Zoology, University of Gauhati, India; ³ Institute for Bienenkunde, Lunz, Austria; ⁴ eudaptics software gmbh, Helferstorferstraße 5/8, A --1010 Vienna, Austria. Supported by the Austrian scientific foundation, grant P13210-BIO.

The Giant honeybee Apis dorsata occurs in South East Asia, from Pakistan to the Phillipines, from the Himalaya to Borneo and Sri Lanka. This bee nests in the open and is highly migratory, which depend on saisonal aspects of forage and predation. A study on the diversification of dorsata lineages must especially focus upon the local intermix of colonies originating from different regions, and must discriminate samples at colony level, to display the relatedness between different colonies. We investigated ecological variation of dorsata populations in Assam, which is part of the geographical bottleneck between Southeast Asia and the Indian subcontinent. This topographic location is likely to route the dorsata gene streams, passing it either from the Bengali or from the Birmesian regions. Just in the central part of this bottleneck the Brahmaputra river is situated, the second biggest river in the world; its tributaries comprising water and sand banks form areas up to 15 km wide. It is likely that this riparial area functions as an ecological barrier for A. dorsata migration swarms. If so, this river will lessen gene flow, which may divide the A. dorsata population in Assam into two groups, that of the North bank and that of the South bank of the Brahmaputra river. To test this hypothesis, we selected the method of factor analysis of morphometric characters, which has been proved successfully in revealing lineages in Apis species. We introduced a refined multivariate statistics and a powerful primary component analysis, using the self-organising maps (SOM) neighbourhood algorithm to classify 49 A. dorsata samples at the meso- and microlevel by 30 wing characters. In SOMs, multidimensional data spaces are converted into lower dimensional abstractions, unlike the discriminant analysis, which reduces multidimensionality by linear principles. It offers a convenient way to visualise clusters as well as the topological neighbourhood of colonies in data space. This allows to estimate the rate at which swarming colonies migrate within four distinct regions of Central Assam. The calculated transfer rates at which dorsata swarms migrate across the Brahmaputra river were similar in both directions (N-S, S-N), but are only 50% of that rate at which they migrate along the river banks. This is the first evidence that the topographical barrier of the Brahmaputra river induces diversification of Apis dorsata lineages.

[0786] A PRELIMINARY COMPUTER MODEL OF *GLYPTOTENDIPES PARIPES* (DIPTERA: CHIRONOMIDAE) LARVAL DISTRIBUTION IN LAKES OF CENTRAL FLORIDA, USA

R. J. Lobinske¹, A. Ali¹ & J. C. Allen², ¹Univ. of Florida, Inst. of Food and Agricultural Sciences, Mid-Florida Research and Education Center, 2725 Binion Rd. Apopka, FL 32703-8504, USA, E-mail RLobinske@aol.com; ²Univ. of Florida, Dept. of Entomology & Nematology, Bldg. 970, P. O. Box 110630, Gainesville, FL 32611-0630, USA:

Using larval Chironomidae and selected water and sediments physico-chemical data collected seasonally over a two year intensive sampling of two eutrophic large lakes in central Florida, USA, a preliminary computer model has been developed for distribution of *Glyptotendipes paripes* larvae utilizing the software MatLab, version 5.3. The model uses matrix parameter maps of lake bathymetry and sediment percent dry weight, with varying inputs of water level, Secchi disk transparency and Chlorophyll *a* concentration (as estimators of phytoplankton abundance) to generate matrix maps of predicted larval distribution and relative abundance. Adjusted water depth and sediment dry weight determines the overall areas of likely occurrence of the larvae, and Secchi transparency influences the overall abundance of the simulated population. To examine temporal dynamics of simulated populations, life history functions using Leslie or Lefkovitch matrices are used to simulate survival and development of larval populations, and redispersal of the population during reproduction and egg-laying are simulated using convolution filters.

Index terms: Glyptotendipes paripes, Chironomidae, computer model, urban pests, aquatic entomology.

[0787] MICROSATELLITE MARKERS OF TWO AGRICULTURAL PESTS, THE MEDFLY, CERATITIS CAPITATA AND THE OLIVE FLY, BACTROCERA OLEAE

K. D. Mathiopoulos¹, A. Augustinos¹, E. Stratikopoulos¹, P. Mavragani-Tsipidon², A. Mintzas' & A. Zacharopoulou', 'Dept. of Biology, Univ. of Patras, Greece, e-mail: zacharop@upatras.gr; 2Dept. of Biology, Univ. of Thessaloniki, Greece.

Medfly, Ceratitis capitata, is rated as one of the world's most destructive agricultural pests. A native of eastern Africa, the fly has invaded most of the warmer parts of the world causing immense devastation to more than two hundred fruit species. On the other hand, the olive fly, Bactrocera oleae, is a devastating but highly specialized pest of the olive tree. It is the principal olive pest in all olive oil producing Mediterranean countries and has invaded all new olive producing countries. Microsatellites are tandem arrays of simple sequence repeats. They are extremely useful in genetic and population analyses because they are very abundant, they are randomly distributed along the genome and they are highly polymorphic. They can be easily identified and scored. In addition, the high degree of polymorphisms facilitates genetic mapping by recombination, since microsatellite markers are inherited as co-dominant, Mendelian characters. Using (AT)15, (GC)15, (AC)15 and (GA)15 as probes we acreened microsatellite enriched libraries from the medfly and the olive fly genomes and isolated several microsatellite containing clones. Sequence analysis determined the nature and length of the microsatellite locus. In situ hybridization of the clones on the respective polytene chromosomes determined their cytological position. The degree of polymorphism of specific microsatellito loci was determined by analysis of field collected individuals. Several of these microsatellite loci were conserved between the two species, thus giving the opportunity to PCR amplify a microsatellite locus with the same primer pair for both the medfly and the olive fly. The availability of polytene chromosomes in both the medify and the olive fly provides the additional possibility of linking genetic with cytogenetic data. In situ hybridization of the microsatellite locus on the polytene chromosomes and the polymorphic nature of microsatellites make possible the correlation between genetic and cytogenetic maps and facilitates the construction of integrated maps which is the main focus of this project.

[0788] COMPUTER-ASSISTED TOOLS FOR THE SPECIES RECOGNITION OF ECONOMICALLY IMPORTANT INSECTS AND MITES

. Meijerman & S.A. Ulenberg, Dept. of Entomology, Zoological Museum Amsterdam, Pl. Middenlaan 64, 1018DH Amsterdam, the Netherlands, E-mail meijerman@bio.uva.nl.

The University of Amsterdam, the Expert Centre for Taxonomic Identification, Amsterdam and CAB International, UK, are collaborating in a project aiming to provide both specialists and non-specialists with easy to use and apply tools for the species recognition of insects and mites that cause economic damage in agriculture, horticulture and forestry, and their natural epemies. The end product is a series of interactive CD-ROMs based on ETI's 'Linnaeus II' software for biodiversity documentation and species identification. Each CD-ROM contains up-to-date taxonomic (biodiversity) information on economically important species and related non-pest species, and a computer assisted identification key. A cross reference system for the major host plants, interactive distribution maps, an illustrated glossary for technical terms and a section on methodology are also included. In progress are Tortricidae of Economic Importance', 'Agromyzidae of Economic Importance' and 'Diaspididae of Economic Importance'. Further work on Aleyrodidae and their natural enemies, and on the natural enemies of Agromyzidae is planned. The CD-ROM 'Eurasian Tortricidae of Economic Importance' will be demonstrated.

Index terms: Tortricidae, pests, identification key

[0789] NON-PARAMETRIC MODELLING AND EXPERIMENTAL TESTING OF BLOWFLY POPULATION DYNAMICS

S.J. Moe, Univ. of Oslo, Dep. of Biology, P.O. Box 1050 Blindern, 0316 OSLO, Norway. E-mail: imoe@bio.uio.no.

Periodic fluctuations in abundance is a characteristic feature of many insect populations. It is necessary to understand the underlying mechanisms in order to predict or regulate insect populations. A.J. Nicholson (1954) demonstrated that population-intrinsic factors produced sustained oscillations in experimental blowfly populations (Lucilia cuprina). Non-linearities and time-lags in density dependence are of particular importance because they can give rise to complicated population dynamics such as cycles or chaos. We used a non-parametric modelling method, GAM (generalised additive modelling), to estimate density dependences in time-series data from experimental populations of Lucilia sericata. This method makes minimal assumptions about density-dependent functions and is therefore very useful for describing stage-specific density dependences, in particular for identifying non-linear relationships. The model indicated that 1) larval survival was nonlinearly dependent on larval density (highest survival at intermediate densities), 2) adult survival was density-independent, and 3) reproduction was dependent on adult density. These predictions were tested experimentally in order to evaluate the model. The experimental results confirmed both the non-linear relationship between larval density and survival and the density independence of adult survival. The humped larval survival function is probably a result of faciliation by group feeding at low densities and competition for food at high densities. The reproductive rate was dependent on past larval density rather than on present adult density, which demonstrates delayed density dependence. Because adult density at any time is correlated with larval density of the same individuals their effects can not be separated by time-series analysis, only by experimental testing. The accordance between the model predictions and the experimental results shows that the non-parametric modelling method can be a powerful tool for analysing ecological time series and for generating new hypotheses. ecotoxicology

[0790] SPECIES, SPECIMENS AND SOCIETY: CONTRIBUTIONS FROM BIOLOGICAL COLLECTIONS

S. O. Shattuck, CSIRO Entomology, P. O. Box 1700, Canberra, ACT, 2601, Australia

The millions of specimens held by biological collections form the corner stone of our understanding of global biological diversity. These specimens are also essential for the taxonomic research which transforms these individual data items into a rich picture of the world around us. Traditionally the results of taxonomic research have been published in paper-based journal articles and monographs. These journal articles and monographs are often the product of years of work and provide a snap-shot of our understanding of the taxa under study at a given time. While this time honoured and widely used publishing model has serviced us well in the past, the ever increasing rate of new knowledge acquisition, combined with electronic publishing, poses challenges to maintaining this model in the future. The problem is compounded by the fact that biological collections are constantly growing and changing as a result of new discoveries and taxonomic research. Existing taxonomic publications struggle to maintain their value and usefulness in the face of this rapidly changing world and competition from electronic information sources. To overcome these limitations a new publishing paradigm is needed. This new publishing process builds on well established taxonomic traditions and adds the flexibility and timeliness of electronic publishing. Publishing will continue to be based on a "monograph" model, but instead of these monographs remaining as static documents of years or decades, they are transferred to an "encyclopedia" model. They move from a static publication model to a living publication model, a model where "revisions" are updated regularly to better reflect current taxonomic understanding. For this new model to succeed, these new publishing methods need to be integrated into routine collection management practices and everyday taxonomic research activities. In this way information will flow freely from collections and research into publications which are made available without the delays normally associated with the paper-based publishing process. As a first step towards this total-taxonomic-information-management system, the Australian National Insect Collection has developed BioLink, a software package which manages both taxon- and specimen-based information. BioLink offers not only information management and reporting tools, but also analytical tools including build-in GIS capabilities and geographic modeling tools. BioLink offers a complete package for the collection, maintenance, analysis and dissemination of a wide range of biodiversity information

[791] DEVELOPING ELECTRONIC FIELD GUIDES: FIRST RESULTS USING COSTA RICAN BUTTERFLIES AND MASSACHUSETTS AQUATIC MACROINVERTEBRATES

<u>R. D. Stevenson¹</u>, F. SaintOurs¹, R. A. Morris², M. Passell² & W. A. Haber³, ¹Dept. of Biology and ²Dept. of Math and Computer Science, Univ. of Massachusetts, Boston, MA, USA and ³Missouri Botanical Garden P.O. Box 299 St. Louis, MO 63166 USA; E-mail robert.stevenson@umb.edu

Field guides are important tools for people to learn about and enjoy biodiversity and natural history. They are also used in pest management and public health monitoring. Among insects, the most common field guides are for butterflies. Following the lead of the birding community, there are now an increasing number of citizens groups monitoring butterfly populations, based on the species they have learned using field guides. Despite their clear value, economic and technological barriers have prevented the publication of a much wider array of guides for insects. Now the digital revolution is rapidly relaxing these constraints. Digital devices, graphical software tools and the connectivity of the WWW are making it relatively cheap to produce Electronic Field Guides (EFGs) that have several advantages over dichotomous keys and traditional paper field guides. EFGs can be tailored for specific user groups and local coverage, incorporate more information, especially images, and are easier to update. We have a project to produce software tools (http://www.cs.umb.edu/efg) that will help biologists to make there own EFGs. Output of the guides is generated dynamically from an objected oriented database using Java. Information is displayed in HTML (but we have started the process of using XML for output). The guides store information about species in taxonomic trees, the leaves of which are "species pages", that describe life stages, ecological interactions, spatiotemporal distribution, and provide links to other species and bibliographic information. Inclusion of a variety of data types including text, images, movies, and sounds is possible. The keys are broad, shallow acyclic graph structures that use high quality images and context sensitive help. Examples of EFGs for Ithomid butterflies from Costa Rica and the aquatic macroinvertebrates from coastal Massachusetts will be shown. Issues for EFG authors, such as the type and amount of information that can be included, controlling the user output and intellectual property rights, are discussed.

Index terms: Bioinformatics, field guides, technology, butterflies, aquatic insects.

[0793] BIOSYSTEMATIC DATABASE OF WORLD DIPTERA. NAMES: KEYS TO INFORMATION

F. C. Thompson¹ & N. L. Evenhuis², ¹Systematic Entomology Lab., ARS, USDA, Washington, D.C. 20560-0169, USA, e-mail: cthompso@sel.barc.usda.gov; ²Bishop Museum, 1525 Bernice St., Honolulu, Hawai¹i 96817-0916 USA, e-mail: neale@bishopmuseum.org

The BioSystematic Database of World Diptera (BDWD) is a cooperative effort of the World's leading dipterists to provide a comprehensive index to the names of flies (Order Diptera). The database is disseminated annually on CD-ROM (on the Diptera Data Dissemination Disk) and is available on the World-Wide-Web with quarterly updates at USDA Entomology Laboratory Systematic Diptera the site (http://www.sel.barc.usda.gov/Diptera). All the nomenclatural details (name, author, year, page, type, current status, valid name, valid author, family) are included. For valid names, abbreviated distributional data are provided. While the database is still being constructed, all name records are available. Those that have been checked by specialists and have been peer-reviewed are identified and dated. Currently the fruit flies and a number of small families have been completed. Altogether, there are more than 160,000 names, including all family-(4,324) and genus-group names (21,000) and about half of the species-group names (130,000K). The reference file includes little more than 7,000 citations. Ultimately the database will contain more than 250,000 names and 25,000 references. Currently more than 100,000 different kinds of flies are known to Science, with some 2,000 new ones being described annually. The BDWD has participated with the Species 2000 program and Integrated Taxonomic Information System (ITIS) since their initiation. Likewise, the BDWD will contribute to the Global Biodiversity Information Facility, Electronic Catalog of Names of Known Organisms. The BDWD is endorsed by the Council for the International Congresses of Dipterology, a scientific member of the International Union of Biological Sciences. The BDWD is sponsored by the Systematic Entomology Laboratory, Plant Sciences Institute, Beltsville Agricultural Research Center, Agricultural Research Service, USDA, Washington, D.C. and the Bishop Museum, Honolulu, Hawai'i. Index Terms: Flies, Nomenclature

[0792] SPECIES INFORMATION DATABASE KONCHU ON JAPANESE, EAST ASIAN AND PACIFIC INSECTS, SPIDERS AND MITES ON INTERNET

O. Tadauchi⁴, H. Inoue², Y. Takematsu³ & H. L. Xu¹, ¹Entomological Laboratory, Faculty of Agriculture, Kyushu University, Fukuoka, 812-8581 Japan, E-mail tadauchi@agr.kyushu-u.ac.jp; ²Computation Center, Kyushu University, Fukuoka, 812-8581 Japan; ³Department of Applied Biology, Faculty of Textile Science, Kyoto Institute of Technology, Matsugasaki Sakyo-ku, Kyoto 606, Japan.

A publically available entomology database KONCHU is a general database name, which includes various files of bibliographical and images. The former is a taxon-based entomology database based on main Japanese entomological journals (16 journals (16 journals (16 ifles) at present). Therefore it includes many East Asian and Pacific insects as well as Japanese ones. It has a taxonomical feature as well as a bibliographical one because it treats one taxon, e.g. species, genus, family, as one record. The records of KONCHU are written mainly in English and in Japanese with katakana and kanji characters. Each record of the database is composed of 13 items, such as bibliographical (author, title, journal, volume, page and year), taxonomical (order, family, synonymy), distributions, key words (taxonomy, morphology, ecology, biology, etc) and notes including useful information such as type locality, type depository of new species, host record of parasite. The other database is an image one including various figures taken by digital camera and microscope. Images of some groups of Japan are constructed, such as wild bees. The KONCHU is managed by a text database management system SIGMA. It has been opened to the public on INTERNET as well as at Computer Center of Kyushu University, Fukuoka, Japan. A user can access to the KONCHU by retrieving the following URL: http://konchudb.agr.agr.kyushu-u.ac.jp/. Outline, usage and ex-amples of use of the KONCHU are presented.

Index terms: entomology database, species information, East Asia, bibliography, images.

[0794] REPRESENTATION AND DISSEMINATION OF MIGRATION DATA FROM AUTOMATIC INSECT-MONITORING RADARS

II.K. Wang & <u>V.A. Drake</u>, School of Physics, University College, The University of New South Wales, Australian Defence Force Academy, Canberra, ACT 2600, Australia. E-mail: haikou.wang@adfa.edu.au.

Insect-Monitoring Radars (IMRs) installed at two locations in inland eastern Australia have been making automatic observations of nocturnal insect migration since mid-1998 and mid-1999 respectively. Each IMR is controlled by a microcomputer that both acquires the radar data and analyses it. The microcomputers are also linked to an adjoining Automatic Weather Station (AWS) and, via a modem and telephone connection, to the project's base laboratory in Canberra. An automatic system has been developed to analyse downloaded IMR and AWS data files and generate daily statistical summaries and graphical representations of the migrations observed by the two radars during the previous night. The summaries and graphs show the intensity, altitude, speed, and displacement direction of the migrations, and the orientation, size, and shape of the migrants, together with the surface weather conditions, at each site. Automatic processing using Dynamic Hypertext Mark-up Language (DHTML) and scripts allows these summaries to be posted on a server (http://www.imr.ph.adfa.edu.au) for dissemination via standard internet and World-Wide-Web (WWW) protocols by mid-day of the following day. A higher-quality printed output can also be provided if required, using automátically generated PostScript print files.

A summary of the observations from each IMR is presented on a WWW "front page" which incorporates miniature histograms of the principal migration parameters, a time series of migration intensities over the the previous month, and graphs of the surface temperature and wind through the might. More detailed tables and graphs showing how the migration varied with height and time-of-night can be called up with single mouse-clicks. The summaries and graphs, in both their WWW and printed forms, are illustrated with examples from nights when Australian plague locusts *Chortoicctes terminifera* or native budworms *Helicoverpa punctigera* were amongst the migrants.

Index terms: Chortoicetes, Helicoverpa, forecast, internet, World Wide Web.

[0795] WEB-BASED INTELLIGENT INSECT MANAGEMENT INFORMATION SYSTEM FOR BETTER DECISION-MAKING SUPPORT

Y. L. Xin & J. Baumgärtner, Dept. of Population Ecology and Ecosystem Science, International Centre of Insect Physiology and Ecology (ICIPE), P. O. Box 30772, Nairobi, Kenya, E-mail: yxia@icipe.org

At the International Centre of Insect Physiology and Ecology (ICIPE) a Web-based Intelligent Insect Management Information System (WIIMIS) is being developed. The objective is to assist different users in decision-making support. The users range from policy-makers, NARES scientists, extension workers, decision-makers to grass-root smallholders. WIIMIS is designed according to the needs and interests of these users and consists of four main parts: 1) Web-based Graphical User Interface (GUI), which uses Open GIS approach, 2) System Master Control, 3) Decision-making Function, and 4) Meta-database Management Function which manages data and information. The Decisionmaking Function is based on empirical knowledge and on explanatory simulation models representing crop yield formation as affected by biotic (pests) and abiotic (water availability, soil quality) constraints. Moreover, the Function will be associated with time and space-specific socio-economic factors. Onion crop management in Kenya highlands has been included as a WIIMIS case study. Remote sensing data (climate parameters, soil parameters and NVDI), soil quality ground data and weather station recordings are used to drive the simulation models which predict onion production at different locations and at different times. The results are applied to map the geographical suitability for onion production. WIIMIS can also be developed for the strategic planning of other African agricultural commodities, for natural resource management, as well as for integrated pest management. For users without Internet access, we plan to disseminate the results through other relevant media such as CD-ROM, brochures, leaflets or posters.

Index terms: decision-making, remote sensing, meta-database, model, open GIS, ICIPE

[0796] TOWARDS A DATABASE FOR THE TRICHOGRAMMA SPECIES, THEIR HOSTS AND PLANT ASSOCIATIONS IN THE SOUTH AMERICA

R. A. Zucchi & R. B. Querino, Dep. de Entomologia, Fitopatologia e Zoologia Agrícola, Univ. de São Paulo, ESALQ, Av. Pádua Dias 11, 13418-900 Piracicaba, São Paulo, Brasil. E-mail razucchi@carpa.ciagri.usp.br

Trichogramma is the largest genus of the family Trichogrammatidae, with approximately 180 species worldwide. However, according to the most recent catalogue of the South American Trichogramma species published in 1997, only 24 species were recorded. Probably this small number of Trichogramma species in South America is because the surveys are carried out mostly in agricultural areas. For this reason, the known Trichogramma hosts are mostly lepidopterous pests. Consequently, little is known on the species which occur in natural habitats and their hosts in these areas. Except to some surveys which are being conducted in a Brazilian natural reserve (Querino's thesis in progress), the data for the South American countries have been related to collect in agricultural areas. Since 1997, some new records of Trichogramma were found in Argentina by Botto, Chile by Pintureau, Peru by Whu and Valdivieso and Uruguay by Basso, besides the data from Brazil and Uruguay (T. lasallei) obtained by us. The objective of this paper is to update the 1997 Trichogramma Catalogue with the records published in the last three years in order to place it into a database. Only the papers with taxonomic procedures were included herein, as follows: Argentina. T. nerudai (introduced species, E. Botto, per. comm.). Brazil. (1) T. lasallei from Anticarsia gemmatalis on soybean (first record by Querino); (2) T. bruni from Heliconius phyllis on Passiflora sp. fruits (first record by Querino). Chile. T. nerudai from Rhyacionia buoliana on Pinus radiata and on Tuta absoluta (latter record by RBQ). Peru. (1) T. exiguum from Argyrotaenia sphaleropa; (2) T. pintoi (introduced species) from Helicoverpa zea; (3) T. pretiosum from Erinnyis ello on cassava, Heraclides thoas on citrus and Hypsipyla grandella on cedar; (4) T. rojasi (host unknown). Uruguy. (1) T. exiguum from Argyrotaenia sphaleropa and Bonagota cranaodes on vine; (2) T. lasallei from Diatraea sacchuralis on sugar cane (first record by RBQ). Two previous records had not been included in the 1997 Catalogue: (1) T. distinctum Zucchi recorded by Basso and Morey in Uruguay. (2) T. exiguum (according to De Santis and Fidalgo's 1994 catalogue) in Argentina and Guiana. Therefore, three species of Trichogramma (T. lasallei, T. nerudai and T. pintoi), 11 new hosts and 8 plant associations were found in South America lately. Currently 27 Trichogramma species are recorded in South America. Index terms. Egg parasitoids, hosts, plant association.
[0797] PROBLEMS AND STATUS OF TAXONOMIC RELATIONSHIPS AMONG CEPHIDAE

[0799] ASPECTS OF THE ECOLOGY OF THE WHEAT STEM SAWFLY (HYMENOPTERA: CEPHIDAE) IN NORTH AMERICA

D.K. Weaver¹, W. L. Morrill¹, R. J. Bartelt², A. A. Coss², M. J. D. Grieshop¹ & G. D. Johnson¹, ¹Dept. of Entomology, Montana State Univ., Bozeman, MT 59717 USA, Email weaver@montana.edu; ²National Center for Agricultural Utilization Research, USDA-ARS, 1815 N. University Ave., Peoria, IL 61604 USA.

Cephus cinctus, the wheat stem sawfly, is a major pest of wheat and other cereals the northern Great Plains of North America. It occurs throughout much of North America, but in regions away from the northern Great Plains populations are confined to feral grasses. It is likely that the host plants in the crop and grassland habitats differ in their developmental phenology, thus resulting in cereal cropland being an unused host reservoir in regions away from the areas of economic loss. Recently, Montana populations of this insect have moved into the earlier maturing wheter wheat crop from spring wheat, indicating the pest is adapting to cultural practices. The wheat stem sawfly has an obligatory diapause, and it is suspected that geographically diverse populations in North America have differing requirements to break prepupal diapause. After diapause is broken, metamorphosis is completed, and adult males emerge several days before females. Mature females will lay unfertilized eggs, resulting in male offspring, if they do not mate. The mating system of this insect is quite complicated. In cereal crop systems, abundant newly emerged individuals will occasionally mate immediately in the fallow crop residue, but the majority of the mating occurs at the border of the current year's crop. Here, small groups of males form spatially discreet leks that serve to influence receptivity and mating with nearby females perched on vegetation. Lek events are short-lived and recurring, but appear to be triggered by a combination of favorable temperature and bright insolation. Males in a lek area do not appear to relocate, but mated females appear to move into the standing crop to oviposit. This lek-driven mating system utilizes a powerful, nearinstantaneous release of pheromone compounds to facilitate mating. A number of compounds have been identified as having a behavioral and sensory role in this pheromone blend. The lek system appears unusual in a large, continuous acreage of cultivated suitable hosts, but may have developed to facilitate reproduction in relatively arid ancestral grasslands where bunchgrasses and small patches of suitable hosts predominated.

Index terms: Cephus cinctus, pheromone, chemical ecology, lek

[0798] DO HOST-PLANT INTERACTIONS AND SUSCEPTIBILITY TO SOIL CULTIVATION DETERMINE THE ABUNDANCE OF GRAMINIVOROUS SAWFLIES ON BRITISH FARMLAND?

<u>A.M. Barker</u> & C.J.M. Reynolds, The Game Conservancy Trust, Burgate Manor, Fordingbridge, Hants, SP6 1EF, U.K. E-mail: abarker@game-conservancy.org.uk

Relatively little is known about the graminivorous sawflies of the two genera Dolerus and Pachynematus, which feed on cereals and grasses in farmland habitats. Dolerus species are univoltine with spring flying adults and larvae present in the field from May to July; Pachynematus species are bivoltine with spring and summer generations. Both overwinter as pupae underground. In Britain these sawflies are not economic pests but they have an important role in the wider ecology of agricultural ecosystems as important sources of food for birds. In a four-year farm survey, we found that larvae of these two sawfly genera were over six times more abundant in fields of sown perennial rye-grass Lolium perenne than in winter wheat and spring barley crops or long-established grazing pastures. To investigate the factors behind this distribution, we conducted oviposition and rearing trials and experimentally investigated the effect of ploughing on overwintering survival. We found that the three most common Dolerus species and one of the two common Pachynematus species generally preferred perennial rye-grass to winter wheat (Triticum aestivum) and spring barley (Hordeum vulgare) as oviposition hosts. Growth and survival of larvae of five Dolerus species and one out of two Pachvnematus species tested were also significantly higher on rve-grass than on winter wheat or spring barley. Subsequent trials have identified a range of grasses that make more suitable hosts than either cereal. Differences were sufficiently marked to have had a strong influence on the distribution of larvae between crops in the field. In addition, in trials in which we used emergence traps on cultivated and uncultivated areas of the same fields we found that in some years the soil disturbance caused up to 50% extra overwintering mortality, although the extent of this mortality varied from year to year, possibly as a result of variation in the severity of winter weather. This mortality will reinforce the effects of host-plant requirements in leading to decreasing abundance in ploughed cereal habitats. Shifts in patterns of crop rotation towards intensive cereal production with yearly cultivation and also more 'efficient' farming with fewer wildlife-friendly grassy field boundaries may account for recorded decreases in graminivorous sawfly abundance on British farmland.

Index terms: Dolerus, Pachynematus, winter wheat, spring barley, perennial rye-grass

[0800] ACOUSTIC DETECTION AND MONITORING OF CEPHUS CINCTUS SAWFLY LARVAE IN WHEAT STEMS

R. W. Mankin¹ & D. K. Weaver², ¹USDA-ARS-CMAVE, P. O. Box 14565, Gainesville, FL 32604, USA, E-mail rmankin@gainesville.usda.ufi.edu; ²Dept. of Entomology, Montana State Univ., P.O. Box 173020, Bozeman, MT 59717-3020, USA.

The behavior of *Cephus cinctus* Norton larvae in wheat is difficult to study because they are hidden from view inside the stems. We tested the feasibility of using acoustic techniques to nondestructively identify infested stems and monitor larval activity. Adult females were allowed to oviposit in small pots of wheat. After three weeks, a small accelerometer was clamped to the base of each stem and sounds were recorded for -3 minutes. Infested stems and uninfested stems in motion produced short clicks -0.5 msec in duration. The clicks could be detected in the moderate background noise of a research laboratory without using an insulated room or anechoic chamber. No clicks were recorded for from stationary, uninfested stems. After recording, the stems were cut and the locations and weights of any larvae were noted. The signals were analyzed using custom-written digital signal processing software. Methods were developed to distinguish larval movement and feeding activity from background noises. In the initial study, we identified putative larval sounds from 17 of the stems tested. All were infested with larvae (mean weight = $5.25 + 4 \cdot 0.77$ mg). The mean rate of clicks produced by larvae in the infested stems was 1.41 + 4 - 0.26 clicks per minute. Our experience in the initial study led to development of an improved device for clamping the accelerometer to the wheat stem. The use of nondestructive techniques will enable the future monitoring of long-term activity patterns.

Index terms: sound, behavior, activity pattern.

[0801] IMPACT OF CULTURAL PRACTICES ON POPULATIONS OF THE WHEAT STEM SAWFLY (HYMENOPTERA: CEPHIDAE) AND ITS ASSOCIATED PARASITOIDS

W. L. Morrill, S. E. Sing, J. B. Runyon & D. K. Weaver, Dept. of Entomology, Montana State Univ., Bozeman, MT 59717 USA E-mail: wmorrill@montana.edu

The wheat stem sawfly, Cephus cinctus, is an important pest the northern Great Plains of North America. Records indicate that sawflies first occurred in native prairie grasses and were held in check by parasitoids. Wheat was infested when tillage began about a century ago. Many farmers established narrow "strip" fields to minimize soil erosion and also used alternate-year, or "summer fallow" to conserve moisture from 2 years for one crop. These practices affect pest insect and weed populations. *Cephus cinctus* larvae overwinter in lower stem sections, or "stubs". Wasps emerge in June and disperse to standing crops. Although several eggs may be laid in each stem, only one larva survives to maturity due to cannibalism. Larvae complete their development while enclosed within the stems. Infested stems yield less, and usually break or "lodge", before harvest. Insecticide application and other traditional control practices are not effective, therefore a biological control program should be developed. Bracon cephi and B. lissogaster (Hymenoptera: Braconidae) are larval parasitoids that commonly attack C. cinctus in Montana. Levels of parasitism in fields are affected by wheat production practices, and range 5 - 90%. We compared sawfly larval population densities and percent larval parasitism in different winter wheat production systems. The variables were field size (narrow strip fields vs larger block fields) and weed control methodology (herbicide vs tillage). Data indicate that sawfly damage is higher in field borders, therefore overall losses decrease as field size increase. Intensive spring soil tillage of fallow fields suppresses parasitoid populations. In another study, we intensively sampled spring wheat fields to document the spatial pattern and abundance of wheat, wild oat (Avena fatua), sawflies, and parasitoids. Sawfly wasps are more prevalent at the field edges, but larval infestations extend across fields. Wild oat influences the patchiness of larval infestation in wheat. Sawfly wasps readily oviposit in wild oat, but the resulting larvae do not survive.

[0803] BIOLOGICAL CONTROL OF WHEAT STEM SAWFLIES: PAST AND FUTURE

T. G. Shanower¹, ¹USDA-Agricultural Research Service, 1500 N. Central Ave., Sidney, MT 59270, USA; E-mail: tshanowe@sidney.ars.usda.gov

Several species of grass-feeding stem sawflies (Hymenoptera: Cephidae) are important pests of wheat and other grain crops in the northern hemisphere. At least six species have been reported as pests including Cephus fumipennis in China, C. cultratus in central Asia, and C. pygmaeus and Trachelus tabidus in the Mediterranean region. The latter two species are also widespread in Europe and were introduced into eastern North America more than 100 years ago. A third species, C. cinctus, attacks wheat in western North America though its origin is uncertain. The biology of these species is similar. Females oviposit in cereal or grass stems and larvae feed within the stem. The larva moves to the base of the plant as it matures and cut a groove around the inside of the stem. The lumen of the stem is plugged below the groove, forming a chamber for the diapausing larva during the winter or dry season. The weakened stem breaks at the groove leaving a stub. Increased temperatures, moisture and/or photoperiod terminate diapause. Pupation occurs within the stub and adults emerge several weeks later. Stem feeding by sawfly larvae reduce grain weight up to 30%. Fallen, unharvested grain is an additional and unquantified loss. Yield losses of up to 35% have been reported from several countries. Annual losses due to C. cinctus in North America are estimated at approximately US\$100 million. Biological control efforts were first initiated against C. cinctus. Three parasitoids were released in western Canada from 1930-40: two were imported from England and the third came from the eastern US. A second biological control attempt was undertaken in the western US from 1952-55, using parasitoids imported from France. No exotic natural enemies have been established against *C. cinctus*. Biological control efforts against *C.* pygmaeus were carried out 1935-38 in the US and 1937-40 in Canada. Three species were imported from Europe but only Collyria coxator (Hymenoptera: Ichneumonidae) has been established in North America. It appears to play an important role in regulating C. pygmaeus populations, parasitizing up to 80% of C. pygmaeus larvae. The USDA-ARS has initiated a project to find and import effective, new biological control agents for C. cinctus in the western US. Analysis of the failed attempts against this species, and the successful effort against C. pygmaeus, provide insight and important lessons for this new program. This paper reviews previous biological control efforts against wheat stem sawflies, discusses possible reasons for the earlier failures, and outlines the approach and progress of the new project.

Key words: Cephus spp., Collyria spp., parasitoids

[0804] FOREIGN EXPLORATION FOR SAWFLY NATURAL ENEMIES

K. Hoelmer, USDA-ARS, European Biological Control Laboratory, Campus International de Baillarguet, CS-90013 Montferrier-sur-Lez, 34988 St. Gély du Fesc Cedex, France, E-mail khoelmer@wanadoo.fr.

Sawflies (Hymenoptera: Cephidae: Cephini) which feed and develop within the stems of small grain crops are widespread throughout the the northern hemisphere, particularly in the Palearctic region. Wheat is the primary crop impacted, but these sawflies also attack rye, barley and timothy, as well as various native, non-crop grasses. Cephid species causing significant damage to crops occur in North America, Europe, Asia and north Africa. However, relatively little is known regarding their ecology in wild grass hosts, including the occurrence and impact of natural enemics. Following the successful introduction and establishment of European parasitoids against Cephus pygmaeus in North America, several unsuccessful attempts were made during the early to mid-twentieth century to establish new parasitoids, also originating from Europe, against Cephus cinctus in North America. The failures were attributed to a lack of adaptation to C. cinctus or to the lack of proper synchronization with suitable host stages. Further collections and introductions were not pursued at that time. However, taxonomic uncertainty exists regarding the identity and relationship of various species of Cephus. Important natural enemy taxa are also in need of revision. Further field collections and biological studies are warranted, especially for species in central and eastern Asia for which information is particularly sparse. Such collections would provide new study material for taxonomic revisions, and possibly new populations and/or species of natural enemies for biological control evaluations. Thus, new opportunities exist for the discovery and collection of better-adapted parasitoid populations in regions with climates that are very similar to those of the desired areas of introduction. Greater success in evaluations and releases may also result from faster delivery and better handling of overseas shipments, and from improved knowledge of natural enemy biology, behavior, and ecology. Index terms: Cephus, Trachelus, parasitoids.

[0805] CONDITIONAL MUTUALISMS IN ANT-PLANT-HERBIVORES INTERACTION IN TROPICAL SAVANNA

K. Del-Claro, Univ. Fed. Uberlândia, InBio, CP593, Cep 38400-902, Uberlândia, MG, Brazil. delclaro@ufu.br

The outcomes of mutualistic interactions are dependent upon the ecological settings in which they occur. In this directions we will show results of two studies conduced in Brazilian cerrados. Controlled ant-exclusion experiments in a system involving an extrafloral bearing Malpighiaceae, *Peixotoa tomentosa*, revealed that herbivory and fruit production are dependent on ant associated species behavior. Also the interaction between herbivore-ant behavior and herbivore-ant-plant morphologies can change the meaning of each relationship. In the association between the honeydew-producing membracid *Guayaquila xiphias* and its ants attendants, two years of controlled ant-exclusion experiments showed that ant effects on treehopper survival and fecundity were conditioned by time, and varied with shifts in the abundance of natural enemies. In both studies the results also revealed that plants and herbivores are positively or negatively affected depending on ant presence and species.

Index terms: Guayaquila xiphias, Camponotus, Thysanoptera, Malpighiaceae, Araliaceae,

[0807] ANT-WHITEFLY INTERACTION IN A NEOTROPICAL FOREST: ANT ATTENDANCE REDUCES FUNGAL AND PARASITOID ATTACK

<u>I. M. Queiroz</u> & P. S. Oliveira, Departamento de Zoologia, Universidade Estadual de Campinas, C.P. 6109, 13083-970 Campinas SP, Brasil. E-mail: jqueiroz@obelix.unicamp.br.

Sap-feeding whiteflies (Aleyrodidae) have increasingly attracted the attention of applied entomologists due to the severe damage that these homopteran insects may cause to economically important crop plants. Whitefly damage to plant results mainly from colonization by sooty mold encouraged by honeydew build-up, which markedly depreciates the commercial value of plant-derived food products. Continuous collection of honeydew by tending ants can confer a range of benefits to homopterans such as aphids, scales, and treehoppers. Surprisingly, however, despite the widespread ocurrence of anthomopteran associations in temperate and tropical regions, there is no experimental study on ant-whitefly interaction. We investigated the interaction between the honeydewproducing whitefly Aleurothrixus aepim (Hom: Aleyrodidae) and tending ants on shrubs of Croton floribundus in a forest reserve in SE Brazil. Ovipositions of A. aepim were randomly divided in two experimental groups: control (ants present) and treatment (ants excluded). Adults emerged in significantly greater numbers from control than from treatment aggregations, the latter being heavily attacked by fungi due to accumulation of honeydew. Decimation by fungi due to honeydew build-up was 3 times more frequent at ant-excluded than at ant-tended groups. Control aggregations with low levels of ant attendance produced significantly fewer adults than those more frequently tended by ants. Parasitoid wasps were more frequent on ant-excluded than on control whitefly aggregations. This is the first demonstration of an ant-derived benefit to honeydewproducing whiteflies. Given that aleyrodid honeydew causes severe damage to several crop plants in tropical and temperate areas, our results suggest that the honeydew-gathering activity by tending ants can be relevant for the management of agroecosystems. Index terms: Aleurothrixus aepim, Aleyrodidae, Homoptera, honeydew, mutualism

[0809] PATTERNS OF SPECIALIZATION AMONG LEPIDOPTERAN HERBIVORES OF *INGA* (FABACEAE: MIMOSOIDEAE) AND THEIR PARASITOIDS

<u>S. Koptur</u>, Dept. of Biological Sciences, Florida International Univ., Miami, FL 33199, USA, E-mail kopturs@fiu.edu.

Lepidopteran eggs and caterpillars encountered on five common species of montane Costa Rican Inga over a two-year period were reared for identification and parasitization information. Fifty species in sixteen families of Lepidoptera were reared: eleven spp. of microleps (Oecophoridae, Gelechiidae, Torticidae); 32 spp. of moths in eleven families (Limacodidae, Megalopygidae, Pyralidae, Percephoridae, Saturniidae, Geometridae, Eupterotidae, Noctuidae, Notodontidae, Arctiidae, Ctenuchidae); 2 skipper spp. (Hesperiidae) and 5 butterfly spp. (Pieridae). All Inga spp. have extrafloral nectaries that serve to attract both ants (more common at lower elevations) and parasitoids (more frequent at higher elevations where ants are scarce). Several parasitoid species reared from herbivores were also collected at nectaries. Egg parasites included species of Many caterpillars were killed by Cecidomylidae, Encyrtidae, and Scelionidae. parasitoids, primarily flies (Tachinidae) and wasps (Braconidae, Eulophidae, Ichneumonidae), though some were consumed by entomophagous fungi. Eight of the herbivore species occurred on most of the *lnga* spp., while most were restricted to one or two species. Herbivore species that were found on more than two species of Inga were parasitized more frequently than those species found on only one hostplant species. Index terms: Pieridae, Megalopygidae, Hesperiidae, Braconidae, Tachinidae.

[0810] A FRAMEWORK FOR INSECT MIGRATION STUDIES – AND SOME RECENT ADVANCES

H. Dingle, Dept of Entomology, Univ. of California, Davis, One Shields Ave., Davis, CA 95616, USA. Email: rdhdingle@ucdavis.edu.

Following Drake et al. (1995), we can think of a migration system as consisting of an arena in which migration takes place, a population trajectory, and a behavioral syndrome based in the genes and molded by natural selection. Habitat duration in the arena influences the frequency and occurrence of migration, and this is often determined by climate. A clear example occurs in Australian butterflies where climate variables such as soil moisture levels profoundly affect the proportion of migrants among butterfly regional faunas. Population trajectories are often wind guided, but in robust flyers like butterflies may be under the control of the individual insect and involve well-developed orientation mechanisms. Examples of orientation will be presented for both Australian and North American butterflies. Migration syndromes involve not only flight itself but also a variety of correlated traits from life history characters to flight muscle enzyme properties. These are revealed by studies of migratory and flight polymorphisms, and I shall provide examples from rapidly evolving species of seed bug (Henniptera). Finally, I shall demonstrate that the syndromes are based in the genes. Throughout I shall stress important gaps in our knowledge and suggest some directions future studies might take. Index terms: Flight, butterflies, Henniptera, polymorphisms, climate

[0813] INSECT MIGRATION AND POPULATION PROCESSES IN INLAND AUSTRALIA OBSERVED WITH MONITORING RADARS

V.A. Drake & H.K. Wang, School of Physics, University College, The University of New South Wales, Australian Defence Force Academy, Canberra, ACT 2600, Australia. E-mail: a.drake@adfa.edu.au.

In the semiarid environments of inland Australia, erratic rainfall leads to highly variable and essentially unpredictable spatial and temporal patterns of vegetation growth. These regions host a number of species of migratory insects that are well adapted to exploiting ephemeral vegetation flushes, and which can develop very large populations when conditions remain favourable for several generations. Some of these species are pests and cause major economic impacts when population growth is followed by migration into adjoining or distant dryland and irrigated cropping areas. A current study of the movements of these populations aims to relate them to the changing distribution of resources, with the twin objectives of developing understanding of how the species' migratory adaptations function and of improving pest-forecasting capabilities. Data acquisition for the study is centred around a pair of automatic monitoring radars that quantify the intensity, direction, speed, and altitude of nocturnal migration at two locations within the study area. The direct observations of insect movement that these radars provide are supplemented by satellite data on vegetation state and rain-producing clouds, and by a limited program of surveys (of both hosts and pests) and light trapping. Wind-borne transport opportunities are identified from regional meteorological analyses, and the various observations are integrated within a Geographic Information System. The potential of this suite of observing and analysis techniques is illustrated with data on spring

novements of Helicoverpa punctigera and other moths, and summer movements of Australian plague locusts Chortoicetes terminifera. Index terms: Chortoicetes, Helicoverpa, moth, locust, forecast.

[0814] INVESTIGATING OPTIMAL MIGRATION STRATEGIES IN BUTTERFLIES: THE USE OF LOCAL AND CELESTIAL CUES TO ADJUST COURSE AND FLIGHT SPEED

<u>E. G. Oliveira</u>¹, R. B. Srygley² & R. Dudley³, ¹Depto. Biologia Geral, Inst. Ciências Biológicas, Univ. Federal de Minas Gerais, 30161-970, Belo Horizonte, MG, Brazil, Email evandro@mono.icb.ufmg.br; ²Dept. Zoology, South Parks Road, Univ. of Oxford, Oxford OX1 3PS; ³Section of Integrative Biology, Univ. of Texas, Austin, TX, 78712, U.S.A.

Butterfly migrations occur worldwide and are particularly common in the tropics, where distribution of rainfall appears to underlie both the phenology and direction of movements. In such cases, migration may require butterflies to discriminate favorable meteorological conditions in order to initiate light and to be equipped with orientation and navigation mechanisms to reach particular geographical destinations. In addition, migration may involve high energetic expenditure, and butterflies may be required to adopt optimal or more efficient migratory strategies in order to minimize costs. Over the last several years, we have investigated these questions on a multi-species migration system in Panama and Colombia. Results from clock-shift experiments performed with two butterfly species (Aphrissa statira and Phoebis argante) supported the hypothesis that a time-compensated sun compass is used for migratory orientation. Vector analysis of butterfly airspeed, track direction, wind speed, and wind direction to estimate butterfly heading and drift showed that butterflies (A. statira, Phoebis argante, and Marpesia chiron) change their headings to compensate for crosswind drift. This result suggests use of a sun compass in coordination with directional information obtained from local landmarks. Butterflies were less likely to compensate for crosswind drift when local landmarks were absent. In contrast, no evidence for wind drift compensation was found in the day-flying uraniid moth Urania fulgens. Also as predicted from optimal migration theory, butterflies (P. sennae) adjusted their airspeed according to wind direction, flying at a lower speed with tailwinds. However, the two sexes seem to adopt different migratory strategies, as only females exhibited this last behavior. Males may minimize migration time to destination in order to increase their chances to fertilize newly emerging females. Finally, as suggested by aerodynamic theory, flight speed of U. fulgens decreased as endogenous energy reserves were gradually depleted. Together, these findings support the general notion that insect migration comprises specialized behavioral and physiological processes, and that insects approximate an optimal migratory strategy. Research on behavioral mechanisms may provide the basis for understanding the adaptive significance of butterfly migrations and for planning their conservation.

Many studies have investigated changes in flight-related traits in insects over evolutionary time (e.g reduced dispersal on true oceanic islands, evolution of migration syndromes in heterogeneous habitats). Here we produce evidence of rapid evolutionary changes in flight traits in ecological time. We present data showing evolutionary changes in flight-related traits in Lepidoptera in response to changes in availability of breeding habitat (due to rainfall, habitat fragmentation, climate change etc) occurring on an ecological time scale. We discuss implications of these rapid changes for insects persisting in modern Index terms: Spodoptera exempta, Pararge aegeria, Hesperia comma, phenotypic

plasticity.

[0818] MOVEMENT OF APHID PARASITOIDS OVER DIFFERENT SPATIAL SCALES STUDIED USING MOLECULAR MARKERS

H. D. Loxdale¹, C. P. Brookes² & W. Powell³, ^{1, 2, 3}. Entomology and Nematology Dept., IACR-Rothamsted, Harpenden, Herts, AL5 2JQ, U.K. E-mail: hugh.loxdale@bbsrc.ac.uk

There is considerable interest in the use of primary Hymenopterous parasitoids as biological control agents in IPM strategies to combat aphids. Within agro-ecosystems, such strategies could involve the manipulation of extant parasitoid populations, encouraging them to move between crop and alternative or 'reservoir' hosts in nearby uncultivated land. For these approaches to succeed, knowledge of the population structure and dynamics of the parasitoid/s concerned is highly desirable, along with information about host specificity, i.e. 'generalism' or 'specialism'. Recently, we have demonstrated that morphologically similar primary parasitoids Aphidius ervi sensu lato attacking sympatric populations of pea aphid (Acyrthosiphon pisum) and nettle aphid (Microlophium carnosum) appear to display host specificity and reproductive isolation. Whilst host forms of the parasitoids will readily cross and produce viable offspring in culture, field collected samples showed fixed allelic differences at the phosphoglucose mutase locus. The result emphasises the importance of thoroughly studying the population structure of 'parasitoid species' before assuming them to be 'generalist'. Besides such fundamental concerns about host specificity, if parasitoids are to be mass released or natural populations manipulated, it is important to understand 1, how far particular genotypes or strains travel; 2, how long particular genotypes/strains persist in the field; 3, whether there is gene flow between populations attacking different hosts or occupying different habitat patches and 4, how many times individual female parasitoids attack particular host colonies, as reflected in patterns of genetic variability. Detailed information on these various aspects is scarce. A major problem is the haplo-diploid reproductive system of parasitoids, which can result in populations becoming homozygous at isozyme loci. Because of this tendency, we have designed a suite of microsatellite DNA markers and are presently using these to investigate spatio-temporal parameters in the primary parasitoid, Diaeretiella rapae attacking the cabbage aphid, Brevicoryne brassicae infesting oilseed rape, Brassica napus in southern England. In this talk, I shall describe how the use of a range of polymorphic microsatellites is providing insights into the population structure and dynamics of D. rapae, including behaviour, attack strategy and breeding systems, at spatial scales ranging from single leaf through to farm scale. It is hoped that the information gained can aid the design of IPM strategies as well as contributing to simulation models of parasitoid population spread and effectiveness

Index terms: Hymenoptera, Aphidius spp., Diaeretiella rapae, isozymes, microsatellites

[0820] INTERSPECIFIC INTERACTIONS, POPULATION DYNAMICS & COMMUNITY STRUCTURE

W. W. Murdoch¹ & S. L. Swarbrick², 1, 2. Dept. of Ecology, Evolution & Marine Biology, Univ. of California, Santa Barbara, CA, 93106-9610, USA

Entomologists have discussed for decades whether, and under what circumstances, it is better to release multiple natural enemies rather than the single "best" enemy to achieve biological control. Population dynamics theory provides some guidance, but no single answer. In practice, release of several to many species is common, and apparently competing species of natural enemies coexist in many cases of successful biological We will discuss the results of a field experiment in a citrus grove where control. California red scale, Aonidiella aurantii, is under control, putatively by the parasitoid Aphytis melinus, but other enemies are also present. Red scale density was increased experimentally and the responses of two parasitoid species and a number of predators are being measured.

[0821] LIFE HISTORY AND ITS ROLE IN INTERSPECIFIC INTERACTIONS

<u>G. H. Walter</u>, Department of Zoology and Entomology, The University of Queensland, Brisbane Qld 4072, Australia. E-mail: g.walter@mailbox.uq.edu.au.

Interspecific interactions dictate a great deal of what we observe in ecological systems. The most significant interactions in "structuring" these systems are those that have a functional basis, and it is around these that we need to develop realistic generalisations for theoretical purposes. Functional interactions are mediated by specific mechanisms that evolved to serve a particular "purpose" or function, and they can be contrasted with those interactions that take place incidentally (mainly interspecific competition). The latter have no such mechanistic basis. They are consequently variable in process as well as outcome, and the course they follow is influenced even by small variations in numerous contingent environmental circumstances. The life history properties of organisms that are relevant to developing realistic generalisations about interspecific interactions are those that mediate functional interactions. These proximate mechanisms lead to the observable patterns of resource use, host specificity, and so on. They are stage-specific and are governed by the physiological state of the organism. How do such interactions evolve? Two answers are available, with these being dependent upon the underlying interpretation of natural selection. One view sees evolution progressing competitively, through selection working to increase or optimise "efficiency". The alternative view does not involve intraspecific competition as a primary driver of evolutionary change. Selection works primarily on the proximate mechanisms and their effective functioning within particular environmental contexts. Such functional interactions are "complex and co-ordinated" in being made up of a sequence of subsidiary steps, each inconsequential in itself, but which together and in sequence achieve a particular end point (the function). Such a structure implies that adaptive change does not take place under "everyday" ecological conditions (as accepted under optimality theory), but occurs only when change is imposed by consistently altered environmental and biotic conditions. Complex mechanisms are therefore stable under the usual conditions occupied by individuals of particular species, and are species-wide in distribution. These alternative views clearly have different implications from one another for the interpretation of local diversity ("community structure") and the use of organisms in population management.

Index terms: life history, interspecific interactions, evolution

[0823] INTERSPECIFIC INTERACTIONS AMONG PARASITOIDS IN AGROECOSYSTEMS

C.E. Bográn¹ & K.M. Heinz¹, ¹Department of Entomology, Texas A&M Univ., College Station, TX 77845-2475, USA. Email: cabo@tamu.edu.

Even though there is evidence to suggest a significant role of interspecific interactions among parasitoids on host population suppression, few studies have addressed this issue experimentally. Agroecosystems offer unique advantages to manipulative studies on interspecific interactions among parasitoids. In these systems, host plant variation is minimized by planting dates, cultivars and agronomic practices. Plant variation can influence the second trophic level (the herbivores), which in turn is a major determinant of the third trophic level (the parasitoids). The inherent control of variability at the lower trophic levels in agroecosystems, simplifies comparisons at the higher trophic levels. Bemisia whitefly (Hompotera: Aleyrodidae) and three of its parasitoids were used as models to 1) evaluate the occurrence and dynamics of interspecific interactions among parasitoids in a cotton agroecosystem; 2) assess the impact of interspecific interactions on the biological control of Bemisia argentifolii; and 3) examine the potential role of interactions on the composition of parasitoid communities. Encarsia pergandiella, a heteronomous hyperparasitoid (males develop as secondary parasitoids and females develop on 3^{sd} and 4^{sh} instar *B*. argentifolic) and two primary parasitoids, *Eremocerus* mundus, (males and females develop on 2^{sd} and 3^{rd} instars) and *Encarsia formosa* (a uniparental species that develops on 3^{rd} and 4^{th} instars) were the parasitoids included in our studies. Field manipulations were performed using large inclusion cages (3 x 3 x 2 m) that enclosed whitefly infested cotton plants. Parasitoids were released into cages in all species combinations or under different initial densities and conditions (simultaneously or in sequence). In each experiment, parasitoid and host populations were sampled periodically to compare population growth rates of parasitoids and host suppression levels among parasitoid combinations. Results showed asymmetrical competitive interactions and coexistence among the three parasitoids. The presence of competitors reduced population growth rate of E. formosa and E. pergandiella but not the population growth rate of E. mundus. Initial population density affected the outcome of competitive interactions among E. mundus and E. pergandiella. In most cases competitive interactions did not affect host population suppression. However, releases of E. formosa together with E. pergandiella showed lower levels of host suppression than those expected in the absence of competitive interactions. Differences in the distribution of parasitism along the vertical axis of cotton plants suggest that host utilization patterns may promote coexistence. Our studies demonstrate the potential impact of interspecific interactions on the dynamics of parasitoid and host populations and their role in parasitoid community composition. Index terms: Bemisia, Encarsia, Eretmocerus, competitive interactions.

[0822] HYPERPARASITISM AND ECTOPARASITISM: THE IMPACT OF OMNIVOROUS INTERACTIONS ON POPULATION MANAGEMENT

N. J. Mills, Insect Biology, Wellman Hall, Univ. of California, Berkeley, CA 94720-3112, USA, E-mail nmills@nature.berekeley.edu

Interspecific interactions between insect parasitoids can take a variety of forms, but the two most frequent direct interactions are hyperparasitism and ectoparasitism. The parasitoids of codling moth (Cydia pomonella, Lep.: Tortricidae) serve as a model to illustrate the generality of omnivory in capturing the functional significance of such interactions. Ascogaster quadridentata (Hym.: Braconidae) is a primary parasitoid of the codling moth attacking the egg stage of its host and developing as an endoparasitoid to kill the host as a prepupa within its cocoon. Although some hyperparasitoids have obligate relationships, developing only on primary parasitoids, the more frequent case is facultative hyperparasitism in which the parasitoid can also develop as a primary parasitoid of a phytophagous insect host. Dibrachys cavus (Hym.: Pteromalidae) is an important facultative parasitoid of the codling moth developing as a gregarious ectoparasitoid of codling moth cocoons and as a hyperparasitoid of the cocoons of several parasitoids, including A. quadridentata. Larval ectoparasitism is generally considered a form of primary parasitism. However, under some circumstances, by virtue of their more rapid development, larval ectoparasitoids develop at the expense of co-occurring endoparasitoids and are functionally equivalent to facultative hyperparasitoids. Hyssopus pallidus (Hym.: Eulophidae) is a gregarious ectoparasitoid of codling moth larvae that not only develops at the expense of A. quadridentata when they co-occur on the same host, but also experiences a substantial fitness gain by producing twice as many normal-size adult progeny from clutches laid on host larvae previously parasitized by A. quadridentata. These interactions are captured by a discrete-time, one host - two parasitoid model in which the facultative nature of hyperparasitism and ectoparasitism are represented by omnivory. Although hyperparasitism and the fitness advantage of ectoparasitism might be considered antagonistic relationships that should be avoided in classical biological control, analysis of the model indicates that these omnivorous relationships can frequently lead to enhanced reduction in the abundance of a phytophagous host. Thus contrary to popular belief, omnivory at the third trophic level should be promoted in the management of insect pest populations.

Index terms: Cydia pomonella, Ascogaster quadridentata, Hyssopus pallidus, biological control

[0824] INTERSPECIFIC INTERACTIONS AMONG ENTOMOPHAGOUS INSECTS IN PROTECTED CULTURES

H. F. Brødsgaard & A. Enkegaard, Dept. Crop Protection, Danish Institute of Agricultural Science, Research Centre Flakkebjerg, DK-4200 Slagelse, Denmark.

Interspecific interactions among arthropods in protected crops has become increasingly important as the use of still more complex biological control programs have been implemented in to glasshouse crops. In many areas of Northern Europe, ornamental growers are trying to use biological control of pests by means of beneficial arthropods because the number of registered effective pesticides is decreasing. One of the many features in which ornamental crops differ from vegetables is the wide range of arthropod pest species that may attack an ornamental crop species. Many crops are attacked by six to ten different pest species that have to be controlled simultaneously by a set of beneficials. Due to the facts that many pest species are difficult to control, the damage thresholds are very low, and the cropping cycles often are very complex several beneficial species have to be introduced not only against the pest complex in general but against each pest species. Many of the presently used heneficial arthropods are not monophagous. Hence, intraguild predation among introduced predators or predators switching away from the target pests are likely to occur. Several examples from laboratory experiments document intraguild predation among biological control candidates. Fewer studies suggest intraguild predation in glasshouse crops. However, both control failures and control delays due to intraguild predation are reported and in such cases the outcome of the control programs may differ from what can be expected based on the experience that has been generated from the much simpler greenhouse vegetable systems. The positive and negative aspects of using polyphagous predators have been discussed for years and the use of monophagous beneficials in biological control programs have been emphasised by many authors. In the present paper we will discuss the role of intraguild predation with a system approach and with focus on system stability and end control results.

[0825] FACTORS INFLUENCING DISTRIBUTION AND ABUNDANCE OF DIPLOLEPIS (CYNIPIDAE) IN CANADA

J. D. Shorthouse, Dept. of Biology, Laurentian Univ., Sudbury, Ontario, P3E 2C6, Canada.

All 12 species of cynipid wasps of the genus Diplolepis induce galls on either the leaves or stems of wild roses in Canada. There are 10 species of wild rose in Canada and all are host to at least one species of Diplolepis. Some species of roses are widely distributed across Canada south of the tree line whereas others are narrowly distributed. Likewise, some species of Diplolepis are found across most of Canada whereas others have a restricted distribution. Some species of Diplolepis are found on one species of rose whereas others are found on 2-3 species. Roses are common in montane, grassland and forested regions of Canada where they are ephemeral shrubs with patches becoming established following disturbance. Patches in grasslands may persist for >40 years whereas patches in openings in forested regions usually persist for 15-20 years. *Diplolepis* and their galls are likewise ephemeral with their distribution and abundance determined by presence of their host shrub, weather conditions at the time of adult emergence and oviposition, ability of inducers to survive winter temperatures, attack by parasitoids and inquiline cynipids, and size and distance between host patches. Diplolepis inducing galls on leaves support a component community of parasitoids and inquilines whereas most species inducing galls on stems have only parasitoids associated with their galls. Comparing the distribution and complexity of associated component communities reveals important patterns in evolution of the Diplolepis complex.

Index terms: Diplolepis, galls, roses, community, zoogeography

[0827] HOW GALL WASPS BECAME GALL WASPS

F. Ronquist¹ & J. L. Nieves Aldrey², ¹Dept. Systematic Zoology, Evolutionary Biology Centre, Uppsala Univ., Norbyv. 12, SE-752 36 Uppsala, SWEDEN, E-mail: fredrik.ronquist@ebc.uu.se; ²Museo Nacional de Ciencias Naturales, CSIC, José Gutierrez Abascal 2, ES-28006 Madrid, SPAIN.

Most gall-forming insects are considered to have evolved through a slow transition from phytophagous but not gall-inducing forms through forms making very simple galls to true gall inducers. The most cited scenario for the origin of gall wasps postulates such a slow transition from stem feeders on herbs in the family Asteraceae to species inducing true galls. However, recent phylogenetic studies suggest that the stem feeders on Asteraceae are not primitive but evolved from ancestors producing typical galls. Instead, the first gall wasps are likely to have induced conspicuous single-chambered galls in the seed capsules of Papaveraceae. Here, we present evidence that these early gall inducers evolved from parasites feeding internally on hymenopteran larvae that lived in, and perhaps induced, similar galls. These ancestral gall parasites lived more than 83 million years ago. The transition from insect parasites to gall inducers involved few morphological changes and left no surviving intermediate forms, which suggest that it was rapid. This indicates that the elusive gall-inducing principle of gall wasps may be a simple modification of a mechanism used by their insect-parasitic ancestors to control the development of the host larva. Furthermore, it means that none of the three traditional adaptive explanations for the origin of galling insects are likely to apply to gall wasps.

[0826] MOLECULAR PHYLOGENETIC ANALYSIS OF GALL STRUCTURE AND EVOLUTION IN APHIDS

T. Fukatsu, Natl. Inst. Biosci. Human-Tech., Tsukuba, Ibaraki 305-8566, Japan, E-mail: fukatsu@aibh.go.jp

In aphids, there are two subfamilies, Hormaphidinae and Pemphiginae, almost all members of which form conspicuous galls on their primary host plant. They provide us with an opportunity to investigate the evolution of diversity in insect galls which are the product of intimate and sophisticated plant-insect interactions. The tribes Cerataphidini, Nipponaphidini and Fordini are particularly interesting groups in the subfamilies because (i) they embrace a considerable number of gall-forming species, (ii) their galls show a variety of shape, size and structure, (iii) gall formation in the respective groups can be assumed to be of a single evolutionary origin, and therefore (iv) independent phylogenetic analyses of these three groups allow us to conduct comparative evolutionary analyses. In this paper, we infer phylogenetic relationships in the respective groups based on mitochondrial rDNA sequences, and evolution of their galls are analyzed on the phylogeny. Evolutionary relationships between various gall-related characters are discussed such as gall formation site on the plant, basic structure of the gall, gall size, colony size, folds and projections on the gall wall, thickness and lignification of the gall wall, formation of the gall opening, defense by soldier individuals, etc.

Index terms: aphids; galls; evolution; molecular phylogenetic analysis; mitochondrial ribosomal RNA genes

[0828] CIRCADIAN TEMPERATURE PATTERNS IN TWO CECIDOMYIID GALLS OF MACHILUS THUNBERGII (LAURACEAE)

Chi-Ming Yang¹, Wen-Yang Jen¹ & <u>M. M. Yang²</u>, ¹ Institute of Botany, Academia Sinica, Nankang, Taipei, Taiwan 115, R.O.C.; ² Dept. of Entomology, Nat. Chung Hsing Univ., 250 Kuo Kuang Rd., Taichung, Taiwan 402, R.O.C. E-mail: mmyang@dragon.nchu.edu.tw.

The temperature of two Daphnephia cecidomyiid galls of Machilus thunbergii leaf was recorded with a copper-thermocouple being plugged into the gall chamber and were compared with those of the air and soil, and relative humidity. They are oval-pointed and obovate galls and distributed in the northwestern and southeastern sides of Datun Mt. range in the Yangmingshan Mt. National Park at northern Taiwan. From the macroscopic view, the temperature of gall inside always follows that of the air outside. From the microscopic view, however, a general circadian temperature pattern was observed under whatever temperature condition. While the air temperature risen between midnight to midday, the gall temperature was always higher than the former until the maximal; then while the air temperature fell from midday to midnight, the gall temperature was always lower than the former until the minimal. In addition, the discrepancy between the gall and air temperature was gradually amplified during the rising period, and that gradually narrowed down during the falling period. Therefore, two circadian transition points existed at around midday and midnight each day. However, the above circadian rhythm disappeared during the cold wave period. In such weather condition, the temperature of the gall chamber is always lower than that of the air. It is apparent that the gall wall plays no role as a temperature insulator at all for the insect living inside. We propose that the circadian rhythm of gall chamber temperature is a function of the circadian behavior of the insect residing inside the gall. Further studies are necessary for identifying the behavior contributed to the gall temperature fluctuation.

Index terms: circadian rhythm, Daphnephia, Taiwan

[0829] SPECIATION IN GALL-INDUCING INSECTS

T.P. Craig¹, J. K. Itami¹ & J. D. Horner², ¹Department of Life Sciences, Arizona State Univ. West, P. O. Box 37100, Phoenix, AZ 85069, USA; ²Department of Biology, Box 298930, Texas Christian University, Fort Worth, TX 76129, USA

The characteristics of gall-inducing insects permit rapid speciation through a variety of modes including sympatric speciation. This will be illustrated by studies on the host races of a gall-inducing tephritid fly Eurosta solidaginis. Speciation mechanisms typically are divided into categories based on the degree of geographic isolation: allopatric, parapatric, and sympatric. The probability that speciation will occur by any of these modes depends on population characteristics including: dispersal ability, habitat specificity, mating behavior and relationship to natural enemies. Gall-inducing insects have several characteristics that favor sympatric speciation, which are direct consequences of the gallinducing habit. These same characteristics also increase the speed of speciation in allopatry. First, sympatric speciation models assume that there is strong disruptive selection for habitat use. Gall-inducers are highly host specific, so if a population of a species colonizes a new plant there will be strong disruptive selection for host use: that is each population performs best on its own host plant. Thus following a host shift there would be strong selection for the evolution of reproductive isolating mechanisms. A second critical assumption of sympatric speciation models is for the presence of strong habitat-based assortative mating. Sympatric speciation is favored when relatively few genes are involved in reproductive isolation. Habitat-based assortative mating lessens the number of loci involved because the same genes may control both habitat selection and assortative mating, Gall-inducing species commonly mate on their host plant. Gallinducers' extreme host specificity and strong host fidelity in mating site selection results in assortative mating and favors sympatric speciation. Third, fitness gains associated with the newly acquired host plant can also increase the probability of the successful establishment of a population as the result of a host shift. Since many natural enemies of gall-inducing insects locate their hosts by locating their host plants, a host shift can increase fitness through the colonization of enemy-free space. Finally, the small size of insects has several consequences that facilitate speciation. Small size, in general means that dispersal is relatively limited, and the strength of dispersal barriers is increased. Short generation time, and large population size means that new genotypes are rapidly generated. This increases the probability for genetic combinations permitting host shifts and speciation to occur. Index Terms: Eurosta solidaginis, gall, sympatric speciation, assortative mating.

[0830] THE GALL MIDGES (DIPTERA: CECIDOMYIDAE) FROM COASTAL SHRUB ZONE OF RIO DE JANEIRO STATE (BRAZIL)

V. C. Maia, Museu Nacional, Depto. Entomologia. Quinta da Boa Vista, São Cristóvão. 20940-040 Rio de Janeiro, R. J. Brazil. E-mail: maiavcid@acd.ufrj.br

The coastal shrub zone (restinga) is a very complex environment whose biodiversity is exceeded only by pluvial forests. Three restingas of Rio de Janeiro State - Restinga of Barra de Maricá, Itaipuaçu and Carapebus - were investigated: the first one from January to December, 1997; the second from November, 1997 to October, 1998 and the last one from May, 1998 to April, 1999. The flora is relatively well known in these restingas due to surveys developed by brazilian botanists. Data on Cecidomyiidae fauna are scarce. Collections of the galls were made monthly in the three areas. The geographic coordinates of the collection points were obtained using the Global Positioning System. Samples of host plants were pressed and later identified mainly by Profs. Andrea Costa and Rui Valka (Depto. Botânica, Museu Nacional). Samples of dried galls are incorporated in the Diptera collection of Museu Nacional. Larvae and pupae of the gall midges were obtained from the dissection of each kind of gall under a stereoscopic microscope. This procedure also enabled the determination of the gall dwellers' habits (inquilinous, predaceous, parasitoid or gall making). The exuviae and adults were obtained in the laboratory. Larvae, pupae, exuviae and adults of Cecidomyiidae were preserved in 70% alcohol and they were later mounted on slides. The gall midges were identified by the author and the other arthropods obtained from the galls - micro-Hymenoptera, Formicidae and Pseudoscorpiones - were identified by Dr. John La Salle (International Institute of Entomology, London); Dr. Antônio Mayhé Nunes (UFRRJ, Rio de Janeiro) and Dr. Mark Harvey (Western Australia Museum), respectively. One hundred and eigth species of gall midges were found in association with 53 species of plants distributed among 42 genera and 32 families. Ninety three gall midge species were eccidogenous, 4 predaceous, 5 inquilinous and 6 were free living. Galling species were associated with 47 plant species belonging to 36 genera and 28 families. The majority of the galls occurred on the leaves (N=63), 13 on bud, 9 on inflorescence, closed flower or flower peduncule, 3 on fruits and 1 on tendril. The Myrtaceae were the richest family in number of galls followed by Burseraceae and Nyctaginaceae. Seventy nine Cecidomyiinae species were found at Restinga of Barra de Maricá, 64 at Carapebus and 41 at Itaipuaçu. Sorensen's index revealed that the restingas of Barra de Maricá and Itaipuaçu are more similar in Cecidomylinae fauna, confirming a positive relation between geographical proximity and fauna similarity.

[0831] GALLING APHIDS AS PHYSICAL ECOSYSTEM ENGINEERS : THE VASCULAR SYSTEM IN APHID GALLS AS A MASS-FEEDING APPARATUS

D. Wool ¹ & R. Aloni ², Departments of Zoology ¹ and Plant Sciences ², Tel Aviv University, Tel Aviv 69978, ISRAEL.

Galling insects create a favorable environment for their descendants by modifying the developmental pathways of their host plants. The primary function of these modifications is to insure the food supply of the gall inhabitants. We study the development of the vascular system in different galls induced on Pistacia trees (Anacardiaceae) by gallforming aphids (Fordinae, Pemphigidae; Homoptera). Aphids feed from the phloem in the vascular system, and their galls contain the parthenogenetic offspring of single fundatrices. Each species galls a different site on the leaf and makes a gall of a specific shape. Clone sizes vary among species, from less than 100 to several thousand , all of which must obtain food in the gall. The plant vascular system is greatly modified to meet these needs. While in the vascular bundles of the ungalled leaf, the xylem differentiates towards the center and the phloem towards the periphery, in the gall new vascular bundles are formed in which the order is reversed, placing the phloem close to the gall cavity where the aphids are located . In closed, bag-like galls the vascular system is organized into an elaborate network of feeding tubes, enveloping the gall cavity a few cell layers beneath the surface. In the smaller, leaf-margin galls the structure is again different . The differences may be related to the structure of the meristematic tissues at the galling sites. The mechanisms by which these modifications are induced are unknown, but probably involve modifications of the balance between plant hormones (auxin/ cytokinin) at the galling site at the early stages of leaf differentiation. Our comparative study of the histological structure of galls of different species on the same host may give us some clues for the mechanism.

Index: galling aphids, Fordinae (pemphigidae), gall anatomy, vascular system

[0832] TEMPORAL VARIATION IN HOST-PLANT PREFERENCE AND OFFSPRING PERFORMANCE: CONSTRAINTS ON HOST-PLANT SPECIALIZATION

J. T. Cronin¹, W. G. Abrahamson² & T. P. Craig³, ¹Dept. of Biology, Univ. of North Dakota, P. O. Box 9019, Grand Forks, ND 58202, USA, E-mail jeronin@badlands.nodak.edu; ²Dept. of Biology, Bucknell Univ., Lewisburg, PA 17837, USA; ³Dept. of Life Sciences, Arizona State Univ. West, Phoenix, AZ, 85069-7100, USA.

Genotypes of the same plant species can have drastically different effects on the fitness of herbivorous insects. Under such circumstances, natural selection is expected to favor a preference by female herbivores for the plant genotypes that confer the highest fitness to their offspring. However, there are numerous possible constraints on the adaptation of herbivores to particular plant genotypes, or the occurrence of a positive correlation between preference and performance. One seldom-considered constraint is year-to-year variation in the acceptability or suitability of plant genotypes to an herbivore. In this study, we used 12 years of data from the same 20 clones of goldenrod (Solidago altissima) to examine the temporal variation in oviposition preference and offspring performance of a stem-galling fly, Eurosta solidaginis. Over the course of this study, correlations in preference between years, and performance between years, were positive in 90% and 60% of the comparisons, respectively. Interestingly, a significant majority of the correlations between rank preference and performance were negative (84%). This unexpected result is apparently a consequence of stem-galling flics aggregating their attacks onto few, preferred, goldenrod clones. The relatively high density of offspring on these preferred clones precipitates intense intraspecific competition with a consequent reduction in per-capita performance. We also found that the magnitude of change in rank preference or performance of goldenrod clones between years was quite high. Each goldenrod clone changed in rank position by an average of 31% between successive years. We suggest that these consistently high year-to-year fluctuations in preference and performance by E. solidagins are likely due to significant genotype x environment interactions. For example, water availability, nutrient levels and the abundance of interspecific herbivores are known to affect the acceptability and suitability of goldenrod clones to E. solidaginis, and these effects are clone specific. Temporal fluctuations in these environmental variables are common; thus, they may be responsible for the fluctuations in ranks. These results are significant because such temporal fluctuations in preference and performance are likely to favor a more generalized diet by herbivorous insects.

Index terms: clonal variation, Eurosta solidaginis, gall insect, host specialization, preference-performance correlation, Solidago altissima

[0833] CONSEQUENCES OF HOST PLANT RESISTANCE AND SENESCENCE TO THE SURVIVORSHIP AND DEVELOPMENT OF A NEOTROPICAL GALLING INSECT

<u>M. M. Espírito-Santo¹</u> & G. W. Fernandes¹, ¹Lab. Ecologia Evolutiva de Herbívoros Tropicais, DBG/ICB, Universidade Federal de Minas Gerais, 486, 30161-970, Belo Horizonte-MG, Brazil, E-mail esanto@mono.icb.ufmg.br.

Plant traits usually have a great influence in the ability of gall-making insect to explore their resources, directly killing the developing gall or reducing its growth. In this study, the mortality factors of the gall-inducer *Neopelma baccharidis* (Homoptera: Psyllidae) directly caused by its host plant, Baccharis dracunculifolia (Asteraceae) were analyzed. Furthermore, the influence of plant growth, reproduction and water status in gall mortality and eclosion were evaluated. In March 1999, 984 galls of the same cohort were randomly marked on 109 individuals of B. dracunculifolia in the field. Galls were verified each month during their development, from April to August. Dead and ecloded galls were collected and analyzed for mortality factors caused by the plant. The major mortality factor of N. baccharidis was plant resistance after gall establishment (19% of the original cohort), which killed the galls mainly until the third month of development. Shoot senescence killed 9.5% of the galls, and is minimized in June and after by gall ability to accelerate the development and eclosion in senescent shoots. However, the size at eclosion of this galls tended to be smaller, possibly affecting future fitness of the adults. Egg retention/abortion accounted for 7.7% of the observed mortality. None of the plant traits analyzed affected the intensity of mortality or eclosion, which are probably affected by other factors not analyzed in this study. Mortality of N. baccharidis caused directly by B. dracunculifolia was very important in controlling the gall-maker population, killing 36.2% of the original cohort of galls, mainly in the two first months of development, which are critical to gall survivorship. These results highlight the importance of (1) plant resistance not only affecting gall formation, but all the development of established galls and (2) the ability of the gall-maker to minimize the impacts of plant phenological shifts, such as senescence during the dry season.

Index terms: Neopelma baccharidis, Baccharis dracunculifolia, plant traits, gall mortality, gall eclosion

[0834] ASPHONDYLIA SPECIES OF ITALIAN FAUNA (DIPTERA: CECIDOMYIIDAE)

<u>M. Solinas</u>, Dept. of Arboriculture and Plant Protection, Univ. of Perugia Borgo XX Giugno 06121 Perugia, Italy, E-mail msolinas@unipg.it.

Asphondylia is a cosmopolitan, very large genus of the Cecidomyiidae family, with over 250 described species, including many agricultural pests. Most species produce bud, flower, and/or fruit galls on a great many families of plants. The galls produced by Asphondylia species are called "ambrosia galls" for the inner wall of the gall chamber is normally covered with a symbiotic fungal mycelium on which the midge larva feeds and develops to maturity. Both for morphological and behavioural features, concerning adults and larvae, it is quite easy to recognise this genus, whereas not always it is the same with species identification, especially when different host-plant species are presumbly colonised by the same Asphondylia species. Comparing the list of Asphondylia species in the Catalogue of Palaearctic Diptera (Skuhravà, 1986) with the list of the Italian Asphondylia species of the genus, and four of them (i. e., A. gennadii, A. lupini, A. miki and A. pruniperda) are sometimes agricultural pests in Italy. General angects such as the species between the host-plant, the fungus, and the gall-maker midge, as well as the economic importance of the agricultural pests in Italy, will be discussed.

[0835] SYNCHRONIZATION OF GALLER'S APPEARANCE WITH HOST PLANT PHENOLOGY

M. Tokuda, S. Satou & J. Yukawa, Entomological Laboratory, Faculty of Agriculture Kyushu University, Fukuoka, 812-8581 Japan, E-mail: tokudam@agr.kyushu-u.ac.jp.

Pseudasphondylia neolitseae is univoltine, making galls on the leaves of Neolitsea sericea (Lauraceae). In 1999, the galls were surveyed at various heights of host trees using a vehicle with a 12m long crane in Fukuoka, northern Kyushu. Galls were found mainly in the canopy layer, the most vigorous and sunny part of trees. The leaf opening phenology on canopy branches was about 10 days later than that on lower branches less than 3m in height. In southern Kyushu, however, the galls were usually made on the leaves of lower branches, non-vigorous and shady part. The percentage of galls that failed to develop was higher at the sunny part than that at the shady part both in northern and in southern Kyushu. In addition, the canopy layer seems to be an unfavorable galling site for such a short lived, diurnal, and tiny gall midge as *P. neolitseae*, because much windier and drier conditions with direct sunlight have a bad influence on the activity of adult midges and larval survival. Nevertheless, the adults inevitably oviposited on the higher branches in northern Kyushu, since their emergences could not synchronize with leaf-opening phenology on the lower branches. These results suggest that the synchronization is one of the important factors regulating the population density of gallers.

Index terms: *Pseudasphondylia neolitseae*, Cecidomyiidae, canopy layer, plant vigor, *Neolitsea sericea*

[0836] RESOURCE ALLOCATION VERSUS SEASONAL VARIATIONS AND THE COMMUNITY OF GALLING-INSECTS ON THE TROPICAL DIOECIOUS SHRUB BACCHARIS CONCINNA (ASTERACEAE)

<u>E. S. A. Marques</u>¹, F. M. Caldeira Castro² & G. W. Fernandes², ¹ Dept. Biology/Health & Wellness, Miami-Dade Community College, 11011 S.W. 104th Street, Miami, FL 33155, USA, E-mail: sefraz@ix.netcom.com; ²Ecologia Evolutiva de Herbívoros Tropicais/DBG, CP 486, ICB/Universidade Federal de Minas Gerais, Belo Horizonte MG - Brazil - 30161.

The occurrence of dioecy in plants suggests the existence of differential patterns of resource allocation between the sexes. Baccharis concinna (Asteraceae) is an endemic, dioecious woody shrub that shows continuous production of growth and flower meristems throughout the year. It supports one of the richest communities of galling-insects known for the tropics totaling 15 morphospecies. Resource allocation studies on the tropical dioecious shrub B. concinna have shown that female plants have longer apical shoots, with greater biomass of leaves, stems and twice the biomass of flowers, while male plants have longer lateral shoots. Nevertheless, our first study found no differences on total biomass of vegetative parts between male and female plants, and as expected no differences were encountered in the richness and abundance of galling-insects on this host plant. A second study evaluated the growth rates of lateral shoots over 12 months and revealed that lateral shoot growth rates were on average 2cm greater on male plants, but contrary to our expectation, this differential growth did not result on male plants being more attacked by galling-insects than female plants. Galling-insect species attacked both male and female plants and with similar abundance throughout the year. Galling-insect richness was mainly affected (42%) by seasonal variations in plant quality/microhabitat condition and was independent of plant gender and shoot growth rates. Although male and female plants allocated resources differently to apical and lateral shoots, shoot growth rates and seasonal variations in plant quality/microhabitat conditions accounted for only 29% of the variation in galling-insect abundance. We concluded that the community of galling-insect species did not respond to gender differences in resource allocation but are mainly affected by seasonal variations in plant quality/microhabitat conditions. The sex-biased herbivory hypothesis will be discussed within the genus Baccharis in the tropics.

Index terms: Baccharis concinna, dioecy, galling-insects, resource allocation, and seasonal variations

[0837] TIMING OF GALL-FORMATION CAUSING DIFFERENTIAL PERFORMANCE OF A STEM MOTHER IN *NEOTHORACAPHIS YANONIS* (APHIDIDAF)

Y. Tosaka1, T. Nishida1 & N. Ohsaki, ILab. of Insect Ecology, Graduate School of Agriculture, Kyoto Univ., Kyoto, 606-8502, JAPAN, E-mail juza@kais.kyoto-u.ac.jp

We examined a hypothesis that equal sex allocation observed in a gall aphid, Neothoracaphid yanonis was secondarily derived from LMC in the ancestral state. N. yanonis has five generations a year, with the fundatrix, i.e., the overwintered generation, forming a gall on a leaf surface of Distylium racemosum. The first generation shift to Quercus serratu, the secondary host and there reproduce parthenogenetically for a few generations before the third generation return again to D. racemosum. The third generation produced male and female nymphs, which disperse, develop to adults, and then mate. The numerical sex ratio of the nymphs at birth was female biased (1:2), but the males were just twice larger than females, resulting in equal investment for either sex as predicted by Fisherian theory. Observations on the mating system suggested random mating to occur because (1) multiple mothers laid nymphs within a single leaf, (2) newly hatched nymphs, particularly female nymphs dispersed from the natal leaf, and (3) reproductive adults were also highly dispersing. In spite of the suggested random mating, dissection of mother aphids revealed that almost all (97%) mothers produced two sons though the clutch size varied from 2 to 10, with the average of 6. The constant male production has been traditionally regarded as the evidence of LMC under varying resource condition (Ymaguchi, 1985). However, we found that constant male production occurs even under random mating. This suggestion that LMC might be once common in the native habitat. Thus, we tentatively conclude that the present random mating in N. yanonis may have derived from LMC in the ancestral state.

Index terms: Fisherian theory, sex ratio, constant male production.

[0838] HOST PLANT DEFENSE INHIBITING SYNCHRONY WITH ITS FRUIT GALL MIDGE, ASPONDYLIA AUCUBAE

K. Imai¹ & N. Ohsaki¹, ¹Laboratory of Insect Ecology, Graduate School of Agriculture, Kyoto Univ., Kyoto, 606-8502, JAPAN, E-mail kensuke@kais.kyoto-u.ac.jp

Studies of plant-gall former interaction suggest that synchrony between the susceptible period of plants and gall formers is critical for fitness of gall formers, and that gall formers may have synchronized with their host plant susceptibility through adaptation over time. However, how the susceptible periods of plants are determined and how gall formers keep their synchrony with the limited susceptible period has not been studied so extensively to date. A fruit gall midge Asphondylia aucubae (Diptera, Cecidomyiidae) lays egg in the immature fruits of Aucuba japonica, a common understory tree species of temperate broad-leaved evergreen forests in Japan. Adult life spans are I day in duration, and the adult season of our study area is a period of 10 days in mid-June. However, immature fruits of A. Japonica don't largely change their shape and look available for egg-laying from early-May to early-August. Anatomical research in 1999 revealed that: (1) before mid-June the inner-seed-coat of fruits inhibit the insertion of female ovipositor, and (2) after mid-June the nucellus of immature fruits (material of gall) is atrophied and gall formation may be difficult. These mechanisms should force adult midges to emerge and egg-lay in a quite limited period; therefore their synchrony with plant susceptibility may be difficult. Such mechanisms should be a host plant defense inhibiting synchrony with A.aucubae. Existence of such a defense mechanism may suggest the existence of an arms race over synchrony between gall formers and host plants.

[0839] HOST ALTERNATION BY MULTIVOLTINE GALL MIDGES OF THE GENUS ASPHONDYLIA

N. Uechi, D. Yamaguchi & J. Yukawa, Entomological Laboratory, Faculty of Agriculture Kyushu University, Fukuoka, 812-8581 Japan, E-mail uechi@agr.kyushuu.ac.jp

At least 200 galling species of the genus *Asphondylia* have been recognized in the world. These species are morphologically quite similar to one another, and therefore species identifications have chiefly been based on host data, life history information, and the shape of galls. In Japan, some *Asphondylia* gallers on 20 plant species have been left unnamed. Most of them cannot complete their annual life history on a single host species, because plant organs available for oviposition do not exist in the emergence seasons of adults. Therefore, they have to find alternative host plants. However, the host alternation has not yet been evident in the genus *Asphondylia* except for a few species. We studied, in Kyushu, Japan, the life histories of several *Asphondylia* species on respective host plants, focusing on their emergence and host plant phenology. From these studies we found possible combinations of host plants with which some of *Asphondylia* species can complete their annual life cycles. Recently, some of our findings were confirmed by DNA analyses. The combination of field surveys and DNA analyses will clarify the taxonomic status and life history of further species of the genus including a serious crop pest like the soybean pod gall midge.

Index terms: Cecidomyiidae, plant phenology, life history, DNA analysis.

[0840] PLANT QUALITY AND TROPHIC CASCADES: THE EFFECTS OS PLANT STRESS AND VIGOR ON INSECT ASSEMBLAGES

M. Williams & J. Cronin

ABSTRACT NOT RECEIVED

[0841] RESPONSE OF *PHYTOLYMA LATA* (HOMPOTERA: PSYLLIDAE) TO VARYING HOST DENSITY IN GHANA, WEST AFRICA

M. R. Wagner¹ & J. R. Cobbinah², ¹School of Forestry, Box 15018, Northern Arizona Univ., Flagstaff, AZ 86011-5018, USA, E-mail Mike.Wagner@nau.edu; ² Forestry Research Institute of Ghana, UST PO 63, Kumasi, Ghana.

Phytolyma lata (Homoptera: Psyliidae) is a gall-forming psyllid that attacks two commercially important timber species, Milicia excelsa and Milicia regia, in West Africa. This insect has been exclusively responsible for the widespread failure of Milicia spp. grown in plantations in West Africa. A series of three field and screen house experiments was conducted to assess the relationship between the density of the host plant (Milicia) and its susceptibility to the psyllid. Replicated plantings of 11, 25, 50, and 100% Milicia in mixtures with Terminalia superba were established. Two months after planting gall numbers were significantly lower in the 11% Milicia mixture when compared to the control. A combination of experimental approaches was used to demonstrate that shading of Milicia not plants apparently modified host plant resistance but did not affect natural enemy regulation. These results suggest that mixed species plantations may be an effective management strategy of forest pests in tropical plantations.

Index terms: Milicia, companion planting, tropical plantations, pest management.

[0843] GENOTYPIC VARIATION IN PR-PROTEIN ACTIVITY IN WILLOW AND RESISTANCE TO A GALLING INSECT

O. Paulsson & <u>S. Larsson</u>, Dept. of Entomology, Swedish University of Agricultural Sciences, Box 7044, SE-750 07 Uppsala, Sweden, E-mail Stig.Larsson@entom.slu.se

Great genetic variation in resistance exists among genotypes of Salix viminalis to the cecidomytid Dasineura marginemtorquens. On resistant plant genotypes 95% of the newly hatched larvae die within 48 hours without being able to initiate galls. On susceptible genotypes >90% of the larvae successfully form galls and develop into pupe. We have found peroxidase activity to correlate with resistance. A resistant willow genotype exhibited five times higher peroxidase activity compared with a susceptible genotype. The midges themselves do not induce peroxidase activity. At present, we cannot say which environmental factor(s) that trigger increased peroxidase activity. We hypothesize that peroxidases suppress gall formation through catalysis of lignification of the cell wall, thereby making it more rigid to gall initiation, and/or by catabolism of auxins suggested to be essential components in gall formation. In addition, chitinase activity was also higher in resistant plant genotypes. Few other data exist on mechanisms of resistance at the molecular level against gall-forming insects. Interestingly, the interaction between the insect and the plant resembles a plant-pathogen interaction (i.e. peroxidases and chitinases are pathogenesis-related proteins).

Index terms: Dasineura marginemtorquens, Salix viminalis, peroxidases, induction

[0842] PLANT RESISTANCE AGAINST GALL-FORMING INSECTS: THE ROLE OF PLANT HYPERSENSITIVITY

T.G. Cornelissen¹, D.P. Negreiros¹, C. Saraiva¹ & G.W. Fernandes¹, ¹Univ. Federal de Minas Gerais, Lab. Ecologia Evolutiva de Herbívoros Tropicais, ICB, CP 486, 30161-970, Belo Horizonte, MG, Brazil. E-mail: tatiana@icb.ufmg.br.

Hypersensitive reaction (HR) is an important type of induced defense of plants against herbivores. Previously thought to be an exclusive type of defense against pathogens, HR is also a widespread mechanism whereby plants resist the attack by herbivores, particularly galling insects. In this long term study we evaluated the importance of this kind of resistance against the galling insect Contarinia sp. (Diptera: Cecidomyiidae) on Bauhinia brevipes (Leguminosae). We sampled more than 15,000 shoots and 17,000 galls during four consecutive years of study. We also provided first data on how widespread and important is HR against a wide range of gall-forming insects in eight different plant species in the Brazilian savannas. Over several consecutive years, this host-driven mortality factor killed more than 90.0% of the galls induced by *Contarinia* sp. (1995: 97.5% ± 2.4; 1996: 93.4% ± 2.2; 1997: 93.8% ± 2.4; 1998: 94.3% ± 2.1) on B. brevipes leaves. The response to this insect herbivore is not related to density of attack or even to the vigor (growth) of the host organ. Studies on other eight tropical savanna species corroborated the occurrence and importance of IIR on insect herbivores population dynamics. HR was found to be common in the plant kingdom, irrespective of plant phylogeny and growth forms. This cellular host plant defense mechanism might involve cell suicide, or apoptosis, and molecular studies of HR in B. brevipes have been already realized in our laboratory. We established a protocol to B. brevipes DNA extraction, and we obtained pure DNA samples, confirmed by eletrophoretic analysis.

Index terms: plant hypersensitivity, plant defenses, induced responses, Contarinia sp

[0844] LONG-TERM POPULATION DYNAMICS OF GALL MIDGES IN EVERGREEN FORESTS

J. Yukawa, Entomological Laboratory, Faculty of Agriculture Kyushu University, Fukuoka, 812-8581 Japan. E-mail: jyukawa@agr.kyushu-u.ac.jp.

Field populations of the following univoltine gall midges have been studied since 1970 in the forests of broad-leaved evergreen trees in southern Kyushu, Japan. *Pseudasphondylia neolitseae* leaf galls on *Neolitsea sericea* (Lauraceae); *Lasioptera camelliae* leaf vein galls on *Camellia japonica* (Theaceae); *Asphondylia sphaera* fruit galls on *Ligustrum japonicum* (Oleaceae); *Daphnephila machilicola* leaf galls on *Machilus thunbergii* (Lauraceae) and *Daphnephila machilicola* leaf galls on *Machilus thunbergii* (Lauraceae) and *Daphnephila* sp. leaf galls on *Machilus japonicus* (Lauraceae). The population fluctuations of the first two species were relatively stable for many years. The analyses of life table data indicated that these populations have been regulated well by density dependent bottom-up effects. In contrast, the population was strongly influenced by the alternation of a good and bad year for fruit production and by the abortion of a large number of flower buds. The *Daphnephila* species were attacked by four parasitoid species, of which a pteromalid acted as a key factor but was not a density dependent mortality factor. Thus, the gall midge populations fluctuated in different manners even though they coexist side by side in the same broad-leaved evergreen forest which have been considered to provide inhabitants with stable conditions to live.

Key words: Cecidomyiidae, life table, bottom-up effect, parasitoid, population density

108451 AN INOUILINE APHID. TAMALIA INOUILINUS N. SP., CO-OCCUPYING GALLS OF THE COMMUNAL APHID TAMALIA COWENI (HOMOPTERA: APHIDIDAE)

D. G. Miller III, Dept. of Biology, Trinity Univ., 715 Stadium Drive, San Antonio, TX 78212 USA E-mail: dmiller@trinity.edu.

Foundress females of the Manzanita Leaf-gall Aphid, Tamalia coweni, readily co-occupy galls on Arctostaphylos spp. (Ericaceae) without engaging in overt agonistic behavior. The recently described squatter aphid, Tamalia inquilinus, invades and occupies galls of T. coweni, thereby exploiting this communal aspect of the host species. I describe this unique form of social parasitism in galling aphids and show how the specialized squatter aphid may be adapted to withstand the hazards of predators and dessication, both of which are more prevalent in its opportunistic life history strategy relative to the host species T. coweni. I place squatting behavior into the context of social behavior and social parasitism, suggesting that the lack of discrimination by T. coweni foundresses may facilitate intrusion of galls by T. inquilinus.

Index terms: social parasitism, social, squatter

108471 NEOTYPHODIUM DIVERSITY IN GRASSES AND THE ISSUE OF INSECT RESISTANCE

Clement, U.S. Department of Agriculture, Agricultural Research Service, Washington State University, P.O. Box 646402, Pullman, WA 99164-6402, USA, E-mail: slclement@wsu.edu.

Genetic variation for herbivore resistance in natural plant populations and agricultural plants is often associated with intrinsic factors such as chemical and physical defense mechanisms. Apart from heritable genetic and environmental factors, other factors such as plant microbes mediate host plant-herbivore interactions. For example, the presence of endophytic Neotyphodium fungi in some C3 grasses confers resistance to phytophagous insects through the production of specific alkaloid compounds. However, Neotyphodium infection does not universally confer resistance to insects as revealed, for example, by the species-specific nature of aphid resistance in Neotyphodium-infected wild barley (perennial Hordeum spp.). Experimental data show: 1) that the reproduction and survival of Russian wheat aphid (Diuraphis noxia) and rose grass aphid (Metopolophium dirhodum) is adversely affected by some wild barley-Neotyphodium associations, and 2) that wild barley endophytes have no adverse effect on bird cherry-oat aphid, (*Rhopalosiphum padi*). The endophyte-infected wild barleys originated from the Asian areas of origin of D. noxia (ancestral range of M. dirhodum is unknown). In other experiments, R. padi exhibited differential survival on different tall fescue (Festuca arundinaceae)-Neotyphodium associations originating from non-agricultural settings in Tunisia. The Palearctic home ranges of R. padi and tall fescue overlap. The observed aphid responses were likely the result of variable alkaloid production by an experimental suite of diverse host grass (species, genotype)-Neotyphodium (species, strain) associations. This research documents wide variability in plant-endophyte-insect interactions involving wild host grasses and aphids with overlapping home ranges (D. noxia and wild barley in Asia; R. padi and tall fescue in the Mediterranean Basin), as well as the important role played by diverse Neotyphodium fungi in mediating plant-insect interactions.

Index terms: Diuraphis noxia, Metopolophium dirhodum, Rhopalosiphum padi, grass resistance, endophytic fungi.

[0846] HOST-PLANT ARCHITECTURE AND THE DYNAMICS OF GALL-INDUCING SPECIES

P. W. Price, Dept. of Biological Sciences, Northern Arizona Univ., Flagstaff, AZ 86011-5640, USA, E-mail: peter.price@nau.edu.

Gall-inducing insects respond to host plant modular structure in highly specific ways, especially when they utilize buds and shoots which provide highly heterogeneous resources. This strong specificity yields patterns of module utilization that highlight the importance of host plant architecture, enabling new insights to hypotheses on host plant aging and architectural complexity effects on insect herbivores. Responses of sawflies to the architecture of trees and shrubs are compared showing dramatically different population dynamics on each architectural type. Also, shrubs with strong and weak apical dominance on shoots result in different dynamics for cecidomyiid gall midges. Strong preference among gall-inducers for rapidly developing modules also reduces the importance of host plant architectural type in promoting herbivore community richness per host plant species. The study of gall-inducers refines our understanding of the precision of the ovipositional preference-larval performance linkage in relation to the details of plant architecture.

Index terms: gall-inducing insects, plant architecture, sawflies, Hymenoptera: Tenthredinidae, preference-performance linkage

[0848] ENDOPHYTIC FUNGI, HOST PLANT GENOTYPE AND INSECT HERBIVORES

K. Saikkonen & M. Helander, ¹Dept. of Biology, Univ. of Turku, FIN-20014 Turku, Finland, E-mail karisaik@utu.fi.

Interactions among endophytic fungi, host plants and herbivores are usually studied emphasizing fungal mediated plant-herbivore interactions. Some seed-borne grassendophytes, particularly in agronomic arena, have inevitably shown to negatively affect herbivores. Contrary, most studies with natural grass systems and especially with horizontally by spores transmitted tree-endophytes have shown more variable effects ranging from beneficial to deleterious on herbivores. This variability is likely related to variation in the number of types and concentrations of alkaloids produced by fungi. In a case of horizontally transmitted endophytes in woody plants, it may also indicate differences in plant quality for fungi and herbivores without causal relationship between fungal infection and herbivore performance. We have examined endophyte medicated plant-herbivore interactions in a series of field experiments using clones or half-sib progenies of host plants (both grasses and woody plants). For example, we have compared the performance of several insect herbivores with endophyte abundances of 10 half-sib progenies of matured mountain birch (Betula pubescens ssp. tortuosa) growing in two environments (river slope, tundra). This allows us to examine both phenotypic and genetic correlations between fungal endophyte frequencies and herbivore performance on these trees. Importance of type of endophyte infection (systemic vs. non-systemic), the mode transmission (vertical vs. horizontal) and environmental factors is discussed.

Index terms: herbivory, endophytic fungi, mode of transmission, environment, phenotypic and genetic correlations.

[0849] EFFECT OF ENDOPHYTES ON THE DICHOTOMY BETWEEN TOLERANCE AND DEFENSE IN FORAGES GRASSES

<u>T.L. Bultman</u>, Division of Science, Truman State University, Kirksville, MO, USA., Email: tbultman@truman.edu

Resistance by plants to herbivore attack is thought to take two fundamental forms. Plants may avoid attack through defense or escape; alternatively, plants may tolerate attack through regrowth following damage. A negative relationship between tolerance and defense might be expected if each strategy is associated with a metabolic cost to the plant. Effects of plant symbionts on the tradeoff between tolerance and defense has been little The purpose of my study was to investigate how a fungal symbiont studied. (Neotyphodium coenophialum) of tall fescue influences tolerance to and defense against bird cherry-oat aphids, Rhopalosiphum padi. Seeds infected and uninfected with N. coenophialum were planted individually into pots filled with potting soil and watered as needed. Plants were grown for 6 weeks and then were damaged by clipping at 3cm above the soil surface. After 2 weeks of regrowth, four aphids were placed within clip bags onto the newest fully expanded leaf blade for 4 days. Population growth rate of apterous aphids during the 4 day period was lower on infected plants ($F_{1,100}$ =01.4, p=0.001). Furthermore, the effect of damage on aphid population growth depended upon fungal infection (F1,100=6.8, p=0.01); damage induced susceptibility to aphids in uninfected plants, but induced resistance in infected plants. Rate of regrowth by plants between the time of damage and the bioassay (a 2 wk period) was higher for infected plants (T=3.28, df=51, p=0.002). Another experiment with similar design, except that it used perennial ryegrass and its endophyte, Neotyphodium lolii, showed no constitutive or inducible effect of the fungus on R, padi reproduction. We conclude that Neotyphodium can enhance both the defense (constitutive and induced) and tolerance of plants to R, padi, but the effects may depend upon plant and fungal species.

Index terms: defense, fungi, Rhopalosiphum padi, tolerance

[0850] INTERACTIONS BETWEEN ABOVE- AND BELOW-GROUND FUNGAL ENDOPHYTES: EFFECTS ON A LEPIDOPTERAN HERBIVORE

M. Vicari¹, P.E. Hatcher², M.F. Dutton³ & P.G. Ayres⁴, ¹Dept. of Biology, York Univ., 4700 Keele St., Toronto, ON M31 IP3, Canada; ²School of Plant Sciences, Univ. of Reading, Whiteknights, Reading RG6 6AS, UK; ³Dept. of Physiology, Univ. of Natal, Congella 4013, South Africa; ⁴I.E.N.S., Biological Sciences Div., Lancaster Univ., Lancaster LA1 4YQ, UK.

Neotyphodium endophytes infect the above-ground tissues of grasses, are widespread in natural grasslands, and are well known for their ability to deter feeding by insects. Arbuscular mycorrhizal (AM) fungi are also common in grasslands, but few studies have investigated the effects of dual infection of host plants on insects. The purpose of this investigation was to determine how infection of Lolium perenne by the AM fungus Glomus mosseae and the foliar endophyte N. lolii affects the performance of lepidopteran herbivores sensitive to the latter. Preliminary experiments were conducted to assess the suitability of three British lepidoptera. The graminivorous generalist Noctua pronuba was insensitive to N. *lolii*, while the generalist Arctia caja showed a tendency (p = 0.07) towards reduced growth on N. *lolii*-infected (+N) plants but could not complete its development even on uninfected (-N) plants. The generalist *Phlogophora meticulosa*, however, demonstrated both antibiosis and antixenosis on +N plants, and was able to complete its development on L. perenne; thus it was selected for further investigation. Experiments were conducted in which G. mosseae [present (+AM) or absent (-AM)] and *N. lolii* infection of *L. perenne* were factors. The growth and survivorship of 2^{nd} - to 5^{ch} -instar larvae feeding on excised leaves were monitored. Survivorship of 2^{nd} - and 3^{rd} -instar larvae was reduced by *N. lolii*; that of 2^{nd} - and 5^{ch} -instar larvae was reduced by *G.* mosseae. Effects of the two fungi on larval survivorship were additive. N. lolii mitigated a detrimental effect of limiting phosphorus (P) on survivorship of 5th-instar larvae. effects of *G. mosseae* on larval survivorship were P-independent, although there were weak AM^*P interactions with larval growth. The maximum dry weight of 6^{th} -instar larvae was reduced by both G. mosseae and N. lolii, but those feeding on +AM+N plants had similar dry weight and consumption to those feeding on +AM-N plants. N. lolii caused an increase in relative consumption rate (RCR) and a decrease in efficiency of conversion of ingested matter (ECI), while G. mossene had no effect on RCR or ECI. Larvae foraging among intact +N and -N plants inflicted more damage on the latter, but the difference was decreased when both plants were +AM. Neither fungus affected foliar Kjeldahl nitrogen concentration, and G. mosseae had little effect on foliar concentrations of the insect deterrent peramine. The implications of these findings for Neotyphodiuminsect interactions will be discussed.

Index terms: Phlogophora meticulosa, Neotyphodium lolii, Glomus mosseae

[0855] INTERACTIONS BETWEEN PREDATOR SPECIES, THEIR PREY AND THE HOST PLANT

S. D. Wratten & C. N. Merfield, Ecology & Entomology Group, Soil, Plant & Ecological Sciences Division, P.O. Box 84, Lincoln University, Canterbury, New Zealand.

Most studies on invertebrate predation concern single predator or parasitoid species and evaluate their behaviour and ecology with little consideration of other natural enemies in the same or different guild, or of tri-trophic-level effects between plant, prey/host and the natural enemy. In many agricultural habitats however, there may be hundreds of natural enemy species potentially interacting and the crop itself may respond to herbivore feeding via wound-induced changes in plant defences. The interaction between the plant, the herbivore and the predator can therefore involve "top down" (ie predator) and/or "bottom up" (ie plant) effects on the herbivore population. This paper will explore two systems in which these interactions have been recently studied. The first is a tomato/caterpillar/predatory carabid interaction while the second concerns commensal relationships between predatory arachnid species. Work on the lepitopteran Spodoptera litura on tomato (Lycospersicon esculentum) and the non-climbing carabid predator Megadromus antarcticus showed that the carabid increased S. litura mortality with a subsequent decrease in leaf damage. Leaf wounding produced a possible decrease in herbivory and there was a trend for the presence of the carabid on the soil to interact with wound-induced changes in the plant; the latter caused a higher proportion of lavae to move to the soil surface, where they were available to the epigeal predator. Using time-lapse video techniques in the field and in the laboratory showed that when some predatory mite species (whirlygig mites: Anystis spp. and mites in the super-family Erythracoidea) had pierced a dipteran egg, the latter was more likely to be predated by harvestmen (Arachnid: Opiliones). The latter type of commensal interaction, between predators in the same guild with similar feeding mechanisms, has been very rarely demonstrated in predator-prey systems and maybe more common among predators in cropping systems than previously assumed.

[0854] LONG-TERM, RESOURCE-BASED LIMITATION OF GALL-INDUCING SAWFLY POPULATIONS EXEMPLIFYING A COMMON PATTERN

<u>P. W. Price</u>, Dept. of Biological Sciences, Northern Arizona Univ., Flagstaff, AZ 86011-5640, USA, E-mail: peter. price@nau.edu

A Darwinian approach to population dynamics works from macroevolutionary patterns in morphology, life history, behavior and phylogenetic relationships, to macroecological patterns in distribution, abundance, and population dynamics. Using gall-inducing sawflies and relatives (Hymenoptera: Tenthredinidae) such patterns are illustrated showing common macroevolutionary patterns of a saw-like ovipositor, monophagy, strong female ovipositional preferences linked to high larval performance, and specialization on rapidly growing, vigorous shoots. The macroecological consequences involve species that are generally distributed very patchily over a landscape, they are uncommon or rare, and populations remain low and relatively stable, constrained by a low carrying capacity, dictated by a limiting resource of vigorous host plant modules. The mechanistic reasons for the macroevolutionary effects on macroecological patterns are explained. Thus there is a flow of influences from Phylogenetic Constraints to Adaptive Syndromes to the Emergent Properties, the last being the ecological features of distribution, abundance, and population dynamics. Given that the patterns are documented and the mechanistic explanation for patterns are understood, we have the basis for the theory on population dynamics of these sawflies. Such a theory has strong predictive power, it involves a broad comparative framework, and it allows a synthesis of population dynamics across many taxa involving both latent and eruptive species.

Index terms: macroevolution, macroecology, population dynamics, Hymenoptera: Tenthredinidae, sawflies

[0856] DO NATURAL ENEMIES PREVENT OUTBREAKS OF EPIRRITA AUTUMNATA IN SOUTHERN FENNOSCANDIA?

M. Tanhuanpää & K. Ruohomäki, Section of Ecology, Dept. of Biology, Univ. of Turku, FIN-20014 Turku, Finland.

Research on population dynamics of herbivorous insects has concentrated on outbreaking and cyclic species although most species are always present at low densities. The tendency of a species to reach high densities is often related to certain life history traits. However, all the populations of an outbreaking species do necessarily not have outbreaks. Within a species, impact of different life history traits can be largely climinated, making it easier to identify the ecological traits affecting population dynamics. Yet, there are few studies assessing factors affecting dynamics of outbreaking and nonoutbreaking populations within a species. Periodic outbreaks are frequently more pronounced in northern populations of herbivore species with wide distributions. *Epirrita autunnata* is a forest lepidopteran with a Holarctic distribution but outbreaks only in northern and mountainous Fennoscandia. Genetic differences between populations, e.g., in size and hence, fecundity, are apparently not associated with the occurrence of E. autumnata outbreaks. Thus, extrinsic factors must be involved. According to the generalist/specialist predation hypothesis, in southern Fennoscandia, there are numerous prey species for each predator and thus, most predators function as generalists. While, in the subarctic, alternative prey is scarce and predators often need to specialize on one or few prey species. This study evaluates the appropriateness of the generalist/specialist hypothesis in explaining the contrasting dynamics of E. autumnata populations in southern and northern Fennoscandia. The study focuses on nonoutbreaking populations with the purpose of revealing whether the lack of outbreaks in southern Fennoscandia is due to the higher number of generalist predators. The approach taken is to experimentally evaluate the impact of natural enemies on survival of E. autumnata in each life history stage. Mean survival rate of E. autumnata larvae in the southern Fennoscandia varied from 8 to 14 percent whereas year-specific pupal survival rate ranged from 15 to 50 percent. Pupal predation by small mammalian predators was temporally density dependent in the southern but not in the northern populations. Adult predation decreased the number of larvae produced for the next generation by 60-86 percent and egg mortality by 20-40 percent. Although some of the mortality rates may have been overestimated, such high density independent mortality combined with density dependent pupal predation offers a plausible explanation for the lack of *E. autumnata* outbreaks in southern Fennoscandia. The results of this study suggest that the lack of E. autumnata outbreaks in southern Fennoscandia is most likely due to regulation by natural enemies.

[0857] FACTORS INFLUENCING TOP-DOWN CONTROL OF INSECT POPULATIONS.

N. J. Mills, Insect Biology, Wellman Hall, Univ. of California, Berkeley, CA 94720-3112, USA, E-mail nmills@nature.berekeley.edu

There has been a tremendous amount of interest in tritrophic interactions between plants and natural enemies, driven both by the need to integrate host plant resistance and biological control in the management of arthropod pests, and to understand the relative importance of direct and indirect interactions in ecological communities. There have been many documented examples of the direct effects of physical, chemical and nutritional qualities of plants on the attack rate, survival and reproduction of natural enemies. In addition, it is well known that these same qualities of plants have an indirect effect on natural enemies by influencing the distribution, abundance and vulnerability of herbivores. Here we focus on two aspects of tritrophic interactions between plants and natural enemies. Firstly, we make a comparative analysis of the influence of plant variation on the different groups of natural enemies (parasitoids, predators, pathogens and nematodes), and secondly, we explore the influence of plant variation on interspecific interactions between natural enemies. A comparative approach identifies common patterns in the influence of plant traits on natural enemies and highlights those traits that differentially influence natural enemy groups. We document examples of the influence of plants on the interspecific interactions of natural enemies, and consider approaches needed to better identify these effects in plant-arthropod-natural enemy systems.

Index terms: plant variation, natural enemy, interspecific interactions

[0859] BOTTOM-UP AND TOP-DOWN REGULATION OF INSECT POPULATIONS

P. Gutierrez¹ & J. Baumgärtner², ¹Ecosystems Science, 151 Hilgard Hall, Univ. alifornia, Berkeley, CA, USA 94720, ²ICIPE, P.O. Box 30772, Nairobi, Kenya

Species dynamics are affected by intraspecific competition for resources (usually physical factors such as space, chemicals, sunlight, food, etc.), and by other species directly below, laterally (interspecific competition) or above it in the trophic chain (predation in a general sense). Bottom-up processes are those that act through the quantity and quality of resources acquired by individual organisms to affect population intrinsic parameters such as birth rates and resource related death and emigration rates. Lateral or competitive processes may be viewed as bottom-up because they affect the process of resource acquisition. Top-down processes, on the other hand, are those that act through predation, parasitism and disease. In a general sense, any population is a resource for a higher trophic level, and as such is engaged in a bottom-up process relative to its consumer. What has not been clear is how these processes should be incorporated into a food chain model that still maintain the necessary structural constraint that the same ecological principles should apoly to any trophic level. Here we answer this question viewed from the perspective of the consumer. "What proportion of the consumer's demand for each of its requisites are met, and how does the proportion affect consumer birth and death rates individually and collectively?" Ecological principles of supply and demand are used to solve this problem. These principles are applied to physiologically age- mass structured tritrophic local and metapopulation dynamics in a real world setting.

Index terms: Bottom-up top-down regulation, metabolic pool, number and mass dynamics, metapopulation dynamics.

[0858] WHEN AND WHY TOP-DOWN REGULATION FAILS

P. Kindlmann¹ & A.F.G. Dixon², ¹Fac. Biol. Sci., Univ. South Bohemia and Czech Acad. Branisovska 31, 37005 Ceske Budejovice, Czech Republic, E-mail pavel@entu.cas.cz; ²Sch. Biol. Sci., Univ. East Anglia, Norwich, NR4 7IJ, U.K.

The population dynamics of deciduous tree-dwelling aphids have been studied over long periods of time and in considerable detail. Within a year, the dynamics of these aphids are very complicated and in looking for the mechanism of regulation this needs to be taken into consideration. An initial dramatic increase in population size in spring is typically followed by a steep decline in abundance during summer and sometimes a further increase in autumn. During spring and summer all the generations are parthenogenetic, short lived (2-4 weeks) and fully winged. In autumn, sexuals are also produced, which mate and give rise to the overwintering eggs that hatch the following spring and give rise to fundatrices, the first parthenogenetic generation. Analysis of empirical data has revealed the regulatory mechanism that is responsible for the summer decline in numbers: migration. This increases linearly with density and declines with improving food quality. In contrast to most other groups, the empirical data do not lend support to a marked effect of natural enemies, or a severe scramble for resources by these aphids. Therefore, these factors do not seem to play a substantial role in regulating the abundance of these aphids. Food quality determines the rate of development and size of an individual more than intraspecific competition, and food quality is not affected by aphid numbers substantially. An explanation of the low effect of natural enemies on aphid dynamics is offered: Because of their high mobility, food availability seems to be much less restrictive for adults compared with juveniles, which are confined to one patch. Therefore functional response does not seem to play an important role for adults. Egg and larval cannibalism are common in insect predators. Thus a strong selection pressure on predators to lay their eggs only in patches in early stages of their development and avoid those containing conspecific larvae determines the strategies of predatory adults to much greater extent than availability of food in one prey patch. In addition, the potential fitness of an adult insect predator mainly depends on the future trends in resource availability throughout the period of development of its larvae, because they, unlike the adult, are confined to a patch. Thus, adult oviposition strategy is likely to be determined by the bottlenecks in resources that occur during the period of its offsprings' development. Therefore, the longer the developmental time of a predator, the smaller the degree of depletion of the patch by this predator species. As a consequence, the relative "efficiency" of predators as biological control agents is negatively correlated with their generation time relative to that of their prey (GTR).

[0860] TOP-DOWN REGULATION OF SPRUCE NEEDLEMINER AND OTHER FOREST LEPIDOPTERA

A. Berryman^a & M. Münster-Swendsen^b, ^aDept. Entomology, Wash. State Univ., A. A. Berryman^{*} & M. Münster-Swentsen, Dept. Entoniology, main out carry, Pullman WA 99164 USA, ^bDept. Population Ecology, Univ. Copenhagen, DK-2100 Copenhagen, Denmark

We outline an approach for detecting, from time series data, whether populations are being regulated by bottom-up or top-down forces, and then apply the approach to data on the spruce needleminer, Epinotia tedella, in Denmark. The results support the hypothesis that spruce needleminer populations are regulated by top-down interactions with a guild of larval parasitoids. We then show how these results may apply to a number of other forest Lepidoptera and comment on the reason for top-down regulation in this group of insects. Index terms: Epinotia tedella, population regulation, parasitoids, time series analysis

[0861] THE ACTIVE ROLE OF PLANTS IN ATTRACTING PARASITODDS: DOES IT BENEFIT THE PLANTS?

T. Turlings & M. E. Fritzsche-Hoballah, Inst. of Zoology, Univ. of Neuchâtel, Case Postale 2, CH-2007, Switzerland, Email: Ted.Turlings@zool.uninc.ch

Maize plants under caterpillar attack initiated the release of a blend of specific volatiles. Parasitoids use these volatiles as cues in search of caterpillars. It has been proposed that the volatiles specifically function as signals to attract parasitoids and other natural enemies of herbivores. However, it is not always evident that an individual plant benefits from the action of parasitoids. In most cases, parasitized caterpillars continue their development and in some cases may eat even more than if they were not parasitized. We will present evidence showing that the induced plant signals indeed help increase parasitism rates by two solitary larval endoparasitoids and that these parasitoids reduce herbivory to such an extent that they may increase the fitness of individual plants.

Index terms: tritrophic level interactions, plant synomones, plant fitness

[0863] PLANT SPATIAL HETEROGENEITY AND HERBIVORE-ENEMY INTERACTIONS: THE UNDERLYING MECHANISMS WHEN THE ENEMY IS A PLANT-FEEDING OMNIVORE

M. Coll & L. Shaltiel, Dept. of Entomology, Fac. of Agric, Food and Environ. Qual. Sci., The Hebrew Univ. of Jerusalem, P. O. Box i2, Rehovot 76100, ISRAEL E-mail: coll@agri.huji.ac.il.

Movement of organisms between habitats is of great importance in determining their abundance and population structure. Most models of predator movement are based on the chance of the predator to locate prey while the effect of vegetation characteristics on predator behavior bas been largely ignored. In recent years, it has become apparent that many species of natural enemies, once considered exclusively predaceous, also feed on plant resources. The interactions between omnivores and their plant habitat are thus characterized by decoupling of the dynamics between enemy and prey populations. Further complexity is added to the system by the fact that many omnivores utilize hoat plants not only as a food source, but for oviposition and shelter, as well. We examine these interactions through studies of two omnivorous anthocorid bugs: Orius insidiosus populations in intercropped agroecosystems and Anthocoris nemoralis on four tree species in the Meditermanan forest. The latter study is aimed at understanding the relative importance of host plants and psyllid prey to the spatial dynamics of the omnivore. Index terms: Anthocoris nemoralis, Orius insidiosus, omnivory

[0862] BEHAVIOUR AND INDIRECT INTERACTIONS IN FOOD WEBS OF PLANT-INHABITING ARTHROPODS

A. Janssen, A. Pallini, M. Venzon & <u>M.W. Sabelis</u>, Inst. of Biodiversity and Ecosystem Dynamics, Univ. of Amsterdam, PO Box 94084, 1098 SM Amsterdam, The Netherlands

With the increased use of biological control agents, artificial food webs are created in agricultural crops and the interactions among plants, herbivores, and natural enemies change from simple tritrophic interactions to more complex food web interactions. Therefore, herbivore densities will not only be determined by direct predator-prey interactions and direct and indirect defence of plants against herbivores, but also by other direct and indirect interactions such as apparent competition, intraguild predation, resource competition, etc. Although these interactions have received considerable attention in theory and experiments, little is known about their impact on biological control. We discuss experimental results on interactions in an artificial food web consisting of pests and natural enemies on greenhouse cucumber. The two pest species are the two-spotted spider mite Tetranychus urticae and the Western Flower Thrips Frankliniella occidentalis. Their natural enemies are the predatory mite Phytoseiulus persimilis that is commonly used for spider inite control, the predatory mites Neoseiulus cucumeris and Iphiseius degenerans and the predatory bug Orius laevigatus, all natural enemies of thrips. The possible interactions among these 7 species are analysed, and we continue by discussing how indirect functional interactions, particularly the behaviour of arthropods, may change the significance and impact of direct interactions and indirect numerical interactions. It was found that a simple food web of only 4 species already gives rise to some quite complicated combinations of interactions. Spider mites and thrips interact indirectly through resource competition, but thrips larvae are intraguild predators of spider mites. Some of the natural enemies used for control of the two herbivore species are also intraguild predators. Moreover, spider mites produce web that is subsequently used by thrips to hide from their predators. We discuss these and other results obtained so far, and we conclude with a discussion of the potential impact of indirect and direct functional interactions on food webs, and its significance for biological control.

[0864] PREDATORS, PARASITOIDS, PATHOGENS, AND POLYMORPHISM: ECOLOGICAL INTERACTIONS AND EVOLUTION IN AN AGROECOSYSTEM

J. E. Losey, Dept. of Entomology, Coinell University, Ithaca, NY 14853, USA

Natural enemies of pea aphids, Acyrthosiphon pisum, can have very complex relationships with each other and with their prey. In fields of alfalfa, many natural enemy species simultaneously exploit aphid populations and the actions of each natural enemy species can have a significant impact on the susceptibility of aphids to other natural enemy species. Individual aphids within a population can very widely in their susceptibility of aphid color morphs to predation and parasitism. Compared to green morph aphids, red morph aphids suffer higher predation rates by Coccinella septempunctata but lower parasitism rates by Aphiditus ervi. Under certain environmental conditions, these two genetically-determined color morphs can shift to a spectrum of other colors. The implications of the existence of these multiple color forms for aphid population dynamics and their potential to cause damage in forage and vegetable systems will be discussed.

[0865] DYNAMIC TROPHIC CASCADES CAUSED BY GENERALIST PREDATORS - FROM PARALLEL TO COUNTERACTIVE EFFECTS

W. E. Snyder, Dept. of Zoology, Univ. of Wisconsin, Madison, WI 53706, USA, Email: wesnyder@facstaff.wisc.edu.

It is difficult to predict whether generalist predators will be effective biological control agents because these predators feed both on herbivores and on other natural enemies. I will discuss the biocontrol effectiveness of carabid beetles in two crops - eucurbits and alfalfa. Working in gardens of squash, we examined whether intraguild predation weakens the ability of two taxa of generalist predators, carabid beetles (Coleoptera: Carabidae) and lycosid spiders (Araneae: Lycosidae), to control herbivore densities. We also measured fruit production to determine if intraguild prodation disrupts the ability of generalist predators to indirectly impact plants through trophic caseades. Carabids strongly reduced densities of squash bugs (Anasa tristis), the dominant herbivores in the system, and thus increased squash yields. However, lycosids had a markedly different impact, causing squash bug densities to increase, and squash yields to decrease. Lycosids increased squash bug densities by killing nabid bugs, which were important predators of squash bug nymphs. The beneficial impact of carabids was counteracted by the detrimental impact of lycosids, so that squash yields were unchanged in the treatment where both predators were present. In a second research project, conducted in alfalfa, we examined interactions between pea aphids (Acyrthosiphon pisum), a specialist parasitoid wasp (Aphidius ervi) that attacks the aphids, and a common generalist predator, carabid beetles (primarily Pterostichus melanarius). In two field experiments, we manipulated carabid densities to measure their direct (through predation) and indirect (through intraguild predation on A. ervi) impact on aphid population dynamics. We found that carabids preyed heavily on pea aphids immediately after harvest, when plants were very short. However, the direct effect of carabids on aphids quickly disappeared during plant re-growth, apparently because aphids gained a refuge from predation in the foliage. In contrast, the indirect effect of carabids due to intraguild predation on parasitoids was slower to develop, but persisted into re-growth. Carabids reduced parasitoid densities by preying on the immobile parasitoid pupae, which the awkwardly climbing carabids could still capture when plants were taller. Thus, despite initial strong predation on aphids, the net longer-term impact of carabids was to increase pea aphid densities by releasing them from control by parasitoids. Together, these studies demonstrate that carabid beetles can act either as biological control agents or, essentially, as pests, and can switch between these opposing ecological roles within a short time.

Index terms: carabid beetle, lycosid spider, generalist predator, intraguild predation

[0866] COMPLEXITY BEGETS STABILITY REVISITED: THE IMPORTANCE OF VARIATION IN TROPHIC INTERACTIONS TO THE MAINTENANCE OF BIODIVERSITY

M.D. Eubanks¹, Dept. of Entomology and Plant Pathology, Auburn Univ., 301 Funchess Hall, Auburn, AL 36849, USA, E-mail meubanks@acesag.auburn.edu

The idea that complexity promotes community stability was one of the fundamental principles of community ecology in the 1950's and 1960's. In models of communities, increased complexity usually refers to an increased number of species, more interactions or connectance between species, greater average strength of interactions, or some combination of these variables. For example, MacArthur (1955) suggested that the more pathways by which energy passed through a community, the less likely it was that the densities of constituent species would change in response to an abnormally raised or lowered density of one species. Elton (1958) compiled a database of observations to support this hypothesis and was a major proponent of the idea that "complexity begets May (1972) was one of the leading opponents of this idea. May's diversity". mathematical models suggested that increased numbers of species, increased connectance, or increased interaction strength all tended to increase instability, not stability. As a result of this and related work, for two decades the prevailing view among community ecologists tended to be that simple communities were more stable. However, in the past ten or so years, new proponents of the "complexity begets stability" idea have produced detailed analyses of communities and new heuristic and mathematical models suggesting that natural communities are often extremely complex and relatively stable. Most of these models rely on the same measures or concepts of complexity used 50 years ago: number of species, connectance, and mean or total interaction strength. I have develop a relatively simple heuristic and mathematical model suggesting that another related measure of complexity is important in the maintenance of diverse communities. I suggest that variation in the intensity of interaction strength (equivalent to variation in ßji) and not just the average or total interaction strength is an important and largely overlooked component of complexity. I also suggest that variation in interaction strength plays an important role in the maintenance of diverse, complex communities. Variation in interaction strength promotes stability because even in diverse communities with relatively high connectance, the strength of interactions among individual consumers and key resources often approach levels that can not support stable interactions and can ultimately lead to the local extinction of one or more species if not relieved. I argue that intrinsic temporal variation in the interaction strengths among members of a community allow species to coexist under these circumstances. Stability, therefore, is often enhanced in natural communities by this variation, without evoking changes in diversity, connectance, or the average or overall strength of interactions.

[0875] CHARACTERIZATION OF THE POPULATIONS OF FRUIT FLIES (DIPTERA: TEPHRITIDAE) COLLECTED IN SEROPEDICA CITY (RJ), BRAZIL BY THE FAUNISTIC ANALYSIS

E. L. Aguiar-Menezes¹ & E. B. Menezes², ¹Embrapa Agrobiologia, Caixa Postal 74505, Seropedica, FL 23890-000, Brazil, E-mail menezes@cnpab.com.br, ²CIMP "CRG" /UFRRJ, BR 465 - km 7, Seropedica, RJ 23890-000, Brazil, E-mail ebmen@zaz.com.br.

Fruit crops are one of the major agricultural activities in the state of Rio de Janeiro. In Seropedica city, several fruit species are commercially cultivated, and are frequently subjected to attack of tephritid fruit flies. In order to characterize the population of these insects, we surveyed species of tephritids by collections of infested fruits in the campus of UFRRJ and surroundings from January 1998 to December 1999. The samples of fruits infested by tephritid larvae were taken to the laboratory of CIMP "CRG"/UFRRJ where they were placed into cages for holding until the flies emerged. A total of 2,578 tephritid fruit flies were recovered. The faunistic indexes of frequency, constancy, abundance and dominance were used to characterize the populations of the fruit flies that belong to the fauna of the Seropedica. Five species were identified: Anastrepha obliqua, A. fraterculus, A. sororcula, A. distincta and Ceratitis capitata. They occurred with the frequency of 43.47%, 16.75%, 10.48%, 7.34%, and 21.95%, respectively. They were presented in all collections, with the exception of A. distincta, which was characterized as accessory species. A. obliqua was the most abundant species. A. fraterculus and C. capitata were common in the region, and A. distincta and A. sororcula were characterized as dispersible. All species were not dominant in the region. We also observed that the faunistic indexes varied according to the fruit host. A. fraterculus and A. sororcula were predominate on guava and Surinam cherry. C. capitata, on coffee and orange, A. obliqua on mango, and A. distincta on inga, were the predominant species.

Index terms: Tephritidae, Anastrepha spp., Ceratitis capitata, faunistic analysis.

[0876] PHANUROPSIS SEMIFLAVIVENTRIS (HYMENOPTERA, SCELIONIDAE), AN EGG PARASITOID OF THE STINK BUG ANTITHEUCUS SEPULCRALIS (HETEROPTERA, PENTATOMIDAE) IN SEROPEDICA CITY (RJ), BRAZIL

E. L. Aguiar-Menezes¹ & E. B. Menezes², ¹Embrapa Agrobiologia, Caixa Postal 74505, Seropedica, RJ 23890-000, Brazil, E-mail menezes@cnpab.embrapa.br; ²CIMP "CRG" / UFRRJ, BR 645 - km 7, Seropedica, RJ 23890-000, Brazil, E-mail ebmen@zaz.com.br.

In the complex of insects that are associated with *Clitoria fairchildiana*, a native shade tree commonly used on the roads, parks and parking lots in the state of Rio de Janeiro, we found the following tritrophic relationship: the stink bug *Antitheucus sepulcralis* feeds on leaves of *C. fairchildiana*, and its egg clusters were usually found parasitized by *Phanuropsis semiflaviventris*. This scelionid is a gregarious endoparasitoid, suggesting a closed relationship with its host. In order to evaluate the impact of this parasitized on the population of *A. sepulcralis*, we collected 5,817 eggs (clusters ranged of 17 to 31 eggs) from March 1998 to February 1999. They were taken to the laboratory of the CIMP "CRG"/UFRRJ where the leaves with the egg clusters were placed into the Petri dishes containing a moistened filter paper for holding until the emergence of the bugs and/or parasitoids. The parasitism percentage was defined as the number of emerged parasitoids divided by the sum of emerged parasitoids and bugs. The overall parasitism percentage was 51.7%, ranging from 3.57% to 100%. During the period of a year, we observed that the parasitism percentage for 86.1% in the fall (March to May/98) to a high of 75.4% in the summer (December/98 to February/99).

Index terms: Phanuropsis semiflaviventris, Anitheucus sepulcralis, Clitoria fairchildiana, parasitism, biological control.

[0877] DECAY OF LEAF LITTER BY AQUATIC INSECTS IN ANDEAN LOW ORDER STREAMS

R. J. Albariño & E. G. Balseiro, Lab. Limnología, Centro Regional Universitario Bariloche, Universidad Nacional del Comahue. Unidad Postal Universidad, 8400 Bariloche, Argentina. E-mail: ralbarin@crub.uncoma.edu.ar

In this study we stressed the importance of aquatic insects on the decay of leaf litter that enter Andean low order canopied streams. Two experiments were conducted in streams running across a forest of Nothofagus pumilio locally called "lenga". Experiment 1 was run in a second order stream during a fall-winter period (118 days). The two treatments consisted of bags with leaf litter of the native deciduous N. pumilio or with the exotic evergreen Pinus ponderosa (of regional forestry importance). Experiment 2 was run in a first order stream during a spring-summer period (135 days). The two treatments consisted of bags with different mesh size, in order to offer open bags for natural insect colonization and closed ones to avoid large insects. Aquatic insects accounted for a 89% of the benthic community. They were represented by five orders: Ephemeroptera, Plecoptera, Diptera, Trichoptera and Coleoptera) with different mean densitics (2.3, 16 0, 65.0, 3.5, 0.9 % respectively). Signs of shredding activity were registered in N. pumilio but were not observed in P. ponderosa. Feeding activities of Plecoptera (Austroperlidae, Gripopterygidae, Notonemouridae), Diptera (Tipulidae) and Trichoptera (Limnephilidae, Sericostomatidae) that gradually colonised litter bags, were responsible of the mass losses Series of N, pumilio leaves. In Experiment 1, N, pumilio decayed two fold faster than P, ponderosa (P<0.05). In Experiment 2, the leaf litter exposed to the whole size spectrum of insects decayed faster than those where large insects were avoided (P<0.05). Large shredders accounted for a 51% of leaf mass loss. Sluedders were more abundant in number and biomass when leaf mass loss was 50% of initial mass; while collectors increased towards the end in both experiments. Ecological aspects of benthic insect community-leaf litter interactions for Andean low order streams will be discussed. Index terms: Benthic detritivores, forested streams, lotic ecology,

[0878] THE LEPIDOPTERA OF THE GALAPAGOS ISLANDS, PATFERN OF DISTRIBUTION AND ECOLOGY

L. Roque Albelo¹, ¹ Invertebrate Program, Charles Darwin Research Station, A. P. 17-01-3891, Quito, Ecuador, lazaro@fcdarwin.org.ec

The Lepidoptera fauna of the Galapagos Islands is analyzed and the number of families, genera and species is summarized. Compared with the Nectropical fauna, the Galapagos fauna is disharmonic. All Galapagos Lepidoptera are of American origin except some species that are nearly cosmopolitan. The number of families, genera and species reported are, 18, 143, 195 respectively. Based on field and museum work it is estimated that there are at least 171 genera and 298 species present in the Archipelago. One genus and 61 species are endemic to the islands. At less 46 species have been accidentally introduced by humans in the last two centuries. The influence of humans on the fauna is analyzed. Endemicity, colonization, distribution patterns and species awarns are discussed. Index terms: Biogeography, dispersal, endemicity, hostplants, introduced species.

[0879] DENSITY DEPENDENT DISPERSAL OF A TEPHRITID FLY

B. R. Albrectsen, Department of Animal Ecology, Swedish Univ. Agri. Sci.; S - 901 38 Umeå, Sweden e-mail: benedicte.albrectsen@szooek.slu.se

Regulation is thought to occur in all biological systems. Few studies have, however, quantified the strength of regulation. Regulation should by definition be density dependent. Dispersal is one such process that in many models is suggested a source of regulation. The aim of this study was to quantify the density dependent element of dispersal in the specialist tephritid (ly *Paroxyna plantaginis*, which is the main seed predator on *Tripolium vulgare* (Asteraceae). Marked flies were released in artificial host plant patches at three different fly densities. I noted the disappearance characteristics as well as movement between patches and invasion of unmarked flies. The disappearance pattern indicated that the dispersal of these Tephritids *is* density dependent. Moreover it seemed to be sex biased, hence females may react more strongly to the local fly density compared to males.

Index terms: Paroxyna plantaginis; Tripolium vulgare; sex-biased dispersal

[0880] SPACE-SEASONAL DISTRIBUTION OF CERATITIS CAPITATA (DIPTERA: TEPHRITIDAE) IN A MASS TRAPPING EXPERIENCE IN A CITRUS ORCHARD IN MALLORCA (SPAIN)

<u>A. Alemany¹</u>, M.A. Miranda¹, R. Alonso¹ & C. Martín Escorza², ¹Univ. of Balearic Islands. Cra. Valldemossa km 7,5, CP: 07017, Palma de Mallorca, Spain, E- mail: analem@uib.es; ² Natural History Museum, CSIC, J. Gutiérrez Abascal 2, CP:28006, Madrid.

Mass trapping of *Ceratitis cupitata* females has been curried out in an isolated plot of orange trees in Mallorca. 125 traps baited with synthetic food attractants (putrescine, ammonium acetate and trimethylamine), and 10 traps baited with Trimedlure for male monitoring, were used. The experience was begun with the first emergence of adults at the beginning of summer and ended with the disappearance of the Mediterranean fruit fly population, which occurred with the arrival of the first cold spells in November. The values of the fortnightly catches estimated by kriging are represented in several three dimensional diagrams, showing the pest evolution. This begins to establish itself on the orchard periphery and to spread progressively inwards until it invades completely, at the time of greatest medfly population density. The influence of bietic and abiotic factors in the *C. capitata* population dynamics is discussed, as well as the presence of two very localised maximum spots, situated at two opposite extremes of the crop, to the west and east, respectively.

Index terms: Ceratitis capitata, insects population, kriging, mass trapping.

[0881] EFFECTS OF DIFFERENT DATES OF SOWING ON COMMON BEAN CULTIVATED ON TILLED AND NON-TILLED SOIL MANAGEMENT SYSTEMS ON THE SEASONAL OCCURRENCY OF PESTS IN PONTA GROSSA-PR

<u>B. Allconi</u>¹ & J. C. Havryluk², ¹Dept. of Agronomy, Ponta Grossa State Univ., Praça Santos Andrade s/n^o, Ponta Grossa, PR, 84.010-790, BR, E-mail balleoni@yahoo.com.² R. Paranaguá, 85, Ponta Grossa, PR, 84050-190, BR.

The trial was carried out in the school farm "Capão da Onça" of Ponta Grossa State University, Ponta Grossa-PR, on common bean (Phaseolus vulgaris), cultivar carioca, sowed on three dates in the season 96/97 (25/11/96; 16/12/96 and 25/01/97) and four dates in the season 97/98 (14/11/97; 21/12/97; 13/01/98 and 24/02/98), on two soil management systems (non-tilled and tilled). The fluctuation of the insects was evaluated with sweep net, each 7 days after the seeds germination. The experimental design was randomized blocs in the factorial system 2 x 3 or 2 x 4, with four replicates, being two soil management systems and three or four dates of sowing. The size of experimental units was 90 m², having each one 18 rows and 0,5 m between rows. The pests Diabrotica speciosa, Maecolaspis jolivetti and Empoasca kraemeri were more frequent in all dates of sowing in both of the soil management systems. The mean and the minimum temperatures correlated with the D. speciosa fluctuation in the season 96/97 and the mean and the maximum temperatures and relative humidity correlated with the pest fluctuation in the season 97/98. The populational fluctuation of M. jolivetti correlated with the maximum, mean and minimum temperatures and pluviometric precipitation in the season 96/97 and with relative humidity in the season 97/98. The dates of sowing influenced in the populational fluctuation of M. jolivetti and E. kraemeri in the season 96/97 and in the three species fluctuation in the season 97/98. The soil management systems and the dates of sowing influenced in the productivity of the common bean in the season 96/97 and the dates of sowing, in the productivity of the season 97/98. The productivities of the common bean were greater in the both, non-tilled and tilled systems in the senson 96/97, compared with that of season 97/98.

Index terms: Phaseolus vulgaris, Diabrotica speciosa, Maecolaspis jolivetti, Empoasca kraemeri, dates of sowing.

[0883] OVIPOSITION OF *HOMALODISCA* SPP. (IIEMIPTERA: CICADELLIDAE: CICADELLINAE) AND ASSOCIATED EGG PARASITISM ON CITRUS: SPATIAL DISTRIBUTION

<u>A. K. Al-Wahnibi</u>^{1,2} & J. G. Morse¹, ¹Dept. of Entomology, Univ. of California, Riverside, CA 92521, U.S.A., e-mail: aliwah99@hotmail.com; ²College of Agriculture, Sultan Qaboos Univ., Sultanate of Oman.

Several Homalodisca species (sharpshooters) in the U.S. have been implicated in the vectoring of strains of Xylella fastidiosa, to a number of important woody crops and ornamentals causing destructive diseases in grapevine (Pierce's disease), almond (almond leaf scorch), peach (phony peach), and cleander (cleander scorch). They could also be involved in the transmission of citrus variegated chlorosis (CVC), a devastating disease in Brazil, should the X. fastidiosa strain causing this disease be introduced into the U.S. In southern California, citrus serves as a major host plant for H. coagulata and H. lacerta, acting as both a feeding and an ovipositional host. In this study, we examined the spatial distribution of Homalodisca eggs and associated egg parasitism on citrus in terms of differences in vertical position (height), sun exposure (tree quadrant), and depth within the tree (shoot section). Ten lemon (Lisbon) trees were sampled by collecting 30 cm shoots from 3 heights (0.5, 1.5, and 2.5 m) and 4 quadrants (east, north, south, west). The shoots were processed in the lab by dividing each shoot into 3 sections of equal length and then separating old egg masses from new egg masses. New egg masses were incubated for emergence of egg parasitoids. No significant differences were observed between the 4 tree quadrants for all of the above variables. However, the highest positions on the tree (at 1.5 and 2.5 m) had lower egg densities than the low position of 0.5 m. Shoot sections were different statistically in egg density variables when new and old egg masses were considered separately. Higher egg density was recorded for the outer shoot section (0-10 cm) than for the inner shoot sections (10-20 and 20-30 cm) when only new egg masses were analyzed. However, the reverse was observed when old egg masses were considered. Egg parasitism rate (proportion of parasitized eggs) was not significant at p=0.05 for all of the main effects tested. We collected two species of mymarid parasitoids from the eggs of Homalodisca: Gonatocerus ashmeadi (93% of emerged parasitoids), and G. morrilli (7% of emerged parasitoids). When old and new egg masses were compared, egg density variables were not different, however egg parasitism rates were significantly higher in new egg masses than in old egg masses. Overall, the proportion of dead unemerged parasitoids was surprisingly high at 43% of all parasitoids in old egg masses. These results are discussed in terms of the behavior and biology of Homalodisca species and their egg parasitoids.

Index terms: Xylella fastidiosa, biological control, Mymaridae, Gonatocerus ashmeadi, Gonatocerus morrilli.

[0882] BIOCOENOTICS OF WILD BEES (HYMENOPTERA, APOIDEA) OF RESTRICTED AREAS OF "CERRADO" IN JAGUARIAÍVA, PARANÁ (SOUTHERN BRAZIL)

M. C. de Almeida & S. Laroca, Depto. de Zoologia, Univ. Federal de Paraná, Caixa Postal 19020, 81531-990 Curitiba, PR, Brazil, E-mail slaroca@netpar.com.br

Qualitative and numerical analysis of the biocoenosis of wild bees (Apoidea) of restricted areas of cerrado (the Brazilian savanna) in Jaguariaíva, PR, Brazil are performed. The areas of study (one of which already deeply modified) represent relicts of cerrado:1. In the Parque Estadual do Cerrado [marginated by the Jaguariaíva and Santo Antônio rivers, with altitudes of ca. of 850 m, 8 km to the north of the Jaguariaíva city], 2. In the place called Desvio [3 km to the east of Jaguariaíva city, in the margin of the highway Jaguariaíva-Sengés, in the exit for Sengés, today Industrial District], 3. In Fazenda Cachoeira [about 12 Km to west of Jaguariaíva, in the Diamante river margin]. The total area of each of the above sites is of about 100.000 m². Those area were chosen considering the following criteria: the similarity in relation to the biotopes of cerrado, the access easiness, as well as the level of human interference. The sampling methodology is that developed by Sakagami & Laroca (cf. SAKAGAMI, LAROCA & MOURE, 1967: J. Fac. Sci., Hokkaido Univ., Ser. Zool. 16: 253-291) and Laroca (LAROCA, 1972: MSc. thesis, UFPR, Curitiba, 61 pp; 1983, PhD thesis, KU, U.S.A, 194 pp.), which consists of capture of all the Apoidea in activities in the flowers, or in flight, without choice. Each specimen received labels with the following informations: place, hour and visited plant. Specimens of the following families were collected (number of genera and species): Colletidae (5, 13); Andrenidae (5, 11); Halictidae (17, 50); Megachilidae (8, 11); Anthophoridae (33, 84) and Apidae (15, 21). The bee specimens were collected on 120 species of plants belonging to 32 families. Given a presumably neighborhood among the vegetation of cerrado and the one of the Atlantic Forest (continental and insular biotopes) the data are focused comparatively. Aspects as relative abundance, diversity (Preston truncate log-normal distribution), phenology and flower preferences are analyzed, by means of soft-wares developed by the authors for that purpose. Special attention is given for parameters that enable inferences on the degree of *environmental health* (or level of the community) systemic disorder) attributed to the anthropic action).

Index terms: neotropical, community, melissocoenotics, bee-assemblage, Braziliansavanna.

[0884] AN ANALYSIS OF THERSHOLD TEMPERATURES FOR THE DEVELOPMENT OF CEREAL APHIDS, SCHIZAPHIS GRAMIMUM IN MIDDLE EGYPT

<u>A. A. H. Amin</u>, Plant Protection Res. Institute, ARC 7, Nadi El-Sayied Street, Dokki, Giza 12311, Egypt, E-mail: aahakaa@yahoo.com

Field studies conducted during three wheat growing season of (1997-1999) in Banie Swief Governorate, Middle Egypt to detect field population of Cereal Aphids, *Schizaphis* graminum, Field generation numbers, thermal heat units required and life table parameters were estimated. The Cereal Aphids, *Schizaphis graminum* was found to have 6 generations during wheat growing season that extended from December to April. Generations occurred at an average of 94.45 ± 1.272 The lower threshold was 8.88 °C. The intrinsic rate of increase was varied according to each generation and season.

[0885] LIFE HISTORY AND LIFE TABLES OF CITRUS LEAF MINERPHYLLOCNISTIS CITRELLA (LEPIDOPTERA: GRACILLARIIDAE)

<u>A.H.Amin</u>¹, G.B.El-Snadany⁴ & A.D.Shamson², 1 Dept. Plant Protec.; Fac. Agric. Ain Shams Univ., Egypt. 2 Dept. Plant Protec.; Fac. Agric. Sanaá Univ., Yemen.

Life history and life table of citrus leaf miner Phyllocnistis citrella was studied at four constant temperatures as well as under greenhouse conditions. The average of incubation period for egg stage was 7.9±0.22 days at 15°C while it was 3±0.0 days at 30°C and under greenhouse; the larval stage lasted for 28.6±0.6 days at 15°C while it was 4±0.0 days at 30°C and under greenhouse conditions; prepupal stage spent 4.50±0.17 days at 15°C while it was 1 ± 0.0 day at 30°C and under greenhouse; pupal stage was 34 ± 0.26 days at 15°C while while it was 5.2 ± 0.13 days at 30°C and 7.3 ± 0.5 days under greenhouse. Adult female longevity was the shortest at 30°C and the longest at 15°C, it lasted 52.1±0.72 days at 15°C while it was 8.6±0.26 days at 30°C and 11.8±1.5 days under greenhouse. Threshold (zero) of development and thermal units required (DD) for different developmental stages were estimated. Life table parameters under three degrees of constant temperature; i.e. 20, 25 and 30°C as well as under greenhouse conditions showed that net reproduction rates were 33.28, 32.23, 16.61 and 41.0 individuals/female/generation. Generation time (Gt) lasted for 42.7, 18.33, 18.0 and 20.1 days under the four tested temperatures, respectively. Intrinsic rates of increase (rm) were 0.388, 0.764, 0.518 and 0.499 individual/day. Fecundity (mx) was 34.2±1.2, 23.8±1.8, 19.3±1.9 and 45.1±5.6 eggs/female under the three tested temperatures and greenhouse conditions, respectively. These results indicate that 25-30°Cseem to be the most favorable weather conditions needed for citrus leaf miner reproduction. Population doubling time (Dt) showed that the population had the capacity to double every 2.230, 1.138, 1.670 and 1.740 days under the above mentioned conditions, respectively. Index terms: Phyllocnistis citrella, life table, life history, threshold of development, thermal units

[0886] IMPROVEMENT OF HONEY-BEE POLLINATION IN ACTINIDIA DELICIOSA

<u>E. Antognozzi¹, T. Gardi¹, S. Moscatello², A. Battistelli² & F. Famiani¹, ¹Dip. Arboricoltura e Protezione delle Piante, Università di Perugia, via Borgo XX Giugno, 06121 Perugia, Italy, E-mail antognoz@unipg.it, ²Istituto per l'Agroselvicoltura, CNR, Viale Marconi 2, 05010 Porano (PG), Italy.</u>

In Actinidia, honey-bees are primarily responsible for pollination. In Italy, in some areas, there are pollination problems due to the simultaneous flowering of other crops which are more attractive to honey-bees. Therefore, in 1998 and 1999 trials were carried out to evaluate the effects on fruit growth and quality of different treatments designed to: 1) measure the relative contribution of wind and insect pollination, 2) increase the attractiveness of honey-bees towards flowers, 3) improve pollination by artificial application of pollen, 4) overcome the negative consequences of inadequate pollination by using growth regulators. Before flowering some fruiting shoots were bagged with nets that only allowed for wind pollination. Moreover, some bee hives were fed with actinidia male pollen (induction feeding) to increase the attractiveness of the flowers. During flowering, pollen collected from flowers of male vines was used for artificial pollination of just-opened flowers by applying it with a "tennis ball" or, after suspension in water, with a hand sprayer. Untreated flowers were used as control. To better evaluate the effect of artificial pollination, immediately after pollen application part of the flowers were bagged with nets to prevent visits by insects. Fifteen days after full bloom, half of the fruits were treated (by dipping) with a solution of thidiazuron (20 ppm). Preventing insect pollination caused a marked fruit drop (= 30%), reduced fruit growth (- 50%), a rounder shape and a reduced number of seeds. Induction feeding of bees resulted in an increase in actinidia pollen gathered by the bees. Both the artificial pollination systems tested resulted in a tendency for greater fruit growth with respect to the control, regardless of the bagging of flowers with nets after the pollen application, whereas, a significant decrease in fruit growth was observed in the control when flowers were bagged with nets. Artificially pollinated flowers also gave fruits which had a higher length to diameter ratio and number of seeds. Moreover, they tended to have a higher soluble solids content and a lower flesh firmness at harvest. Thidiazuron treatment caused a significant increase in growth of all the treated fruits. However, care must be given in the use of such compound as it also tend to reduce the fruit length to diameter ratio. In conclusion, the results show good possibilities for reducing or eliminating pollination problems by introducing induction feeding of bce-hives and/or by applying artificial pollination and growth regulators.

[0887] DETERMINATION OF SPATIAL DISTRIBUTION PATTERN OF EGG AND LARVAL INSTARS OF ELM-LEAF BEETLE XANTHOGALEAROCELLA LUTEOLA (COL.; CHRYSOMELLIDAE)

A. Arbab, J. Jalali & A. Sahragard, Dept. of Plant Protection, College of Agriculture, Univ. of Guilan. IRAN, 41335-3179

Elm leaf beetle is one of the most injurious insects attacking elm trees, *Ulmus spp.*, in Iran. For studding the type of spatial distribution pattern of egg and larval instars, two methods, Taylor's power law and Iwa's regression, were used. The effect of host and geographical directions in changing of crowding indexes of egg and larval instars, were studied. The results indicate that spatial distribution of these stages are aggregative and Iwao's index (B) is affected more than Taylor's index (b) by host, stage of life and place. The knowledge on the spatial distribution patterns of this insect, can be provide essential information for planning a sequential sampling.

Key word: Xanthogalearocella luteola; Spatial distribution; Ulmus spp

[0888] SOME BIOLOGICAL AND ECOLOGICAL ASPECTS OF PSEUDODOROS CLAVATUS (DIPTERA:SYRPHIDAE)

E. Arcaya¹ & <u>F. A. Díaz¹, ¹</u>Univ. Centroccidental Lisandro Alvarado, Decanato de Agronomía, Depto. de Ciencias Biológicas, Tarabana 3023, Lara, Venezuela. Email:dbfrancis@hotmail.com.

Pseudodoros clavatus is the most important aphidophagous syrphid in cultivated plants in Venezuela. Besides, it can be found in some weeds and wild plants where aphids develop. Using Toxoptera citricida as larval food the life cycle of P. clavatus was: egg, 2 days; larvae, 9-10 days: pupae, 6-7 days. The larvae is able to devour 365 aphids during its developmental stage. The adults were kept in a 50 cm high x 30 cm width x 30 cm deep wooden cage with a sliding glass front door and a metallic mesh back cover and fed on polen of Tridax procumbens (Asteraceae) which was supplied placing entire flowers into a 8 dram glas vial containing water and replacing both them twice a week. P. clavatus larvae are able to feed in a variety of aphids including: T. citricida and T. aurantii in Citrus aurantifolia, Rhopalosiphum maydis in Zea mays, Myzus persicae in Sesamun indicum (Pedaliaceae) and Aphis neril in Nerium oleander (Apocynaceae), and in Calotropis procera and Sarcostemma glaucum (Asclepiadaceae). Other host plants which allow the development of aphids colonies that support P. clavatus larvae, are: Capsicum fratescens and Solanun nigrum (Solanaceae), Bidens pilosa (Asteraceae) and Polyscias guilfoylei (Araliaceae). The main natural enemies found in this study include the idiobiont pupal parasitoid Pachyneuron syrphiphagum (Hymenoptera:Pteromalidae).

Index terms: Aphidophagous, Toxoptera citricida, Tridax procumbens

[0889] INFLUENCE OF AGE OF BEAN PLANTS ON THE FECUNDITY AND LEAF CONSUMPTION OF *DIABROTICA SPECIOSA* (COLEOPTERA: CHRYSOMELIDAE)

C. J. Ávila¹ & J. R. P. Parra², ¹Embrapa-Agropecuária Oeste, Caixa Postal 661, 79.804-970- Dourados, MS, E-mail: crebio@cpao.embrapa.br; ²Depto. de Entomologia, Fitopatologia e Zoologia Agrícola-ESALQ/USP, Caixa. Postal 9, 13.418-900-Piracicaba,SP, E-mail: jrpparra@carpa.ciagri.usp.br

The physiological age of a host plant can affect the behavior, survival and reproduction rate of the insects that feed upon it. Studies of that sort can generate results of practical importance to entomological research, as well as to provide data which would help the understanding of the populational dynamics of insects under field conditions. Diabrotica speciosa (Coleoptera: Chrysomelidae) is an important bean plant pest in South America. The adult feeds on the top part of several plant species while the larvae, which live underground, damage the roots and tubers. The aim of this work was to determine the fecundity and leaf consumption by D. speciosa adults when fed on bean leaflets of different physiological ages. The research was conducted at the Insect Biology Laboratory of the Escola Superior de Agricultura "Luiz de Queiroz" (ESALQ), at 25 ± 2°C, 60 ± 10% RH and 14-hour photophase. The number of eggs/female and leaf consumption by D. speciosa under free choice and no choice tests were determined by offering bean leaflets collected from the upper third part of the plants to the adults. The egg-laying capacity and leaf consumption by the adult insects was influenced by the physiological age of the bean plant. The leaflets of younger plants were preferred by the insect for consumption, which also provided a higher fecundity in relationship to the leaflets from older plants. The chemical and/or physical changes that are likely to occur in the bean plant leaf along the development of the plant's phenology, as well as the bioecological implications related to the populational dynamics of the insect in the field are discussed in this paper. Index terms: Corn rootworn, bean, plant age, and preference.

[0891] HERBIVORES ASSOCIATED WITH THE REPRODUCTIVE PARTS OF OURATEA HEXASPERMA IN CENTRAL BRAZIL

B. Baker¹ & <u>H. C. Morais²</u>, ¹Master's Program in Ecology, Univ. of Brasília, Brasília, DF 70910-900, Brazil, E-mail bbaker@unb.br; ²Dept. of Ecology, Univ. of Brasília, Brasília, DF 70910-900, Brazil.

Ouratea hexasperma is a common shrub in the central area of the Brazilian cerrado that flowers and fruits mainly during the dry season. The insects associated with its reproductive parts were studied during the reproductive seasons of 1998 and 1999. In both years we collected inflorescences in Brasília National Park, Fazenda Água Limpa and the reserve of the Instituto Brasileiro de Geografia e Estatística to raise adults. We found at least 17 species of insect herbivores. There were three morphospecies of membracids and one coccoid (Homoptera) attached to most inflorescence stems, and a Scolytidae and another Coleoptera perforating the basal part of some stems. There were two species of Anthonomus (Curculionidae) and a Diptera associated with the buds, and a gall-forming hymenopteran in the ovaries. We also found two thrips morphospecies associated with buds and fruits, and raised one species of Cydia (Tortricidae) and one gelechiid from flowers and one of each from fruits. We raised a species of the genus Compsolechia (Gelechiidae) from both flowers and fruits, and another curculionid from the fruits. Between August and October of 1999 we collected around 30 inflorescences every three weeks in the Brasilia National Park and opened flower buds, flowers and fruits to verify for the presence of immature insects or any indication of previous infestation, such as holes or eaten material. One of the Anthonomus species attacked around 34% and 16% of the buds encountered on the two first dates, while there were galls in 15% and 44% of the buds, respectively. The thrips occupied buds in half of the inflorescences, as did caterpillars. Initially there was a very low number of buds without evidence of predation (25 and 15%), but right after flowering the number of unaffected structures was more than 36%. We observed a great loss of buds, which, combined with predation during fruit maturation, resulted in very low levels of fruit production. Ants were frequently observed visiting inflorescences, and their possible role in the reproductive fitness of *O. hexasperma* deserves further investigation. We also raised many hymenopteran species that are parasitoids of the herbivores encountered and may have an influence on the fitness of the plant.

[0890] INFLUENCE OF THE HOST PLANT ON THE LEAF CONSUMPTION BY ADULTS OF *DIABROTICA SPECIOSA* (COLEOPTERA: CHRYSOMELIDAE)

C. J. Ávila¹ & J. R. P. Parra², ¹Embrapa-Agropecuária Oeste, Caixa Postal 661, 79.804-970-Dourados, MS, E-mail: crebio@cpao.embrapa.br; ²Depto. de Entomologia, Fitopatologia e Zoologia Agrícola-ESALQ/USP, Caixa. Postal 9, 13.418-900- Piracicaba, SP

Diabrotica speciosa (Germar, 1824) (Coleoptera) is a multivoltine insect occurring in several countries in South America. The adult feeds on the top part of several plant species while the larvae damage the roots and tubers in a smaller number of hosts. Studies aimed at the determination of the influence of the host on the feeding behavior of D. speciosa can yield results that will help the understanding of factors which determine the populational dynamics of the pest in the field, providing condition for the improvement and development of strategies aimed at its control. The aim of this work was to determine the leaf consumption of D. speciosa adults in four hosts (bean, corn, soybean and potato) under free choice and no choice tests. The research was conducted at the Insect Biology Laboratory of the Department of Entomology, Plant Pathology and Agricultural Zoology of the Escola Superior de Agricultura "Luiz de Queiroz" (ESALQ), at Piracicaba, São Paulo, state Brazil. Under multiple-choice conditions, the leaf consumption was higher in bean than in soybean, potato and corn. At the double-choice test, in which the preference degree for potato, soybean and corn were evaluated in relation to the standard plant (bean), the leaf consumption was also higher in bean than in the other tested hosts. Under the no choice test, however, the insect had a higher leaf consumption in corn and lower in potato. The bioecological implications related to the feeding standard of D. speciosa adults in the studied hosts are discussed in this paper.

Index terms: Corn rootworm, host plant, and preference

[0892] RAINFALL AND RECENT OUTBREAKS OF THE AFRICAN MIGRATORY LOCUST IN THE LAKE CHAD BASIN

G. Balança, P.-E. Gay, T. Rachadi & <u>M. Lecoa</u>, CIRAD, Centre de coopération internationale en recherche agronomique pour le développement, B.P. 5035, 34032 Montpellier Cedex 1, France, E-mail: michel.lecoq@cirad.fr

Heavy outbreaks of migratory locusts, *Locusta migratoria migratorioides*, were observed in southwestern Chad and northern Cameroon from September to November 1997. For many years, similar outbreaks were a recurrent phenomenon in this region, with the last one occurring in 1989. An analysis of rainfall distribution from 1986 to 1997, was undertaken according to the ecological requirements of this locust. To assess the possibilities of good breeding and gregarisation, the monthly position of the areas receiving an optimal rainfall for this species (50 to 100 mm/month) was studied. The following parameters, assumed to be key factors, were considered: northern limit of the optimal area in May and June, northern limit of the area with excessive rainfall (>100 mm/month) in June, maximal northern limit of the optimal area during the rainy season, maximal northern limit of the area where the rainfall is excessive, duration of optimal pluviometric conditions around Lake Chad during the rainy season. This study showed that the outbreaks were strongly linked to the extent and distribution of rainfall during the 1986-1989 and the 1996-1997 periods. A simple index, calculated on the basis of rainfall data, was correlated with outbreak years. It appeared that two successive years of suitable conditions are necessary to induce an outbreak.

Index terms : Orthoptera, Acrididae, Locusta migratoria, Chad, Cameroun

[0893] DISTURBANCE EFFECTS ON INSECT COMMUNITIES ALONG A SUCCESSIONAL GRADIENT

M.F Barberena and T.M. Aide, Univ. of Puerto Rico, Dept. of Biology, PO Box 23360, San Juan, PR 00931-3360. E-mail: is970678@rrpac.upr.clu.edu.

Disturbances (anthropogenic or natural) differently affect the structure of ecosystems, depending on their frequency, intensity and area affected. Most studies have focused on the effect of either natural or anthropogenic disturbances, with an emphasis on vegetation, but few studies have examined the recovery of animal populations. The Caribbean island of Puerto Rico has been strongly modified by human activities and is affected by a severe hurricane approximately every 21 yr. In this study, we addressed the following questions: How do insect communities change along a successional gradient? Do hurricanes affect insect communities in a similar way, regardless of the successional stage of the site? To answer these questions, we located three sites in the Luquillo Experimental Forest, in Puerto Rico. The sites were pastures that have been abandoned for 4-5 yr, 30-32 yr, and >60 yr. In addition, these sites were recently disturbed by the passage of Hurricane Hugo (1989) and Hurricane Georges (1998). Each site was censused five times between June 1998 and October 1999. In each census we used four trapping methods: pitfall baited with human feces, malaise, interception and litter samples. The insects collected were sorted to family and morphospecies, and assigned to a guild according to it's morphology and natural history. The interception trap collected the highest number of morphospecies, and the pitfall trap the fewest. The total species richness in the sites varied from 195 in the 4-5 yr site, 136 in the 30-32 yr site and 131 in the >60 yr site. The high richness in the younger site was mainly due to a dominance of dipteran and homopteran species. Guilds that were present before Hurricane Georges, continue to be present after the hurricane, but the species composition has changed. In the census before Hurricane Georges, the 30-32 yr site had the highest richness, but after the hurricane the richness decreased by 50% in the 30-32 yr site, the richness in the 4-5 yr site increased 4-fold, and changed little in the >60 yr site. Before Hurricane Georges, the species composition of the 30-32 yr site and >60 yr site were similar, but after the hurricane the composition changed resulting in a greater similarity between the youngest and oldest sites. The similarity between these two sites was due to an increase in the dipteran fauna may be due to an increase in decomposing animal and plant material, and a change in structural complexity following the hurricane. Index terms: anthropogenic and natural disturbances, insect diversity, trophic guilds

[0895] RESEARCH REGARDING POPULATIONS DYNAMICS AND MARKING EUROPEAN CORN BORER (*OSTRINIA NUBILALIS*)

<u>A. Barbulescu¹ & L Rosca², ¹ Research Inst.</u> for Cereals and Industrial Crops, 8264 Fundulea, N. Titulescu Str., 1, Calarasi District, Romania, E-mail: fundulea@cons.incerc.ro; ² Univ. Agricultural Sciences and Veterinary Medicine, Av. Marasti 59, Bucharest, Romania.

There are few things known about field movement of Ostrinia nubilalis. In order to develop an insect release technique, a special attention was paid to the investigations on the European Corn Borer dynamics and the estimation of the natural population by means of pheromone traps and marking and releasing technique. Methodology. ECB moths were labeled after they are the sensity thetic diet in which were added Calco red dye, and ^{32}P as a colorless and transparent solution of NaH₃³²PO₄. The ^{32}P radioactivity's in the diet were 7.4 and 13 kBq/g.. It were registered: no. of pupae/box, no. of moths/box, egg batches/female and percentage of fertile eggs; radioactivity of pupae, moths and exuviae. It was used releasing of a large number of Ostrinia nubilalis males marked with Calco red dye, and recapture of a part of these moths, in pheromone traps situated at different distance in field. Results. Experiments made during 1994-1997 have shown that released tagged ECB moths have been recaptured in pheromone traps at a distance no more than 3000 m from the point of release (300 m/day), and probably this is the distance for which the moths are capable to fly. The flight of the moths was influenced by the wind speed and its direction. Both, 7.4 and 13 kBq/g diet reached our purpose for permanent moths labeling, the biggest part of radioactivity was contained by moths and smallest part by exuvies. The radioactivity of 7.4 and 13 kBq/g, has a slight obvious influence on the longevity of marked ECB. In average, for moths reared with 7.4 kBq/g diet, males exuvies have had 8.55% radioactivity, females exuvies 9.02% and for moths reared with 13 kBq/g diet, 6.85% males exuvies and 7.03% females exuvies in rapport with whole radioactivity in the emergence day. There is a slight difference between radioactivity of males and females. ³²P labeled moths by using 7.4 kBq/g and 13 kBq/g in the diet, could live as long as control moths; meanwhile, the radioactivity in each adult insect has decreased in time after a slope which depend on sex and diet used. Conclusions. ecb is a weak flyer, it seems that its flight is, in average, no longer than 300m/day Presented data indicates that rearing of ECB on radioactive diet affect biological parameters of obtained moths and that rearing medium with 7.4 kBq/g of diet is most suitable for obtaining labeling of moths.

Index terms: Ostrinia nubilalis, flight distance, isotopes, dye labeling.

[0894] COMPARISON OF THE MACROLEPIDOPTERAN ASSEMBLAGES OF SALIX NIGRA AND ACER NEGUNDO: A STORY OF CATERPILLARS, PLANTS, PARASITOIDS, AND PREDATORS

<u>P. Barbosa¹</u> & A. Caldas¹, ¹Dept. of Entomology, Univ. of Maryland, Plant Sciences Bldg., College Park, MD, 20742, USA, E-mail pb5@umail.umd.edu and ac182@umail.umd.edu.

Larval free-feeding macrolepidoptera of two riparian trees Salix nigra (black willow) and Acer negundo (box elder) were sampled and sorted by species and abundance. Data collected established that the majority of species in the assemblages in each tree species occurred at low abundance in each of the 5 years when larvae were sampled. On both trees, assemblages were dominated numerically by relatively few species, a pattern that has been observed for insect assemblages on plants in managed and unmanaged habitats. Absolute sampling of two macrolepidopteran assemblages on box elder and black willow was undertaken by fogging the canopy. Collections of larval Lepidoptera demonstrated that assemblages are numerically dominated by few species, i.e., scarce species constitute a large proportion of our samples. Specifically, the proportion of singleton species in these temperate habitat assemblages parallels that observed in fogging studies in tropical habitats. The similarity index calculated for the species in the two assemblages was relatively low. The latter results were compared to those obtained from absolute sampling (achieved by fogging). The patterns were the same regardless of the sampling approach. Patterns of larval parasitism among species in the macrolepidopteran assemblages also were examined.. Total parasitism of larvae on box elder was significantly higher than that of larvae on black willow. Comparisons of parasitism levels among lepidopteran families showed that in five of seven families larval parasitism on box elder was significantly higher than on black willow. For species whose larvae were found on both tree species, total parasitism was significantly higher when the larvae were on box elder than when larvae of the same species were on black willow. In comparisons of species found on both tree species, larvae in three of seven families suffered significantly higher levels of parasitism when on box elder than when on black willow. The roles of the functional/numerical responses of parasitoids, common and numerically dominant parasitoid species, and plant volatiles are considered as causal mechanisms underlying differential parasitism but are not supported by the data. Age based differential predation by birds on one of the more common macrolepidoptera species also has been observed. Behavioral observations further suggest that the ability of prey larvae to differentiate among predators and other herbivores in the habitat may serve as the basis for other examples of differential predation.

Index terms: Differential parasitism, box elder, black willow, insect assemblages scarce species.

[0896] EFFECT OF FOOD DEPRIVATION ON IMMATURE PHASE OF ASCIA MONUSTE

H. C. H. Barros-Bellanda¹ & F. S. Zucoloto¹, ¹ Dept. of Biology, FFCL – Ribeirão Preto, Univ. of São Paulo, CA 14040-900, Brasil, E-mail hbarros@usp.br.

In general, the lepidopterons are potentially powerful agents in the selection of oviposition places; however some mistakes were described, e.g. large egg-laying; egg-laying in small plant, on small leaf or in old plant, etc. An important consequence of these mistakes is the food deprivation on immature phase; it was observed in Ascia monuste (Lepidoptera, Pieridae), important consumer of Brassicaceae in neotropical region and cannibal on immature phase. The work reported here investigated the effect of food deprivation for 24h on second and fourth instars of *A. monuste*. What's period is more critical? The performance of three groups of caterpillars was compared: control group (C), deprivation on 2ª instar (E1) and deprivation on 4ª instar (E2). The parameters measured were: time for pupation, imago weight (male and female), total emergence, number of eggs per female, hatching and digestive indexes (AD, ECI and ECD) measured on fifth instar. Negative effect of food deprivation was obtained on performance of experimental groups. In E1 group, the principal difference was the high time for pupation, which exposes the individuals to negative biotic and abiotic conditions to survival. In E2 group, adults were less heavy, which has negative effect on reproduction. In conclusion, food deprivation has a direct effect on population survival (E1) or an indirect effect on survival (E2). So, we can say that both periods tested are critical. Furthermore, immatures can resist to food deprivation on 2^a and 4^a instar for 24h (low mortality), have a compensatory behaviour (high ingestion and biomass gained) on fifth instar and do not demonstrate cannibal behaviour during food deprivation.

Index terms: cannibalism, compensatory behaviour, food deprivation, insect, ovipositional mistakes

[0897] DISCRETE TIME MODEL OF POSTFEEDING LARVAL DISPERSAL IN BLOWFLIES

R. C. Bassanezi¹, M. R. Sanches¹ & <u>C. J. Von Zuben²</u>, ¹Dept. of Applied Mathematics, IMECC, UNICAMP, 13083-970, Campinas, SP, Brazil; ²Dept. of Zoology, UNESP, Ave. 24A, 1515, P.O. Box 199, Rio Claro, SP, 13506-900, Brazil, E-mail vonzuben@rc.unesp.br.

Dispersal is one of the most significant and complex aspects in the life history of organisms. The complexity of dispersal is further enhanced by the spatial scale in which it occurs. In blowflies, the postfeeding larvae that have already attained the minimum weight necessary for pupation begin dispersing outside the food substrate, in search of suitable sites for pupation. Some continuous time mathematical models have been proposed to explain the appearance of oscillations in the dispersal of larvae from the food source, specifically for calliphorids. These models emphasized diffusion equations and non-local interactions. The objective of the present study is to investigate the same process of larval dispersal, but utilizing difference equations incorporating probabilities associated with larval movements. Two initial equations represent the dynamics of larval movement: (1)

$$A_{i,j+1} = A_{i,j} + \alpha C_{i,j} \text{ and } (2) \quad C_{i,j} = \omega C_{i,j-1} + \beta C_{i-1,j-1} - \beta C_{i,j-1},$$

where $A_{i,\,j}$ represents the number of larvae buried in the position i at time j , $C_{i,\,j}$

is the number of larvae in the surface of the pupation substrate in the position i at time

 \dot{J} , α is the proportion of larvae that bury in one location, ω is the proportion of larvae that remain stagnant in the same position in an unit of time, and β is the proportion of

In a rotation and the position i to the position i+1 in an unit of time. The results of simulations performed to investigate the oscillations in the dispersal of larvae from the food source, applying expressions obtained through the expansion of the two above equations, are similar to those obtained from the continuous time models. The advantages of the utilization of a discrete model, compared with continuous models, are that the obtainment of explicit solutions and the comprehension of the dynamics of larval movement are both facilitated in a discrete model.

Index terms: difference equations, larval movement, Calliphoridae.

[0899] A SEASONAL CHANGE IN HOST USE OF THE BRAZIL NUT FAMILY CORRESPONDS WITH GENETIC DIVERGENCE IN WOOD-BORING PALAME (CERAMBYCIDAE)

A. C. Berkov, Cullman Molecular Systematics Lab, Dept. of Ornithology, American Museum of Natural History, Central Park West at 79th St., New York, NY 10024-5192, USA, E-mail berkov@amnh.org.

In French Guiana, cerambycid beetles in the genus Palame appear to reproduce exclusively in trees belonging to the Brazil nut family (Lecythidaceae). During a yearlong rearing project (1995-96) in the rain forest of central French Guiana, Palame anceps, Palame mimetica, and Palame crassimana accounted for almost half of the cerambycids reared. Palame anceps emerged exclusively from a single host species, Eschweilera coriacea, during both the dry and rainy seasons. Palame mimetica appeared to make a partial change in host affiliation, from Lecythis poiteaui during the dry season to E. coriacea during the rainy season. Palame crassimana currently includes at least three distinct morphological forms, two of which were reared during this experiment. The 'bicolor' form emerged from four of the five potential host species during the dry season, while the 'unicolor' form emerged solely from Eschweilera coriacea, almost exclusively during the rainy season. It was difficult to find diagnostic morphological characters to support the delimitation of these forms as species, and I hypothesized that they were host races in the process of diverging. This hypothesis has been addressed by sequencing mitochondrial DNA, a 1000 bp segment of the cytochrome oxidase subunit I (COI) gene, to detect potential genetic differentiation. Minimal uncorrected sequence divergence (0 -0.3%) was detected within forms, even among individuals reared from different host species. The 'bicolor' and 'unicolor' forms differed at 10.5% of the bases sequenced. This falls comfortably within the range of divergence detected between other species pairs (9.8 - 14.6%). It was particularly surprising to observe considerable sequence divergence (7.8%) between P. mimetica reared during the dry season and P. mimetica reared during the rainy season. This is high compared to COI sequence divergence among other complexes of closely related insect species. Contrary to what might be expected in a tropical forest with high plant diversity, for Palame, temporal differences in life history appear to present a more effective barrier to genetic exchange than host association. Index terms: *Eschweilera coriacea*, Lecythidaceae, plant-insect interactions, COI. sequence divergence

[0898] A FIVE YEAR STUDY OF MATING FREQUENCIES AND SIZE VARIATIONS IN WILD POPULATIONS OF THE GREEN-VEINED WHITE BUTTERFLY *PIERIS NAPI*

<u>I. Bergström¹</u>, C. Wiklund¹ & A. Knitala², ¹Department of Zoology, Univ. of Stockholm, S-106 91 Stockholm, Sweden. E-mail jonas.bergstrom@zoologi.su.se; ²Department of Biology, Univ. of Oulu, P.O. Box 3000, FIN - 90 014 Oulu, Finland.

Factors affecting female mating frequencies are well studied in the laboratory. However, very few studies of polyandry have been carried out on wild populations. In this study we have examined mating frequencies and size variations in relation to age and generation in bivoltine populations of the green-veined white butterfly (Pieris napi) between the years 1990-94. P. napi has two generations per year in Sweden. The first generation flies in May/June after having spent the winter in the pupal stage. The second generation develops directly and flies in July/August. In this species males transfer a large nutritious ejaculate to the female, this spermatophore is known to increase female lifetime fecundity. Previous laboratory studies have shown that large females have a higher fecundity and that female fecundity increases with number of matings. The results from this study showed a positive correlation between female size and mating frequency in the second generation but not in the first generation. Thus, at least in the second generation, large females seemed to have a double advantage over small females. Large females have both a higher reproductive output due to their size, and are also better to make use of a male's nuptial gift. This is in contradiction with earlier hypotheses that have predicted that male gifts might reduce the value of large size in polyandrous females. This study also showed that the size of the butterflies varied according to sex, generation and year. The interaction between sex and generation was also significant. Although both sexes were larger in the directly developing generation, male size increased more. Thus, sexual size dimorphism increased in the directly developing generation. Another difference between the generations was that females in the first generation mate slightly, although significantly, more times than females in the second generation. Male size has been shown to be positively correlated with a female's unreceptive period after a mating; hence, it is possible that the decreased polyandry in the second generation is a consequence of increased sexual size dimorphism. Index terms: polyandry, sexual size dimorphism, body size, bivoltine populations

[0900] ON THE BIOLOGY OF THREE NEW POLLINATING SPECIES (COLEOPTERA: CURCULIONIDAE: DERELOMINI) OF CAIAUÉ *ELAEIS OLEIFERA* (KUNTH) CORTÉS AND OF THE F1 HYBRID (*E. GUINEENSIS X E. OLEIFERA*) IN THE STATE OF AMAZONAS, BRAZIL

P. Beserra¹ G. Couturier² & M.V.B. Garcia¹, ¹Lab. de Entomologia - Embrapa Amazônia Ocidental, Rodovia AM 010, Km 29, C.P. 319, CEP: 69011-970, Manaus, AM, E-mail: paulo@cpaa.embrapa.br. ²Museum National d'Historie Naturelle - I.R.D., 45, rue Buffon, 75005, Paris, E-mail: couturie@cimrs1.mnhn.fr.

The pollination of the bunches of the oil palm Elaeis guineensis is done principally by species of Derelomini of the African genus Elneidobius. For caiaué Elaeis oleifera, three new species of Derelomini native to Amazonia exist, one belonging to the genus Grasidius n. sp. and the other two to a new genus. The F1 hybrid of E. guineensis with E. oleifera, which exhibits characteristics of high resistance to fatal yellowing disorder, attracts the three Derolomini genera. With the objective of estimating the length of the biological cycles of the new species, the male inflorescences of caiaué and of the F1 hybrid were collected during anthesis, previously isolated and put separately into entomological cages along with each new species of Derelomini. Each day spikelets were removed to verify the evolution of the immature forms of the new species. The three new species of Derelomini use the male inflorescences of caiaué and of the Fl hybrid as a reproductive niche and for the development of progeny. The two species of the new genus completed their biological cycle in 20 days (n=2), and the Grasidius n. sp. completed its biological cycle in 35 days (n=2). These new species of Derelomini have the potential for mass production and inundative colonization in plantations of the F1 hybrids. Index terms: pollination, oil plam, Grasidius

[0901] THREE NEW SPECIES OF COLEOPTERA (CURCULIONIDAE: DERELOMINI) POLLINATORS OF CAIAUÉ *ELAEIS OLEIFERA* (KUNTH) CORTÉS AND OF THE F1 HYBRID (*E. GUINEENSIS X E. OLEIFERA*) IN THE STATE OF AMAZONAS

P. Beserra¹, LP.de A. Miranda² & G. Couturier³, ¹Lab. de Entomologia - Embrapa Amazônia Ocidental, Rodovia AM 010, Km 29, C.P. 319, CEP: 69011-970, Manaus, AM, E-mail: paulo@cpaa.embrapa.br.²Instituto Nacional de Pesquisa da Amazônia, Manaus -AM, C.P. 478, CEP: 69011-970, Manaus, AM, E-mail: ires@inpa.gov.br. ³Museum National d'Historie Naturelle - I.R.D., 45, rue Buffon, 75005, Paris, E-mail: couturie@cimrs1.mnbn.fr.

Insect pollination is a factor in oil palm production. There is a specificity of the pollinating insect fauna of the oil palm *Elaeis guineensis* consisting of five species of Derelomini of the African genus Elaeidobius. This also occurs with the visiting insect fauna of caiaué *Elaeis oleifera* with three new species of Derelomini native to Amazonia, one of the genus *Grasidius* n. sp., and the other two of the new genus. The Fl hybrid *E. guineensis* x E oleifera, which demonstrates high resistance to fatal yellowing disorder, attracts the African and native Derelomini. With the objective of determining if the new species of Derelomini are pollinators of caiaué and of the Fl hybrid, the three new species were collected in the female inflorescences of caiaué and the Fl hybrid in their receptive period and taken to the laboratory, where the acetholysis method was used to verify the presence of pollen adhering to the body of the insects and to determine its botanical origin. The presence of caiaué and Fl hybrid pollen on the three new species of Derelomini was proven. The results indicate that these three new species are pollinators of caiaué and the Fl hybrid. With the potential to enter into a program of mass production and inundative colonization of pollinators in plantations of Fl hybrids. Index terms: pollinator, oil plam, *Grasidius*

[0902] IMPACT OF THE GENOTYPE OF A SYMBIOTIC BACTERIA ON THE FITNESS OF A PHYTOPHAGOUS INSECT

L.M. Birkle¹, C.R. Tosh², K.F.A. Walters² & A.E. Douglas¹, ¹Department of Biology, University of York, York, UK, YO10 5YW. ²Central Science Laboratory, Sand Hutton, York, UK, YO41 1LZ.

Plant phloem sap is utilized not by insects but by insect-bacterial symbioses. In this tritrophic interaction, the bacteria provide the insect with essential amino acids, complementing the unbalanced supply from the plant. Here we explore the dynamics of the three-way interaction by investigating the impact of genetic variation in the capacity of the bacteria (*Buchnera*) to provide the essential amino acid tryptophan on the fitness of the pea aphid (*Acyrthosiphon pisum*) on different plants. A large field-based experiment established the impacts of bacterial genotype, plant cultivar and season on aphid fitness. Further investigation of pea aphid phenotype (related to actual or potential acitivity in tryptophan production) in selected aphid lineages with a range of bacterial genotypes is capable of incorporating and integrating algorithms predicting aphid fitness. The combined datasets of pea aphid fitness, bacterial genotype, pea aphid phenotype and the application of the model engine will enable use to explore the impact of bacterial genotype on aphid fitness.

Index terms: Acyrthosiphon pisum, symbiosis, nutrition

[0903] A COMPARATIVE ANALYSIS OF THE FLIGHT BEHAVIOR OF LYGUS HESPERUS AND LYGUS LINEOLARIS (HEMIPTERA: MIRIDAE)

<u>**LL Blackmer¹**</u>, **S.E. Naranjo¹ & L.H. Williams III²**, ¹USDA-ARS, Western Cotton Res. Lab., 4135 E. Broadway Rd., Phoenix, AZ, 85040, USA, E-mail: blackmer@ix.netcom.com; ²USDA-ARS, Southern Insect Management Res. Unit, Experiment Station Rd., P.O. Box 346, Stoneville, MS, 38776, USA.

In the United States lygus bugs are serious pests of agricultural and horticultural crops, Their feeding causes abscission of reproductive structures, destroys plant terminals, and reduces plant quality and yield. Two of the most important species, Lygus hesperus and Lygus lineolaris, are highly polyphagous, and readily move between hosts as plant quality declines. The distribution of L. hesperus is confined to the western U.S. and southwestern Canada, whereas L. lineolaris is found throughout the U.S. and Canada. Little is known about either species with regards to the factors that influence their tendencies to disperse. A better understanding of the dispersal capabilities of these insects could facilitate the development of more effective control strategies. To such an end, we have been conducting comparative studies of these two species, using a vertical wind tunnel (untethered flight) and flight mills (tethered flight). Under laboratory conditions, males and females of both species initiated flights throughout the day and night (on flight mills). The majority (90-95%) of flights were less than 5 min in duration whether tethered or untethered lygus bugs were tested. Males and females of both species were capable of extended flights (X ± SE, L. hesperus 22.07 ± 10.3 min, L. lineolaris 17.3 ± 2.8 min in the vertical wind tunnel; L. hesperus 32.08 ± 8.2 , L. lineolaris 39.02 ± 11.4 min with flight mills), but flights of longest duration (466 min) were obtained with the flight mills and were 5 to 6 times longer than the longest flight (83 min) observed in the wind tunnel. Differences in cumulative flight duration was influenced by the number of flights that an individual made, those being approximately twice as many for tethered versus untethered fliers $(23.9 \pm 6.4 \text{ vs.} 12.2 \pm 4.8 \text{ flights})$. The initial rate of climb toward the skylight cue in the vertical wind tunnel was approximately 50 cm/s for both species. L. hespenis had a bimodal distribution in its phototactic orientation (or frequency of flights > 5 min for tethered flight) with peaks from 0500 to 0700 h and again from 1900 to 2100 h. The response of L. lineolaris was variable but could more accurately be described as unimodal, with peaks in flight activity between 0600 and 1000 h in the vertical wind tunnel, and between 1900 and 2000 h with the flight mills. For both species, extended flights were rarely observed before 6 days of age. Most of the long duration flights occurred between 1 and 3 wk of age. Additional factors (mating, reproduction and nutritional status, light intensity and wind speed) that might influence flight duration in these two species will be discussed, as well as the advantages and limitations of tethered versus untethered flight mills.

[0904] NUTRITIONAL AVALIATION OF PLANTS OF ERVA MATE ATTACKED AND NOT ATTACKED BY "BROCA" HEDYPATHES BETULINUS

G. A. Borsoi¹ & E. C. Costa², ¹ Programa de Pós-Graduação em Engenharia Florestal (Mestrado) – Universidade Federal de Santa Maria, Santa Maria, RS – Brasil; ² Depto. de Defesa Fitossanitária, Centro de Ciências Rurais – Universidade Federal de Santa Maria, Campus Universitário, prédio 42, 1º andar, 3225 – CEP 97105-900 – Santa Maria – RS – Brasil – e-mail: eccosta@cr.ufsm.br.

The research had purpose to evaluate the nutritional deficiency of erva-mate plants (Ilex paraguariesis St Hil.) attacked and not attacked by Hedypathes betulinus (Klug, 1825), (Col : Cerambycidae), and correlate nutrition variable of soil and leaves, for identify nutritionals instability possible among two parameters analyzed. The area is localized in Catanduvas, SC - Brazil, it is plane and has 20ha. The stand is homogeneous, with eight years old. The sample were submitted chemical analysis in Soil Analysis Laboratory, in Centro de Ciências Rurais, at Universidade Federal de Santa Maria. With the obtainment of medians of the chemicals levels, maked the test of comparisons mediuns "t" and "F, test of homogeny of variances, in the final analysis of simple linear correlation between chemical variables of soil and leaves for two kind of plants. Soil showed levels adequates of N and P, low levels of K, Ca Mg, and right to S, B, Fe, Mn, Zn, Cu, Na, Al, AL+H, Ph and SMP. In the foliar analysis, plants presented levels adequates of K, Ca, B, Zn, and Na, low levels of P, Mn and S and high level of N, Mn, Fe and Cu. This analysis, were expressive the high concentrations of N and low levels of S in the foliar tissue. The test "t"demonstated expressive difference to soil and leaf, between mediums of two kinds of plants. The test "f' demonstrated P of the soil, of leave and Fe of the soil like chemicals variables wich expressives differences in the level of error 5%. The test of homogeny of variances presented the P and Fe of the soil and the K, S and Mn of the leaves, like variables with expressive heterogeny of the variances. Of the variable studied, plants attacked showed the most variation between mediuns. Of the correlations analyzed, between two kind of plants, the most importance were one formed by N and S of leaf, and by K, S, Fe, Mn of soil, because they presented the biggest number of correlations formed with chemicals elements in plants attacked. In most cases plants attacked presented most instability between the nutrients. In attacked plants, the correlations formed didn't demonstrated similaries with majority of the elements chemicals analysed to plants not attacked.

 ³COEX - Mossoró - RN, E-mail: coex_frutas@uol.com.br

Fruit flies belonging to species Ceratitis capitata and to genus Anastrepha are well known around the world as the most destructive pest in fruit producing areas. Being an important quarantine pest, its presence in fruit crops make them impossible for any effort to export. In northeast Brazil, the species that present a large geographic distribution are Anastrepha obligua, A. zenildae and C. capitata, this last one known as the Mediterranean fruit fly. The growing areas of tropical and subtropical fruit crops in the state of Ceará are increasing. Using high technology and irrigation systems, 35,000 hectares are being established in six new agroareas within the state, one of them being Baixo Jaguaribe, located in the eastern region. This study has been carried out to identify and quantify different species of fruit flies. Pheromone traps using Trimedlure to attract C. capitata flies and hydrolyzed protein traps for Anastrepha sp. have been distributed into irrigation producing areas, backyards and towns. Host fruits have also been collected to check the presence of eggs and larvae inside of them. The preliminary results have shown the presence of C. capitata in all areas. In the genus Anastrepha four major species have been detected: A. obliqua, A. zenildae, A. sororcula and A. fraterculus. Species distribution frequency and its population dynamic will be further discussed. Index terms. Fruit flies, Ceratitis capitata, Anastrepha sp., Trimedlure, pheromone trap.

[0907] COMMUNITIES OF SOIL COLLEMBOLA ON THE NORTH AND SOUTH FACING SLOPES OF A MEDITERRANEAN VALLEY

M. BROZA¹, D. POLIAKOV¹, M. GRULA² & G. BRETFELD³, ¹Univ. of Haifa at Oranim, Tivon 36006, Israel, E-mail: broza@research.haifa.ac.il ²Instit. de Speologie "Emil Racovitza", Bucharest, Romania ³Zoological Instit. Univ. of Kiel, Kiel, Germany

Comparison was made between the assemblage of collembolan species on the north- (N-) and south-facing (S-) slopes of Valley Oren, Mt. Carmel, Israel. Its slopes, only 100 m apart at the bottom, represent a dramatic biotic divergence due to the much higher solar radiation on the south-facing slope. Both slopes have the same geological history and structure, the same height above sea level, and more or less the same rainfall. As a result of a difference of up to 500% in the radiation load, the S- slope is much drier than the Nslope. This results in a lower biomass of vegetation cover and, as a consequence, more vulnerability to erosion and intensive wind, which further increase evaporation. Thus there are clearly two very distinct ecological microsites on the N- as opposed to the S- facing slopes. The assemblage of Collembola found, includes 50 Athropheona and 17 Symphypleona species. The list of 67 species includes 13 new taxa. Arthropleona species richness is very similar on both sides, 43 species on the N-slope and 41 on the S-slope. In contrast, we recorded a rich assemblage of Symphypicona on the N-slope (17 species) but only 5 species on the S-slope. Thirty-four out of 50 species of Arthropleona were found on both sides of the valley. Nine species were found only on the N- and 7 only on the S-. Some families showed a greater abundance of species on one slope than the other. Differences in species richness were found between and within slopes according to altitude zone and vegetation. The Sorensen Similarity Index (SSI) used to compare the inter- and intra-slope distribution, as well as plants association. Greater similarity was found between the two vegetation types within any altitude. However, some inter-slope SSI values were higher than the intra-slope similarities. Data on species abundance for Entomobryoidea (17 species) indicated that two species, *Pseudosinella octopunctata* and *Heteromurus major*, were very common (ca. 89%) and found in all altitudes. In contrast most other species were rare, found in only some altitudes. While the two most common species are cosmopolitan at least half of the rest of the list are endemic to the eastern Mediterranean. These data are related to one of the most pervasive patterns in ecology, claiming that locally abundant species tend to be widespread, whereas locally rare species tend to be narrowly distributed. It is suggested that the N- versus S-slope model may represent a micro-cosmos with diverse soil community ideal for experimental field tests of major ecological issues.

Keyword; Entomobryidae, microsite, Israel

[0906] SURVEY OF FRUIT FLIES (DIPTERA: TEPHRITIDAE) IN FOUR CITIES IN PARAÍBA

C.H. Brito¹, <u>I.A. Mezzomo¹</u>, E.L. Araújo² & M.G.A. Lima³, ¹Laboratory of Biological Control, Dept. of Pharmacy and Biology, Paraíba State Univ., Félix Araújo Square, 13B, 58101-450, Campina Grande, PB, Brazil, E-mail jamezzo@zaz.com.br; ²Dept. of Entomology, ESAM, P.O. Box 137, 59600-970, Mossoró, RN, Brazil, E-mail elaraujo@carpa.ciagri.usp.br; ³Dept. of Biology, Ceará State Univ., P.O. Box 1531, 60740-020, Fortaleza, CE, Brazil, E-mail goretti@uece.br

The registered occurences are fundamental for the implementation of integrated pest management of fruit flies, that cause great damages to fruit cultures in Brazil, where there are already more than 90 registered species. For this reason and also because of the lack of studies of this type in Parafba, this research had as its objective innitiate basic studies that will allow the development of a line of research about fruit flies in our state. Occasional collections were made from September 1998 to July 1999 in domestic orchards within the city limits of Campina Grande, Lagoa Seca, Alagoa Nova and Areia. Fruits of the plant and on the ground were collected, which were weighed and counted, being left for 10 days in closed recipients containing sterilized soil. After this period, the soil was sifted to separate the pupae and these were maintained in Petri dishes with humid cotton. Daily, the flies that emerged in the dishes were collected, counted and sexed. Of the 25 different fruit species collected, in 15 there were 1511 pupae and 922 flies, being 518 Ceratitis capitata (56,2%), 91 Anastrepha obliqua (9,9%), 62 A. fraterculus (6,7%), 6 A. antunesi (0,7%), 4 A. sororcula (0,4%), 227 Anastrepha spp. (24,6%) and 14 flies without economic importance (1,5%). Guava (Psidium guajava) was the fruit where the most quantity of pupae and fly species were obtained, however the highest percentage of infestation occured in castanhola (*Terminalia catappa*) (52,5%), umbu-cajá (*Spondias* sp.) (48,0%) and pitanga (*Eugenia uniflora*) (32,6%). The species C. capitata infested 10 fruit species. predominantly in C. Grande; Anastrepha spp. infested 9 fruit species and predominated in Areia; and in 4 fruit species both genera were present, in similar proportions as in L. Seca and A. Nova. The C. capitata, A. obliqua and A. fraterculus species are the most important in the surveyed places

Index terms: Insecta, Anastrepha, Ceratitis capitata, geographic distribution.

[0908] GENETIC AND SOIL NUTRIENT EFFECTS ON RESISTANCE OF COMMON REED TO A GALL-FORMER

Luc De Bruyn^{1,2} & T. Backeljau^{2,3}, ¹ Inst. Nature Conservation, Kliniekstr. 25, 1070 Brussel, Belgium; ² Dept. Biology, Univ. of Antwerpen, Groenenborgerlaan 171, 2020 Antwerpen, Belgium; ³ Dept. Entomology, RBINSc, Vautierstr. 29, 1000 Brussel, Belgium; E-mail : luc.de.bruyn@instnat.be.

The flies of the genus Lipara (Diptera; Chloropidae) induce typical galls on the shoots of the common reed, *Phragmites australis* (Poaceae). In previous studies it was shown that shoot diameter (a measure of shoot vigour) is the major factor determining resistance to herbivore attack. Shoot diameter in turn depends on the growing conditions. Shoots are thicker in moist, nutrient rich environments. The aim of the present study was to assess whether resistance also has a genetical component. Therefore, 6 reed clones were grown in a common garden experiment under two treatments (nutrient rich, nutrient poor) in three subsequent years. Plant resistance to gall induction differs significantly among clones. Resistance consists of two components, resistance to gall induction and increased laval mortality in the gall chamber. Resistance also depends on the nutrient level offered to the reed rhizomes. Shoots growing on a nutrient rich soil are more resistant to gall induction than galls growing on a nutrient poor soil.

[0909] HONEY ANTS ON THREE DIFFERENTS REWARDING ATTRACTANTS

L. M. Buffa & M. A. Delfino, Cat. de Entomología, Univ. Nac. de Córdoba, Av. Velez Sarsfield 299, 5000-Córdoba, Argentina, E-mail lbuffa@com.uncor.edu

Both homopteran-ant and extrafloral nectaries-ant associations are common mutualisms found in differents regions. Many Homoptera, such as aphids, excrete honeydew as they feed on phloem sap. Ants preferentially tend those herbivores that produce the most nutritionally rewarding attractants. Honeydew-producing insects may funtionally be considered as extrafloral nectaries exploited by ants, and this association is generally considered mutualistic. Extrafloral nectaries occur in a wide variety of plant taxa, the extrafloral nectar is a generalized food source eaten by ants, some species use a variety of nectar sources and may forage on two or more plants simultaneously. A wide variety of ant taxa are attracted to many different nectary-bearing plants, mainly Myrmicinae, Formicinae, Dolichoderinae and Pseudomyrmecinae. Existing information suggest that ants switch from visiting a plant extrafloral nectaries to visiting honeydew-producing homopterans. In order to known the ant fauna foraging on extrafloral nectaries of Croton sarcopetalus as well as two honeydew producing aphids: Dysaphis foeniculus on Foeniculum vulgare and Aphis spiraecola on Eupatorium hookerianum, a field work was carried out in an area of Córdoba (Argentina). Weekly samplings of ants were made from October, 1995 to May, 1998. Twenty-three ant species in 11 genera and 4 subfamilies were recorded. The subfamilies Formicinae and Myrmicinae dominated the ant fauna, comprising, together, 19 species of visiting ants. Extrafloral nectaries were visited by several ant species (15), whereas A. spiraecola and D. foeniculus by 12 each one. Camponotus, Linepithema, Crematogaster, Pheidole and Brachymyrnex were found at the three differents rewarding attractants. Pheidole was the genus most abundant and occurrent at extrafloral nectaries and colonies of A. spiraecola, being Camponotus the genus with high species richness. Brachymyrmex was the genus most abundant, occurrent and with high species richness on D. foeniculus colonizing F. vulgare. Pseudomyrmex acanthobius, Pseudomyrmex sp.1, Crematogaster brevispinosa, Zacryptocerus sp.1, Camponotus blandus and Camponotus personatus were registred only visiting extrafloral nectaries. Solenopsis sp.2, Prenolepis sp.2 and Camponotus rufipes only tending A. spiraecola. Pheidole sp.1, Wasmannia auropunctata and Brachymyrnex sp.3 only tending D. foeniculus. Other considerations about the ant fauna in this three differents rewarding attractants are discussed.

Index terms: interactions, ants, aphids, extrafloral nectaries.

[0910] PATTERNS AND PROCESSES OF ARTHROPOD COMMUNITY SUCCESSION AFTER A FIRE

J. C. Burger¹, M. A. Patten², <u>J. T. Rotenberry</u>^{2,3} & R. A. Redak^{1,3}, ¹Dept. Entomology, ²Dept. Biology, ³Center for Conservation Biology, Univ. California, Riverside, CA 92521 USA; E-mail rote@citrus.ucr.edu.

We surveyed arthropods after a fire in southern California coastal sage scrub to investigate (1) the degree to which arthropods recolonized burned sites, and (2) the pattern of post-fire succession across arthropod orders, families, and guilds. We sampled arthropods from burned and unburned sites beginning 2 1/2 years after a fire. Arthropods collected from pitfall traps and vacuum samples were counted and identified to family, morphospecies. and feeding guild. Burned sites contained more arthropods and a guild distribution skewed toward detritivores and herbivores. Psocoptera were significantly and Collembola and Homoptera were marginally more abundant in burned sites. Species richness of the six dominant orders did not differ across sites but arthropod assemblages at the family level did in relation to burn history and grass cover. This study suggests that arthropod recolonization follows a similar pattern that vegetational succession does, in that there is a predictable species turnover and a shift in importance of different functional groups at a site over time. Mid-successional burned areas did not, as expected by current theory, have higher arthropod biodiversity than mature sites. Interestingly, the larger arthropod community appeared to follow a different successional pattern than the Dipteran community at our study sites. Finally, there is cause for concern as to the effect of nonnative grasses on arthropod recolonization.

Index terms: arthropod community succession, recovery after disturbance, wildfire, impact of non-native grassses

[0911] DISPERSAL OF EUROPEAN AND SOUTHWESTERN CORN BORER MOTHS WITHIN AND BETWEEN CORNFIELDS

L. L. Buschman¹, P. E. Sloderbeck¹, R. L. Hellmich II², S. B. Ramaswamy¹ & R. A. Higgins¹, ¹Dept. of Entomology, Kansas State Univ., Manhattan KS, 66506-4004, USA, Email: Ibuschma@oz.oznet.ksu.edu; ²Corn Insects and Crop Genetics Res. Unit, USDA, ARS, Iowa State Univ., Ames, IA. 50011, USA.

Moth dispersal is an important parameter in evaluating the placement of a refuge for resistance management in Bt-corn. This study was designed to evaluate the dispersal of European and southwestern corn borers by evaluating the dispersal of native moths into two Bt-corn fields and by releasing marked moths and trapping for recapture. During the first season of the experiment, first flight European and southwestern corn borer moths were evenly distributed across both fields. Since these moths had to fly into the test fields from surrounding fields, this suggests both species fly extensively during the first flight. oil soluble red and blue dyes (Sudan Red TB and Solvent Blue 35) were added to larval diets to mark moths that were released into the two cornfields. Thirty-nine pairs of European and southwestern corn borer pheromone traps and 22 blacklight traps were installed in the two release fields. Another 3 pairs of pheromone traps were installed around neighboring cornfields. European corn borer moth recapture was 3 and 5% for the early season release and 10 and 6% for the late season release in the two fields. The southwestern corn borer moth recapture was 13 and 26 % for a late season release in the two fields. More males then females of both European and southwestern corn borer were recaptured and males were recaptured at the greater distances away from the release sites. The blacklight traps captured more European corn borer moths, but the pheromone traps caught more southwestern corn borer moths. Both European and southwestern corn borers were recaptured at 1200 ft and in the neighboring fields. During the first season of the experiment, the dispersal patterns for European and southwestern corn borers appeared to be similar, but the European corn borer moths appeared to have more affinity for areas with high moisture or humidity. The trapping locations with the high catches of European corn borers seldom had high catches of southwestern corn borers.

Index terms: Ostrinia nubilalis, Diatraea grandiosella, resistance management, Bt-corn, maize

[0912] BIOLOGY OF THE LEAF GALL MAKER NEOTRIOZA TAVARESI IN STRAWBERRY GUAVA TREE

C. A. Butignol¹ & J. H. Pedrosa-Macedo², ¹ Dep. Entomologia, CCA, UFSC, in course at Dep. Zoologia, SCB, UFPR. P. O. Box 19020, CEP 81531-990, Curitiba – PR – BR. Email: butignol@garoupa. bio.ufpr.br. ² Dep. de Ciências Florestais, SCA, UFPR. Ave. Pref. Lotário Meissner 3400, CEP 80210-170, Curitiba – PR – BR. E-mail: johpema@netoar.com.br

Biology studies of insect species are crucial for acquiring knowledge about the most important events of its life cycle. In Piraquara municipality, state of Paraná, in the south of Brazil, a field study was conducted to determine the life cycle of Neotrioza tavaresi Crawford, 1925 (Hemiptera: Psyllidae), a leaf gall maker in strawberry guava trees (Psidium cattleianum, Myrtaceae). Three (3) cycles were observed (1997, 1998, 1999) in regular field trips in which 50 infested leaves were sampled. Laboratory analyses (dissection) were performed in the galls. It is a univoltine cycle in which adult individuals are found inside the galls from the month August onwards. After month 1 the sexually mature insects with sex ratio 1, leave the galls as it cracks open. The gall cracking is caused by adult insects as they feed on its walls. The release starts in October and ends in the second half of December, having its peak in November. Copulation takes place as soon as they exit the gall and egglaying starts the next day. Females have more than 100 ovarioles containing 217.4 ± 47.5 (n=30) fully formed eggs. This indicates the short sexual adult life-span (aprox. 1 week) of the species, also characterized by a concentrated oviposition. Adult individuals feed and lay their eggs on the shoots of the plant. The bottom of the yellowish eggs are inserted into the leaf tissue, markedly on its adaxial edge. The nymphs hatch and, as they feed on the adaxial side of expanding leaves, change the cell growth. This process starts with the lyse and proceeds with the sinking of the nymphs towards the leaf blade and the round-shape galls develop on the adaxial side. The nymphs go through 5 instars, the first being inside the leaf blade, whereas the others within the gall. The exuviae are stuck on a ball of wax inside the gall. The findings suggest that insect and plant life cycles are closely connected and both shooting and gall opening seem to be triggered by the same conditions. The presence of large numbers of shoots in their early stages of growth favor insect performance as adult individuals can easily find an ideal place for feeding, copulation and laying eggs.

Index terms: Psyllidae, life cycle, Psidium cattleianum.

[0913] PREFERENCES OF LEAF GALL MAKER NEOTRIOZA TAVARESI IN DIFFERENT SHOOTING STAGES OF THE STRAWBERRY GUAVA TREE

C. A. Butignol¹ & J. H. Pedrosa-Macedo², ¹ Dep. Entomologia, CCA, UFSC, in course at Dep. Zoologia, SCB, UFPR. P. O. Box 19020, CEP 81531-990, Curitiba – PR – BR. E-mail: butignol@garoupa. bio.ufpr.br. ² Dep. de Ciências Florestais, SCA, UFPR. Ave. Pref. Lotário Meissner 3400, CEP 80210-170, Curitiba – PR – BR. E-mail: johpema@netpar.com.br

Gall makers require specific developmental stages of the host's tissue in order to succeed. A confinement test was used to determine the most favorable stages for Neotrioza tavaresi Crawford, 1925 (Hemiptera: Psyllidae), to establish itself in the leaf of strawberry guava (Psidium cattleianum Sabine, Myrtaceae) and to develop a gall. This test was conducted with 32 trees (1.5 - 2.5m high) in the municipality of Colombo, state of Paraná in the southern of Brazil (22°25'S, 49°14'W, 945m above sea level). The shoots were mapped and rated with the aid of a scale in wich 0 (zero) corresponds to swelling buds; Ito sprouting with the leaves attached to themselves; 2 to deployed leaves; 3 to internodal distance; 4 to attached apical leaves and 5 to opened young leaves. Twenty insects (10 males and 10 females) released by galls were placed in metalassé bags for 5 days on the branches of each tree in November 4^{th} and 11^{th} , 1997, respectively. The percentage of the different shooting stages and of infested shoots differed significantly as reflected by the Chi-square test (X2=51.8, n=4, P<0.0001), showing that the insects' offsprings chose the shoots in which to establish themselves. The number of branches containing galls was larger in stages 2 (0.31±0.127) and 3 (0.36±0.119), both being at the same statistical level, as demonstrated by the grouping of averages according to their confidence intervals. The number of galls and adult specimens per leaf was larger in the stage 3 (0.92±0.03), the most favorable to the development of psyllids. Stage 5 showed absence of such insects. Index terms: Psyllidae, Psidium cattleianum, stages for infestation.

[0914] PREDICTING MEAN DISPERSAL DISTANCE OF POPULATIONS USING CORRELATED RANDOM WALK EQUATIONS RESOLVED BY SIMULATION

J. A. Byers, Dept. Plant Protection, Swedish University of Agricultural, Sciences SE 230 53 Alnarp, Sweden.

Animal movement and dispersal can be described as a correlated random walk dependent on three parameters: number of steps, step size, and distribution of random turning angles. The mean dispersal distance (MDD) of a population from a source (e.g. bark beetles flying from a brood tree) can be predicted by simulations using the parameters with realistic values. Equations of Kareiva and Shigesada (1983) use the parameters to predict the mean square dispersal distance (MSDD). However, the MSDD is less meaningful than the MDD about which the population would be distributed. I found that the MDD can be estimated by multiplying the square root of the MSDD by a three-dimensional surface correction factor found from simulations. The correction factors ranged from 0.89 to 1 depending on the number of steps and the variation in random turns, expressed as the standard deviation (SD) of the turning angles about 0° (straight ahead). Another equation (Bovet and Benhamou 1988) finds the MDD directly, and this agreed with the MDD obtained by simulation at most SD of turning angles. However, their equation has a significant error that increases as a power function when the SD of turning angles becomes smaller (e.g. $< 6^{\circ}$ at 1000 steps, or $< 13^{\circ}$ at 250 steps). Solutions to the other three variables in their equation are presented. Predicted values of MDD for various organisms (butterflies, ants, and beetles from literature) and the nematode Steinementa carpocapsae (Weiser) are calculated. The coefficient of variation (CV) in the distribution of dispersal distances of a population varied from 0 to 51% as a sigmoidal logistic function of an increase in the variation of turning angles. The CV of dispersal distances also was related to the number of steps as non-sigmoidal Gompertz curves. Equivalent values of AMT (angle of maximum turn) in uniform random models and of SD in normal random models were found that allowed these two models to yield similar MDD values. The step size and turning angle variation of animal paths during dispersal and hostand mate searching are correlated, thus, use of different measured step sizes gives consistent estimates of the MDD.

Index terms: bark beetle, Scolytidae, Coleoptera, dispersion, host selection, mate search, nematode, Steinernema carpocapsae

[0915] DOES GALLING AND FOLIVOROUS INSECTS SUPPORT THE RESOURCE CONCENTRATION HYPOTHESIS? THE CASE OF SCHINUS POLYGAMUS (ANACARDIACEAE)

P.P. Caballero¹ & II. Lorini², ¹Laboratorio de Química Ecológica, Departamento de Ciencias Ecológicas Universidad de Chile, P.O. Box 653, Santiago, Chile. E-mail paulac@abulafia.ciencias.uchile.cl ²Universidad Mayor de San Andrés, La Paz, Bolivia.

The resource concentration hypothesis states that the concentration and/or dispersion of host resources has a direct influence on herbivore insect populations. Plant consumers tend to concentrate at places in which plant resources are abundant and easy to find. We studied the case of Schinus polygamus, a polymorphic evergreen shrub, with high to low aggregated distribution that shows high levels of attack by different herbivorous insects. In 21 patches with different levels of aggregation, we measured level of galling and folivory, height of a focal individual, height, coverage and number of neighbouring conspecifics, and distance between the focal individual an each of the conspecifics. Multiple regression results showed no correlation between folivory and any of the variables measured and significant relationships between galling level and variables related to aggregation of resources. These differences are discussed in relation to differences in biological features of galling and folivorous species involved, such as size, searching behaviour, flight capacity and different degrees of specialization.

Index terms: concentration of resources, gall makers, folivory insects, specialization

[0916] EFFECT OF LARVAL DIETS ON THE SENSIVITY OF ANAGASTA (LEPIDOPTERA, PYRALIDAE) TO MICROWAVES **KUEHNIELLA RADIATION (2.450 MHz)**

F. Cabral¹; G.G. Fagundes¹ & M. E. M. Habib², ¹Dept. of Parasitology, IB, University of Campinas (UNICAMP), SP, 13083-970. Brazil. E-mail fcabral@obelix.unicamp.br. ²Dept. of Zoology, IB, University of Campinas (UNICAMP), SP, 13083-970. Brazil.

The Mediterranean flour moth, Anagasta kuehniella (Zeller, 1879), a world wide distributed pyralid, is well known as one of the most important lepidopterous pests of stored products. Microwaves radiation is being investigated as a promising method for its control. The present study, therefore, was undertaken to evaluate the comparative sensitivity of *A. kuehniella* 3nd instar larvae in three different food treatments, all based on wheat grains, whole meal flour, grain germ and bran. Seven exposure times, to microwaves radiation, were established for each food treatment, and the median lethal exposure time (LET50), was calculated. For each exposition, 100 larvae were utilized and divided in 4 repetitions. A total number of 2100 larvae were utilized during the final tests. The LET₅₀ for larvae which fed on whole meal flour was calculated as 16.59 seconds, with a minimum of 12.37 and a maximum of 28.14 seconds. The grain germ treatment resulted in a LET₅₀ of 15.52 seconds, with an inferior limit of 13.51 and a superior one of 28.14 seconds, without significant differences in relation to those fed on whole meal flour. The larvae which fed on bran, however, showed to be extremely sensitive to the microwaves radiation, since the LET₅₀, in this case was calculated as 2.85 seconds, with an inferior limit of 2.51 and a superior one of 3.23 seconds. Obviously, the deficiency of the bran as a diet was the principal factor responsible for such an exaggerated sensitivity. Researchers of the same laboratory involved in the present study, revealed that the braconid parasite, Bracon hebetor, of the MFM, showed to be highly resistant to the same radiation, since the LET₅₀ was calculated as 106.57 seconds. These results indicate the high efficiency of the microwaves radiation against the 3rd instar larvae of the MFM. Its low cost and safety, could be added to reveal the high possibility to be considered as a and alternative method to control this pyralid pest.

[0917] FORAGING ACTIVITY OF *HETEROTERMES TENUIS* (ISOPTERA: RHINOTERMITIDAE) IN SUGARCANE AREA ACCORDING TO YEAR SEASONS

M.B.S. Campos¹, <u>N. Macedo¹</u> & S. B. Alves², ¹Centro de Ciências Agrárias/UFSCar, Araras, SP. Cx.p.153, CEP 13600-970. E-mail: newmac@cca.ufscar.br.; ² Dep. Entomologia, ESALQ/USP, Piracicaba, SP.

Foraging activity of *Heterotermes tenuis* in sugarcane area during year seasons from Dez/94 to Dez/95 was studied using five types of baits: CF (corrugated fiberboard) + dry sugarcane bagasse ("in natura"); CF + ground maize; CF + dry cowdung; corrugated CF + shredded cellulose and CF (Temitrap^R). Baits were disposed in bundle, four points per local, in five locals previously chosen by termites occurrence, in one hectare area. Fortnightly baits were changed by new baits and the quantity of collected termites were evaluated by a note scale as follows: (0) = absence; (1) = one to ten termites; (2) = ten to hundred termites and (3) = plus than one hundred. Data of the collected insects were correlated with monthly pluviometric precipitation from de region in the studied period and analyzed by χ^2 test. The best baits collecting termites were CF + dry cowdung and CF + ground maize. There were significant differences among seasons in collecting termites and the biggest collects were obtained during de auturn.

Index terms: Heterotermes tenuis, foraging, sugarcane, baits

[0919] POPULATION ECOLOGY OF CORECORIS DENTIVENTRIS (HEMIPTERA; COREIDAE) IN AN EXPERIMENTAL PLOT OF NICOTIANA TABACUM (SOLANACEAE): SEASONAL FLUCTUATIONS, MORTALITY AND PARASITIZATION

C. R. Canto-Silva¹ & H. P. Romanowski¹, ¹Depart. de Zoologia, Inst. de Biociências, Univ. Federal do Rio Grande do Sul, Av. Paulo Gama, s/n, Porto Alegre, RS, Brasil, Cep. 90046-900. E-mail: coreco@zaz.com.br

The study of the population ecology of insects competitors with man is fundamental for the development of technics management and control for its populations. In addition, agroecosystems, with their lower level of complexity, provide appropriate sites for studies on predation and parasitism to be carried out. Nicotiana tabacum is a major crop to export in Rio Grande do Sul, Brazil. The tobacco-leaf-bug, Corecoris dentiventris (Hemiptera; Coreidae) is associated to tobacco crops, causing rolling and wilting of the leaves. Its temporal dynamics, mortality in the immature phases and egg parasitization were studied in an experimental plot of *N. tabacum* at Porto Alegre (30° 05'S and 51° 13'W), RS. Twenty plants were sampled in 31 sampling occasions, from November 1996 to March 1997. In each occasion, the number of individuals in each stadium was registered. Mortalitality per instar was estimated by the difference population peaks in successive instars. Parasitized eggs show a typical colour pattern: parasitization was assessed by their relative frequence. Two generations occurr during the cycle of the crop, there being overlap of the various developmental stages within each generation. Mean mortality rates were 93.6% on the first generation and 99.8% on the second. In both generations, mortality was more intense in 1^{m} to 3^{nd} instar nymphs and eggs. Intense attack by Reduviidae (Hemiptera) was observed in the field. Mean parasitization rate was lower in the first generation (8.9%) than in the second (36.2%). There was a marked variation in mortality and parasitization rates between plants, suggesting an important role for the spatial distribution of these populations on these processes.

Index terms: tobacco, tobacco-leaf-bug, population dynamics, immature mortality, egg parasitization.

[0918] EARLY-MID SUCCESSIONAL TROPHIC PATTERNS IN AN ARTHROPOD COMMUNITY OF SAVANNA ECOSYSTEMS

<u>R. Candia¹</u> & L. Bulla¹, ¹Instituto de Zoología Tropical, Facultad de Ciencias, Univ. Central de Venezuela. Apdo. Postal 47058, Los Chaguaramos 1041-A, Caracas, Venezuela. rcandia@strix.ciens.ucv.ve & Ibulla@strix.ciens.ucv.ve

Most of the central region of Venezuela between the coastal range and the Orinoco river is covered by Trachypogon spp. savannas. These areas are extensively used for agricultural purposes, specially the production of rice, maize, sorghum, and other industrial grains. Large areas are cultivated only for a short period (1-3 years) and left abandoned. The later evolution of these fields and the process of recovery of the original savanna have seldom been studied. In this study we analyzed the changes that took place both in the vegetation and its associated insect community during a 9-year period in old fields, formerly used for sorghum (Sorghum bicolor) production. In this paper we will present the changes in trophic structure of the arthropod community. Arthropods were divided into five groups (herbivores, predators, parasitoids, saprophytes, and omnivores) and their biomass, richness, and abundance were estimated in a sorghum plot, 4 fallow (successional) plots of 1, 3, 6, and 9 years old, and 4 natural savannas of T. plumosus used as a baseline for the estimation of the changes observed in the other areas. Arthropods were captured by 1000 sweeps in each plot. The relation between species number and abundance from a total of 776 species and 78,510 individuals, respectively, was herbivores 459:52,570, predators 120:11,524, parasitoids 140:5,261, saprophytes 46:1,139, and omnivores (all Formicidae) 11:8,016. In terms of biomass (dry weight), herbivores were dominant (85,3%), followed by predators (8,8%), saprophytes (2,7%), omnivores (2,4%), and parasitoids (0,8%). As a rule, successional areas had higher biomass, richness, and abundance in all trophic groups than the natural savannas. During the succession, these three attributes decreased only for parasitoids. Also, the richness of herbivores and predators increased up to the 6-year period, but abruptly decreased in the last period. However, their abundance and biomass decreased during the succession. Saprophyte richness, on the contrary, decreased during the succession but its abundance and biomass increased. Omnivore richness remained the same but its abundance and biomass increased up to the 6-year period and abruptly decreased in the last period. In general, and only if we consider the two extreme successional periods, all three attributes decreased as the succession advanced. All trophic groups (except omnivores) showed a significant positive correlation with vegetation cover, green biomass, richness, and percentage of annual plants. After 9 years of succession, the system seems to be far from complete recovery. Floristic and faunistic species composition still differs significantly from the natural area and we believe a much longer recovery time will be necessary to cancel the effects of human intervention in this system. Index terms: succession, savanna, fallow, trophic groups, Trachypogon sp.

[0920] INFLUENCE OF PHOSPHATE-POTASSIC FERTILIZATION ON THE OCCURRENCE THE NATURAL ENEMIES ASSOCIATED TO SOYBEAN

A.M.Cardoso¹, F.J. Cividanes¹ & W. Natale², ¹Depto. de Fitossanidade, ²Depto. de Solos e Adubos, FCAV-UNESP, Via de acesso Prof. Paulo Donato Castellane, s/n - CEP 14870-000, Jaboticabal, SP - Brasil. E-mail: <amcardoso@zaz.com.br>

This study was developed in the experimental area of the São Paulo State University, Jaboticabal Campus, SP, and its objective was to determine the effect of phosphate-potassium manuring on the occurrence of soybean natural enemies. The levels of phosphorus and potassium tested were, respectively: 0, 80, 120 and 160 kg/ ha of P2O3 and 0, 40, 60 and 80 kg/ ha of K2O. The insect population survey was carried out on a weekly, basis using sweep net and ground cloth as sampling tools. Nutritional aspect of the soil fertility was assessed through analysis of soil collected on harvest day. The highest abundance of natural enemies was observed in the following manuring conditions: Nabis sp., at the potassium level enlargement with absence of phosphate; Geocoris sp., in largest potassium level and intermediate phosphate level; Doru sp., in the largest potassium level and phosphate intermediate level; Cycloneda sanguinea in the potassium intermediate level with absence of phosphate. The lowest abundance of natural enemies occurred in the following manuring conditions: Nabis sp., at the increasing of potassium level and phosphate largest level; Geocoris sp., in the phosphate intermediate level and absence of potassium; Doru sp., in the lowest potassium level and intermediate phosphate level; C. sanguinea, in the largest phosphate level and intermediate potassium level. The occurrence of Lebia sp. did not show evident influence from the phosphate-potassium manuring. Lebia sp. and Doru sp. presented positive correlation's with magnesium and organic matter in the soil, respectively; C. sanguinea and Nabis sp., presented negative correlation's with potassium and phosphate levels in the soil, respectively.

Index terms: Nabis sp., Geocoris sp., Doru sp., Cycloneda sanguinea, Lebia sp; ecology.

[0921] BIOECOLOGICAL STUDIES OF RUSSIAN WHEAT APHID IN ARGENTINA AND CHILE

<u>A.M.Castrol</u>, A.A. Clúa¹, B.B. Bellone², L.B. Almaraz², D.O. Giménez¹ & H.O. Chidichimo², ³, ¹ Dept. of Biology and Ecology and ² Dept. of Production, Fac. of Agronomy, Univ. Nac. La Plata, CC 31, 1900-La Plata, Argentina,³ CICBA ameastro@isis.unlp.edu.ar

RWA (Diuraphis noxia, Morvk.) was first reported in Chile in 1988 close to the Pacific Ocean and in Mendoza, Argentina in 1990. Four years later the RWA reached the Atlantic coast and spread northward and eastward infesting barley, bread and pasta wheat. There was none further report of RWA distribution and population dynamics in both countries, information of great value in terms of pest management. Since 1995 five recollections have been made to determine the presence of RWA. In Argentina, RWA is distributed between 26° 50' SL to 43° 28' SL. The presence of that aphid is remarkable from the isothermal of 20-22°C and the isohiet of 400-600 mm to the isohiet of 2000 mm. In Chile, RWA was found from Osorno (38° 13') to Temuco (38° 20') in the isothermal of 8-10°C and from the isohiet of 1000 mm to the isohiet of 2000 mm. In later spring had a poor presence in the Central Valley and resulted abundant from the 1000 m of altitude compared to the sea level. The most austral RWA population was collected in Teka and the most meridional was found in Tucuman. Conversely to the distribution of this dangerous pest in USA, RWA was found in regions with 2000 mm of rainfall, meanwhile in North America it was not found farthest than the isohiet of 750-1000 mm. The aphids collected showed a wide range of host preference (rye, barley, poa, Bromus, Hordeum spp., wheat) . This pest was first found infesting oats and in low latitudes preferred Sorghum halepensis. Highly variability was found in five isozyme systems between and within populations. The RWA breeding system was studied under natural conditions in La Plata (36° 36' SL, 57° 44' WL). Aphid populations and 10 derived clones of every population were reared on susceptible hosts form March to December under uncontrolled conditions during four years. Only 20% of RWA clones induced sexuals irrespective of the host where they were collected, the period of the year or the region of collection. Probably the air temperature and the shortest daylength in La Plata are not enough extreme conditions for RWA requirements.

Index terms: RWA, *Diuraphis noxia*, distribution, host range, genetic variability, breeding system

[0922] INFLUENCE OF PHOSPHATE-POTASSIC FERTILIZATION ON THE OCCURRENCE OF SOYBEAN INSECT PESTS

<u>A.M.Cardosof</u>, FJ. Cividanes¹ & W. Natale², ¹Depto. de Fitossanidade, ²Depto. de Solos e Adubos, FCAV-UNESP, Via de acesso Prof. Paulo Donato Castellane, s/n - CEP 14870-000, Jaboticabal, SP - Brasil. E-mail: <ameardoso@zaz.com.br>

This study was developed in the experimental area of the São Paulo State University, Jaboticabal Campus, SP, and its objective was to determine the effect of phosphatepotassium manuring on the occurrence of soybean insect pests. The levels of phosphorus and potassium tested were, respectively: 0, 80, 120 and 160 kg/ ha of P2O3 and 0, 40, 60 and 80 kg/ ha of K_cO. The insect population survey was carried out on a weekly, basis using sweep net and ground cloth as sampling tools. Nutritional aspect of the soil fertility was assessed through analysis of soil collected on harvest day. The highest abundance of insect pest was observed in the following manuring conditions: Diabrotica speciosa, in the largest phosphate and potassium levels; Piezodorus guildinii, in the largest phosphate level and without potassium; Cerotoma sp., without potassium manuring and intermediate phosphate level; Anticarsia gemmatalis, in intermediate phosphate-potassium levels. The lowest abundance of insect pest occurred in the following manuring conditions: D. speciesa, in the largest phosphate level and lowest potassium level; P. guildinii, without phosphate-potassium manuring; Cerctoma sp., without phosphate-potassium manuring: A. gemmatalis, intermediate potassium dose and absence of phosphate. P. guildinii presented positive correlation's with calcium and phosphate levels in the soil while Cerotoma sp., presented positive correlation's with calcium levels.

Index terms: Diabrotica speciosa, Piezodorus guildinii, Cerotoma sp., Anticarsia gemmatalis, ecology.

[0923] GENERAL PRINCIPLES OF INSECT MORTALITY DYNAMICS

I. R. Carev, Department of Entomology, Univ. of California, Davis, CA 95616, USA. Email: ircarev@ucdavis.edu.

In this paper I will provide an overview of the mortality dynamics of insects focusing on: (1) principles derived from the results of large scale life table studies on the Mediterranean fruit fly (*Ceratitis capitata*) including slowing of mortality at older ages, mortality crossovers, costs of reproduction, density effects, two-mode aging rates, life span indeterminacy, and subdetectable mortality; and (2) comparative demography of adult insect longevity including between- and within-order comparisons and hypotheses on the environmental and social factors that favor the evolution of extended longevity—resourcebased factors (uncertainty and scarcity) and kin-based factors (parental care; monogamy and eusociality).

[0924] HOW THE NUTRITION OF SPRUCE BUDWORM PARENTS INFLUENCES THE OFFSPRING

N. Carisey & É. Bauce, Département des Sciences du Bois et de la Forêt, Faculté de Foresterie et de Géomatique, Université Laval, Ste-Foy, Québec, G1K 7P4 CANADA, Enail nathalie.carisey@sbf.ulaval.ca.

Spruce budworm (SBW), Choristoneura fumiferana is the most important defoliator of the boreal forest in North America. SBW feeding lasts from mid-May to carly July. In August, the newly-hatched first-instar larvae build an hibernaculum, moult into second instar and enters diapause which lasts eight months until the next Spring without any feeding activity. Energy reserves of diapausing larvae come exclusively from their parents and thus might be strongly influenced by the parent nutrition. In laboratory, SBW larvae were fed with four different diets - various nitrogen and total soluble sugar concentrations found in balsam fir foliages -, moths were mated and offspring performance was determined. Although females from the different diets had similar pupal weight, those fed diet poor in nitrogen and total soluble sugars (PNS) laid 22% less eggs than those fed diet with medium nitrogen and total soluble sugar concentrations (MNS). The hatching rate of eggs from MNS parents was 28% higher than that of eggs from PNS parents. The firstinstar mortality was much higher when parents were fed PNS. Quantities of energy reserves (triglycerids and glycogen) in offspring were similar whatever diet the parents ate and could not explain results on hatching and first-instar mortality. Some other autritional dependant factors have to be elucidated. Offspring mortality from second instar to pupae was higher when parents ate rich nutritive diet than when they ate poor quality food. These results suggest that food quality could induce a selective pressure that could allow spruce budworm to adapt its fitness as outbreak progresses and foliage quality decreases

Index terms : Choristoneura fumiferana, food quality, selective pressure

[0925] LOSS OF TENEBRIONID DIVERSITY IN MEDITERRANEAN ISLANDS AS INDICATOR OF ENVIROMENTAL DEGRADATION (COLEOPTERA TENEBRIONIDAE)

M. C. Cartagena & <u>E. Galante¹</u>, lCentro Iberoamericano de la Biodiversidad. Univ. of Alicante. P.O. Box 99. E-03080 Alicante, Spain. E-mail: galante@carn.ua.es.

The Mediterranean ecosystems, mainly coastal and insular areas, are suffering in the last decades an incessant human pressure that causes a great degradation of those environments. Arthropods are generally used to monitor environmental degradation or to be protected areas. The insular ecosystems have animal populations vanishing to extreme conditions. Moreover, factors such as the population density and demographic structure, and also distribution and abundance of resources, change dramatically when compared with continental situations. Islands are natural laboratories: small, isolated and with relatively simple processes compared to continental situations. Their study is also appropriate because their faunas appear to be more sensitive to environmental changes and more prone to extinction than continental ones. The study of the entomological fauna of these ecosystems, and specially the study of typical land insects as tenebrionid coleopterous, frequently wingless and with limited dispersal abilities, is very important in order to know the environmental conservation. Also this group of insects has a great value in the biogeographical studies, and also as indicators of faunistic relationships among many insular areas. The vulnerability of small insular ecosystems and the tourist pressure along the whole Mediterranean coast conducted us to undertake investigations for detecting their current conservation status and preservation of biodiversity. According to these subjects, we carried out the study of Coleoptera Tenebrionidae fauna, in insular environments from eastern Iberian Peninsula to evaluate the tenebrionid populations and to analyze the changes occurred in the last years.

Index terms: coleoptera, insular ecosystem, conservation

[0926] COMPARATIVE BIOLOGY OF URBANUS PROTEUS (LEPIDOPTERA: HESPERIIDAE) IN CENTROSEMA PUBESCENS, CLITORIA FAIRCHILDIANA, GLYCINE MAX AND PHASEOLUS VULGARIS (LEGUMINOSAE)

A. G. Carvalho¹ & M. R. Silva¹, ¹Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: acacio@ufrrj.br.

This work had as finality the comparative study of the major biological aspects of the Urbanus proteus defoliate species (Lepidoptera, Hesperiidae) through the use of natural feeding based on leaves of the following leguminosae: Centrosema pubescens, Clitoria fairchildiana, Glycine max and Phaseolus vulgaris, in laboratory. The period of the egg's incubation was of about five days. Through the taking of the cephalic capsules, it was verified the occurrence of five larval instars for each of the four kinds of feeding used. The caterpillars feeded with leaves of the C. pubescens presented the biggest average duration in the larval period followed by the ones feeded with C. fairchildiana, G. max and P. vulgaris, respectively. The leguninosae, which provided the biggest weight gain to the caterpillars in the respective larval instars, were: P. vulgaris, in the second and C. fairchildiana, in the third, fourth and fifth instars. The prepupas originating from the caterpillars feeded with leaves of C. pubescens presented higher average duration than the ones feeded with C. fairchildiana, P. vulgaris and G. max. The pupas arising from caterpillars which were feeded with leaves of C. fairchildiana presented higher average weight than the ones feeded with leaves of C. pubescens, G. max and P. vulgaris. The adults which presented bigger average longevity were the ones originating from caterpillars feeded on leaves of C. pubescens, followed by C. fairchildiana, P. vulgaris and G. max, respectively. The females originated from the caterpillars feeded with leaves of G. max presented bigger average number of ovules per virgin female, followed by the ones originated from the caterpillars feeded on leaves of C. fairchildiana, C. pubescens and P. vulgaris, respectively. The individuals feeded with leaves of C. pubescens presented average duration of the life cycle higher than the individuals feeded with leaves of C. fairchildiana, G. max and P. vulgaris. The preference test showed that the U. proteus caterpillars preferred the leaves of C. fairchildiana, followed by the ones of C. pubescens, P. vulgaris and G. max, respectively. The kind of feeding used did not influence in the number of larval instars. There was no mortality of the U. proteus caterpillars due to the kind of leguminosae used in the feeding. The U. proteus species completed the life cycle the four kinds of leguminosae used as food. Index term: Defoliate.

[0927] 2REVIEW OF *CHALCOLEPIDIUS* (ELATERIDAE, AGRYPNINAE, HEMIRHIPINI)

S.A. Casari, Museu de Zoologia da Universidade de São Paulo, Caixa Postal 42 694, 04299-970 São Paulo, SP, Brasil. E-mail: casari@pop.usp.br.

The tribe Hemirhipini includes 26 genera and about 400 species worldwide distributed. The generic revision, with a cladistic analysis, was published in 1994 (Casari-Chen). This work revealed that several species were not congeneric and the revision of some genera to specific level were required. The study of six genera were published, and that of Chalcolepidius Eschscholtz, 1829 is now presented. The Chalcolepidius are recognized especially by integument clothed with colorful scale-like setae, scutellum "triangular" or folded and borders of mesosternal cavity horizontal without suture at base. It was established for four species from Elater, E. porcatus F., E. striatus F., E. sulcatus F. and E. virens F., and three new species, C. limbatus, C. smaragdulus and C. zonatus. Next, several species were described, always based only on the coloration of scale-like setae and shapes of scutellum and 3rd antennal segment. The only revision of this genus is that of Candèze (1857), who presented also a catalogue in 1891 and published several new species. At that time the genus was formed by 33 species, but later many species were described, totalizing 88, with about 160 nominal species. During this work, 8,750 specimens belonging to 85 valid species, including 55 types, were studied. Three species were not examined because the types were not located and any material corresponding to original description was found. For each studied species, a colored picture was taken and the antennae of male and female, pronotum, scutellum, borders of mesosternal cavity, fore leg of male and genital segments and genitalia of male and female were illustrated. The analysis of these characters, together with the pubescence coloration were useful to define the species, now redescribed. The analysis revealed that three species, C. alici Pjatakowa, C. haroldi Candèze and C. unicus Fleutiaux, are not congeneric and should be tranferred to Alaus, 36 species are synonyms, one was revalidate and 11 new species are described. The genus is now composed by 64 species.

Index terms: Coleoptera, Elateridae, systematics.

[0928] EFFECT OF TOMATO HAIRINESS IN SURVIVAL AND FECUNDITY OF T. URTICAE AND N. CALIFORNICUS [ACARI: TETRANYCHIDAE: PHYTOSEIIDAE]

C. Cédola¹ & N. Sánchez¹, Centro de Estudios Parasitológicos y Vectores (CEPAVE) -Universidad Nacional de La Plata – CONICET. Calle 2 nº 584 (1900) La Plata, Argentina

The tomato is one of the most representative crops in the surrounding areas of La Plata (Buenos Aires, Argentina). This crop is attacked by numerous pests, among which, spider mites, Tetranychus urticae Koch (Acari: Tetranychidae) induce the frequent use of acaricid and frequently place the consumer's health in danger. The predator mite Neoseiulus californicus (McGregor) (Acari: Phytoseiidae) is the most widespread phytoseiid mite associated with spider mites. The interaction between arthropod phytophagous and their natural enemies can be modified by the chemical and physical properties of the plants. The variety and quantity of hairs and glandular trichomes characterize the tomato plant. The objective of this work was to determine the effect of tomato hairiness on the survival and fecundity of Tetranychus urticae and Neoseiulus californicus. Survival and fecundity of both species were estimated on two tomato hybrids having different densities of glandular hairs: Parador (23.67 ± 4.77 hair / 19.63 mm 2) and Fortaleza (48.33 ± 8.21 hair / 19.63 mm2). Experiments were conducted in controlled conditions of temperature, relative humidity and photoperiod (25 ± 1 °, 50-75% and 14:10 (L:D) h, respectively). The survival of the immature stages and the adult of T. urticae was not affected by tomato hairiness but the fecundity was. Fecundity of Turticae was significantly lower in Fortaleza. The survival of the immature stages of N. californicus was negatively affected by the hairiness (56% of the cohort reached maturity on Fortaleza compared to 82% of the cohort on Parador). However, survival and fecundity of adults was not affected by the hairiness. Fecundity of *Turticae* and N.californicus on the tomato was lower than that observed in other hoticultural crops. The tomato plant seems to be a less favorable resource to the establishment of T. urticae - N. californicus system than other horticulture crops. An antibiosis process due to glandular hairs could be, at least in part, the cause of this effect, since it was most strongly seen in the Fortaleza hybrid. These results show the necessity to understand tritrophic interactions before implementing the pest management programs for the control of T. urticae, on the tomato

Index term: Tetranychus urticae, Neoseiulus californicus, tritrophic interactions, tomato.

[0929] LIFE HISTORY AND INUNDATIVE RELEASE OF GREEN LACEWING, MALLADA BASALIS

<u>C. P. Chang</u>, Miaoli District Agricultural Improvement Station, 261 Kuan-Nan Village, Kung-Kuan, 363 Miaoli County, Taiwan.

The Mallda basdlis is a well known natural enemy. A series studies on the life cycle of this insect had been done . The life cycle of this insect is observed in the laboratory. The results of these observations are summarized as follows. The insect completed 10 generation in a year averagedly. The duration of each generation varied with temperature. In average, larval stage and pupal stage look 4.38, 11.83 and 11.92 days, respectively. The life span of female and male adults lasted 70.80 and 76.94 days, respectively. The insect needed 28.13 days to complete a life cycle, In average, it laid 13.72 eggs per day and total of 736.34 eggs could be produced by a female adult. Present experiment was conducted to evaluate the effectiveness of using the predator. During strawberry growing season, the mites were controlled by releasing the eggs or larvae of green lacewing on every plant in a 3-week intervals. As a result, 60 to 90% of kanzawai spider mite population and 50 to 90% of two-spotted spider mite population were suppressed by the predators. This measure not only saved the cost of control to more than US \$233/ha, but also increased 15% of fruit production and 7.7% of first class fruit. Besides, the deformed fruit in the predatorreleasing plots was about 6.1% lower than that chemicals controlling plots. Index terms: life cycle, biological control, evaluation, effectiveness.

[0931] BIOLOGY AND REPRODUCTIVE BEHAVIOR OF CENTRIS RODOPHTHALMA (HYMENOPTERA: ANTHOPHORIDAE)¹

E. Chiappa², R. Bascuñán² & S. Rodriguez³, ¹ Supported by FONDECYT Grant 1971141; ² Fac. of Sciences. Univ. of Playa Ancha, 34-V, Valparaíso, Chile. E-mail echiappa @upa.cl; ³ Lab. of Zoology, Catholic Univ., Valparaíso. boxmail 4059, Valpso., Chile. E-mail srodrigu@ucv.cl.

The genus Centris is a widely distributed group of species of the American continent, largely found it in tropical areas but also in arid zones. Only meager information is available on the biology and reproductive behavior of chilean species of Centris. For three years we have been studying the nesting and reproductive behavior of Centris (Wagenknechtia) rodophthalma Pérez, an endemic bee of III and IV Region of Chile, oligolectic on Adesmia glutinosa, A. pedicellata and Geoffroea decorticans (Fabaceae). Observations was conducted in 3 localities of the IV Region of Chile: Varillar, Andacollito and Hurtado. The bees appeared on the first week of August and adult activity was at a high level until last days of October, the peak of daily activity, both females and males, was between 1100-1200. Females searched for nest sites by flying randomly over the floor, the nests were widely scattered, excavated in earth in horizontal surfaces. Nest entrances located under debris, without turrets, borrows unbranched, slighty round 13-15 mm diameter. entered the soil at 45° angle to a depth of 6-7 cm long, terminated in a 1-3 cells. The cells are similar and characteristic of ground-nesting Centris bees, near the center of the closure there was a spoutlike projection that rose from the center and then bent horizontally. The egg curved, was placed on the center of the provisions, the second instar emerged 14 days later, the predefecant larva commenced the cocoon construction 45 days later and completed it in 4 days, C. rodophthalma was protandreus, males searched for females patrolling at the bushes or they perched, but did not established territories. Without courtship the males quickly mount females; copulations lengh is 75"- 80"; females rejected males frequently. They spend the night in groups of 3-6 individuals in the center of the bushes. In a comparative way with, Thornhill & Alcock, (1983) the mating system of this bee can be classified as scramble competition polygyny. Index terms: Centridini bees, mating behavior, larvae, nests, Chile

[0930] VERTICAL-LOOKING RADAR: A POWERFUL NEW TOOL FOR MONITORING INSECT FLIGHT AT ALTITUDE

J. W. Chapman¹, <u>I. P. Woiwod¹</u>, A.M. Dewar², D. R. Reynolds³, A. D. Smith³ & J. R. Riley³, ¹ IACR Rothamsted, Harpenden, Herts., AL5 2JQ, UK, E-mail Ian.Woiwod@bbsrc.ac.uk; ² IACR Brooms Barn, Higham, Bury St Edmunds, Suffolk, IP28 6NP, UK; ³ NRI Radar Unit, Great Malvern, Worcs., WR14 1LL, UK.

Both current and long-term monitoring of migratory insect populations are desirable for a variety of reasons, including the management of pest species and assessment of the impacts of environmental change. Traditional monitoring strategies, such as the Rothamsted Insect Survey's suction-trap network in the UK, do not provide direct information about insect migration at altitudes greater than their sampling height. Therefore, to supplement the information provided by suction traps a means of remotesensing insects at greater altitudes is needed. The expensive and labour-intensive nature of scanning radar technology has previously constrained its use for long-term monitoring, but the recent development of an inexpensive vertical-looking radar (VLR) has now made routine and long-term radar monitoring a practical proposition. VLR equipment has been in operation on the roof of the Entomology & Nematology Department at Rothamsted, south-east England, since May 1999. Coverage extends vertically from 150 to 1200 m above the radar. The unique analysis capabilities of the VLR allows the body mass of over-flying insects to be estimated, as well as providing measurements of their altitude, aerial density, body alignment, speed and direction of movement. These data can be readily stored on a PC database for subsequent analysis. Comparative analysis of the radar data with insect samples routinely collected by the Rothamsted Insect Survey's suction and light-trap networks, and from balloon-suspended aerial nets, should allow identification of many of the larger insects recorded by the VLR. The operation and capability of the VLR, and also the aerial netting technique used for sampling insects at altitudes of more than 200 m are described. Examples of the results obtained by the VLR, such as patterns of diurnal activity and the effects of meteorological factors on insect flight behaviour are presented.

Index terms: VLR, remote-sensing, aerial density, aerial netting, Rothamsted Insect Survey

[0932] BIOLOGY OF THE GUAVA COTTONY SCALE, *CAPULINIA* SP. NEAR *JABOTICABAE* (HEMIPTERA: ERIOCOCCIDAE) AND PHYSICAL EFFECT OF BARK EXFOLIATIONS OF GUAVA PLANT

D. T. Chirinos⁽¹⁾, F. Geraud-Pouey⁽¹⁾ y G. Romay⁽¹⁾, ¹. Unidad Técnica Fitosanitaria, Facultad de Agronomía, La Universidad del Zulia Apartado 15205, Maracaibo 4005, Zulia, Venezuela. Telefax (58 61) 597113. E-mail: dtchirinos@hotmail.com.

The guava cottony scale, Capulinia sp. near jaboticabae (Hemiptera: Eriococcidae), apparently a new species to science or at least on guava (Psidium guajava) became the most destructive pest in Venezuela since its appearance in 1993. During January-August 1999 studies were conducted on biology of the insect and the physical effect of bark exfoliations on its establishment, survival and development under room conditions utilizing potted guava plants. Duration of development of life cycle stages, discriminated by sex, sex ratio, longevity of adults and fertility were determined. To evaluate the physical effect of bark exfoliations three conditions were included: plants with natural exfoliations, with exfoliations mechanically removed and substituted by artificial simulations (paper napkins) and plants without exfoliantions. Eggs hatched after 8 days. The female undergoes two and the male four nymphal instars. First instar nymphs for both sex lasted 8.48±0.03 days and the second instar took 6.05±0.03 y 4.57±0.02 days for female and males respectively. At the end of the second instar the male forms a cigarshaped cocoon of wax filaments where it remains until adult emergence after undergoing inactive third and fourth instars, lasting 2.04±0.01 and 3.66±0.02 days respectively. After the last moult the tenereal adult remains in the cocoon up to one day until forming a pair of waxy caudal filaments which protrude through the distal opening if the cocoon. Adult longevity was 46.67±0.61 y 1.10±0.01 days for the female and male respectively. The proportion female: Male resulted de 1: 1.27 and the fertility 2511.94±57.20 eggs/female. Due to its greater development and longer feeding time the female might cause most of the damage to the plant. The male only feeds during the first and part of the second nymphal instar. The female's high fertility explain the possibility for developing large populations such as those observed when the insect colonized new areas. The duration of development was little affected by bark exfoliations but survival of first instar nymphs was significantly increased when natural or artificial exfoliations existed (70%, P<0.05) as protected setting sites for feeding. As seen in the field lack of exfoliations could constitute a source of resistance, although insufficient by itself, susceptible to potentate its effect in combination with natural enemies in lowering Capulinia sp. populations. Key words: Coccoidea, host plant, survivorship, life hystory

[0933] LIFE HISTORY OF ACRONICTA RUMICIS REARED ON THE NATURALIZED PLANT, RUMEX OBTUSIFOLIUS AS A HOST PLANT

Y. H. Cho¹, O. S. Kwon² & <u>S. H. Nam¹</u>, ¹Dept. of Biology, Taejon University, 96-3, Yongwun-tong, Tong-gu, Taejon, 300-716, Republic of Korea; ²Dept. of Sericulture and Entomology, National Institute of Agricultural Science and Technology, 61, Seodun-tong, Kwonseon-gu, Suwon, 441-100, Republic of Korea.

This study was conducted to investigate the life history of Acronicta rumicis on its new host plant, Rumex obtusifolius which is a naturalized plant in Korea. Prunus yedoensis as an existing host plant was used for the comparison. The study was started on March 1998 and finished on September 1999. A total of 5 generations was reared in the laboratory. The life history was studied from July to September (65 days), using 100 eggs (second generation) for each host plant. The environmental condition was controlled at 27° C, 70% RH, and 14-hour daytime length. Survivorship of the insect showed no difference on both plants. The life cycle took 37.9 ± 0.57 days on R. obtusifolius, and 43.3 ± 0.82 on P. yedoensis. The larval weight of A. rumicis reared on R. obtusifolius was consistantly higher than those reared on P. yedoensis throughout the life stages. It is suggested that A. rumicis is successfully adapted to the new host plant, R. obtusifolius. Index terms: life cycle, survivorship, naturalized plant.

[0935] ESTIMATION OF THERMAL THRESHOLD AND DEGREE-DAY MODEL FOR PREDICTING THE OCCURRENCE OF THE CABBAGE APHID (HOMOPTERA: APHIDIDAE)

F. J. Cividanes, Depto. de Fitossanidade, UNESP/FCAV, Via de acesso Prof. Paulo D. Castellane, s/n, Jaboticabal, SP, CEP 14884-900, Brazil, E-mail fjcivida@fcav.unesp.br.

The cabbage aphid *Brevicoryne brassicae* (L.) had determined under field conditions the period of nymphal development using cabbage as host plant. It was done in experiments where the calculation of the developmental period for all cohorts were based on the time from larviposition to the date on which the first adults appeared. Hourly temperatures were recorded from the point of first larviposition, summed, and averaged up to the midpoint of the day on which the first adults appeared. Developmental thresholds (Tb) and thermal constants (K) were determined by regressing developmental rate against temperature. The threshold temperature was approximated by the intersection of the regression line with the X axis and the thermal constant was calculated as K = 1/b, the inverse of the line's slope. The thermal requirements and the method used to compute accumulated degree-day allowed realistic predictions of adult emergence.

Index terms: Hemiptera, temperature, Brassica oleracea

[0934] EXPERIMENTAL OBSERVATIONS ON THE OUTBREAK OF INFESTATION BY KNEMIDOKOPTES PILAE (ACARINA: KNEMIDOKOPTIDAE) IN PARROTS (MELOPSITTACUS UNDULATUS)

F.Cianficconi¹, M.Principato² & G.Spinelli¹, ¹ Dipartimento di Biologia Animale ed Ecologia, Università di Perugia, Via Elce di Sotto,06123 Perugia, ITALIA; ² Dipartimento di Scienze Biopatologiche Veterinarie, Via S.Costanzo,4,06100 Perugia,ITALIA.

The mange of parrots caused by Knemidokoptes pilae is a serious infestation, which though withslow course, can lead the bird to death for cachexia. Although it occurs frequently, the factors favouring its outbreak are not well known. The biological behaviour of K. pilae seems to be similar to that of other mites, such as Sarcoptes scabiei in mainmals which determines a deep mange, but contrarily of that mite, it does not seem to be infectious at all. In fact, if parrots affected with serious mange are kept for months in captivity with other healthy birds, the illness does not pass on these ones. On the other hand, it seems inexplicable how the infestation can suddenly rise up in groups of healthy birds. We effected therefore some experimental tests with the aim of trying to understand the factors favouring the outbreak of mange. Two couples of parrots, one of which affected with mange, were placed under conditions of high relative humidity (80% RH), maintained constant by a NaCl saturated liquid and two more couples, one of which affected with mange, were kept at a reduced level of RH (55%). In both cases the temperature was stabilized around 20°C. After 46 days, two of the parrots kept at 80% HR showed the first evident signs of infestation: two small holes in their beaks, under their nasal cavities. After 38 more days the infestation was evident on the limbs showing hyperkeratosis and a tiny hole containing a K. pilae female. Three months later the infestation was clinically evident and the first lesions began to rise up on the wings and on the perianal skin. After such period the experimental was stopped. Throughout the experiment, one of the parrots did not show any sign of illness. The birds kept at low RH (55%) were not infected. This simple experiment shows how the rate of environmental humidity is relevant for the infestation outbreak, though some subjects may turn up particularly resistant. We can also assume that the infestation is maintained quiescent for the presence of nymphal instar of the mite remaining among the feathers and penetrating into the skin only when the conditions of RH become favourable. Index terms: mange, mites, Relative Humidity.

[0936] INTERACTIONS BETWEEN CLIMATE, PASTURE GROWTH AND PARASITES IN DEVELOPMENT OF OUTBREAKS OF AN ACRIDID, PHAULACRIDIUM VITTATUM IN SOUTH-EAST AUSTRALIA

A.D. Clifft¹ & G.L. Baker², ¹ Department of Crop Sciences, University of Sydney, NSW 2006, Australia, E-mail clifta@agric.usyd.edu.au; ² Australian Museum, 6 College St., Sydney, NSW 2000, Australia

The Tablelands of south-castern Australia (600->1200 m) are periodically subject to outbreaks of a complex of acridids, dominated by Phaulacridium vittatum, which infest pasture and horticultural crops. Changes in abundance have been studied over a sequence of 15 seasons and key factors influencing abundance identified. Outbreaks are associated with seasons of below average rainfall which increase both survival and the extent of favourable habitat: survival because parasitism by mermithid nematodes is suppressed under dry conditions and the extent of favourable habitats because dry conditions reduce plant cover promoting establishment of broad leafed weeds, favoured food plants of P. vittation. Dispersal of the into newly created, parasite free, habitats results in a population explosion and consolidation of infestations. During the dry seasonal conditions under which outbreaks occur, competition between grasshoppers and stock for the limited available pasture is maximal. Outbreaks persist until either drought intensifies to the extent where it reduces food plant availability, lowering fecundity, or conversely above average rainfall increases mortality from mermithid nematode parasites. High rainfall also reduces the extent of favourable habitats by creating a thick sward, resulting in competitive displacement of broad leafed weeds by grasses. This physically restricts oviposition and disrupts the hatching of eggs. Chronic infestations persist between outbreaks in areas unfavourable for nematodes such as well drained ridges and disrupted habitats like recently established pastures: cultivation for cropping purposes or to establish pasture was more detrimental to mermithid survival than drought. Long term survival of mernuthids is dependent on maintaining the biodiversity of the acridid fauna where differing phenologies ensure turn-over within hosts under a wide range of seasonal conditions. An understanding of the interactions between climate, pasture and mermithid parasites in determining the abundance of acridids has enabled the prediction of both the onset and collapse of outbreaks, allowing the adoption by landholders of farm management practices that minimise the economic impact of outbreaks.

Index terms: Phaulacridium vittatum, mermithid nematode, weeds, cultivation, drought

[0967] DYNAMICS OF THERMOPREFERENCE IN TRIATOMA SORDIDA

<u>M.J. Corchs</u> & C.R. Lazzari, Lab. de Fisiología de Insectos, Dpto. Biología, Univ. de Buenos Aires, Ciudad Universitaria, 1428, Buenos Aires, Argentina. E-mail: yuli@bg.fcen.uba.ar. Supported by: UNDP/Work Bank/WHO (TDR); CONICET, Univ. de Buenos Aires (Argentina).

Although being ectothermic animals, insects can affect their body temperature and metabolism behaviorally. As a consequence, the active choice for places at particular temperatures can be affected by the physiological state of the animal. The comparison between different species and with the climate in natural habitats, help to comprehend the particular adaptation of a given species to certain ecotopes. Triatomines include more than one hundred species that occupy a diversity of habitats. T. sordida is endemic of the "Cerrado", in Central Brazil and now distributes also throughout the Chaco region and central Argentina. This species is found under bark and hollow trees, and acts as a secondary vector of Chagas disease. We studied the behavior of T. sordida in temperature gradients. Adult bugs were reared in the laboratory at 30°C and fed on live chickens. Two experimental arenas (40 cm length x 12 cm width x 3.5 cm heigth) rest over an aluminum plate. In each arena, a temperature gradient (24°C-32°C) was established by means of an electric heater and a cold-water bath, related to each end of the aluminum plate, respectively. Both, cold and warmth sources were thermostatized at 0.1°C. After feeding, male or female bugs were released inside one arena. The position of the insects was recorded at every 30 minutes during 12 days, by means of a computerized system that controlled a video recorder, connected to an IR-sensitive CCD camera. A LD regime of 12h/12h was superimposed over a constant illumination provided by IR-LEDs that is not perceived by bugs. Results evinced that the thermopreference of T. sordida is not a static phenomenon, but shows both a daily variation and a variation according to nutritional status. Recently fed bugs preferred to stay at 28.5°C. After 12 days without feeding, bugs moved towards ca. 25°C. A relative difference of 1°C in the preference of males and females was maintained along the whole experimental period, females staying at higher temperatures. Both sexes showed a daily rhythm of variation, which amplitude reached about 2-3°C, with a maximum occurring during the second half of the scotophase. Similar patterns have been observed in other triatomines, each species exhibiting a particular amplitude, phase and slope in these dynamic processes. The long-term variation can be ascribed to a mechanism of behavioral regulation of the metabolic rate. The daily pattern could be related with the circadian pattern of activity displayed by each species. Index terms: triatomines, temperature, behavior, Chagas

[0938] LIFE HISTORIES OF EPHEMEROPTERA IN COMECHINGONES MOUNTAIN STREAMS

<u>M. del C. Corigliano</u>,¹, A. Barbosa¹ & L. Belver¹, ¹Depto. de Ciencias Naturales, Universidad Nacional de Rio Cuarto, X5804-BYA Rio Cuarto, Argentina. E-mail: mcorigliano@exa.inrc.edu.ar.

The life histories of four species of Ephemeroptera in streams of the Comechingones mountains (Cordoba, Argentina) have been surveyed. The study area was localized in Piedra Blanca stream where monthly Surber net samples were taken in a stretch of runs and riffles, at 640 m.a.s.l. Hydrological conditions and environmental variables were registered. The first right femur of 30 individuals, from each sample, was measured to carry out a size frequency analysis. The studied species were Baetis sp., Camelobaetidius penai, Tricorythodes popayanicus and Leptohyphes sp. Baetidae species populations were bivoltine with two generations, and early spring emergent generation with slow growth in winter and a second generation with fast growth in summer. Leptohyphidae species populations were multivoltine with a longer winter generation and two or three fast generations in late spring and summer. There were observed differences in body sizes and estimated biomass among studied species. Baetidae species had longer developmental times and larger body sizes than Leptohyphidae species. Population densities were 20 times over the average density values reported in published data from streams of other biomes, while body sizes were smaller. Baetis sp. showed the maximal mean density of \overline{X} : 17629 ind. m ², maximum values were registered during summer. All species, except Camelobaetidius penai, were presented along the year in the study site. Torrential streamflow, with strong rainfalls and scouring floods concentrated in the summer, would determine the selection of species of small size, high density and short life cycles.

Key words: Baetis sp., Camelobaetidius penai, Trichorythodes popayanicus, Leptohyphes sp.

[0939] GROWTH PATTERNS OF INCIPIENT COLONIES OF *COPTOTERMES HAVILANDI* (ISOPTERA, RHINOTHERMITIDAE) INITIATED IN THE LABORATORY FROM SWARMING ALATES

A.M. Costa-Leonardo¹ & R.C. Barsotti¹, ¹Department of Biology, Universidade Estadual Paulista, Av. 24-A, 1515, 13506-900, Rio Claro-SP, Brazil. E-mail: amcl@rc.unesp.br. Financial support: CNPq

Knowledge of the subterranean termite biology is essential for their control in the present days. Biological studies of these termites, in particular those that involve entire colonies, are difficult because of their cryptic habits. In this research we report the analysis of incipient colonies which were initiated from alates of the pest termite Coptotermes havilandi. Fifty two colonies were set up in August of 1997 using alates collected from urban swarming of Rio Claro (22° 21' 49 S, 47° 31' 32 W), S.P., Brazil. A pair of mature alates was placed in each 6 cm diameter plastic Petri dish (22 ml), which contained a moistened matrix of decayed pine sawdust. After 6 months, the colonies were transferred to a 250ml plastic container with the same culturing matrix. After 24 months, it was possible to stablish colony growth patterns and caste investment with the entire census of these 52 colonies. At the time of the census each colony had a pair of live primary reproductives and a total population (workers + soldiers + imatures + reproductives) ranging from 64 to 1164 individuals, with a mean of 345 individuals. The number of workers ranged from 53 to 830, with a mean of 223 per colony. The number of soldiers ranged from 6 to 83 per colony with a mean of 25. The number of soldiers plus presoldiers ranged from 6 to 86, with a mean of 26. The present data show a higher population than our previous records for C. havilandi, which never before exceeded 100 individuals per colony. The results show no linear development in the incipient colonies and indicate the use of more adequate conditions than those from our previous study. We also chose at random, 12 transferred incipient colonies to compare their development with 12 colonies kept in 6 cm diameter Petri dishes. The results showed an influence of the container in the growth of the incipient colonies and a positive correlation between queen weights and nonulation size.

Index terms: termite, young colonies, colony population.

[0940] FORAGING POPULATION ESTIMATES FOR TWO COLONIES OF COPTOTERMES HAVILANDI (ISOPTERA, RHINOTERMITIDAE) USING MARK-RECAPTURE STUDIES

A. M. Costa-Leonardo¹, C. R. R. de Camargo-Dietrich¹, F. C. Leonardo¹ & J. T. Lima¹, ¹Department of Biology, Universidade Estadual Paulista, Av. 24-A, 1515, Bela Vista, Rio Ciaro-SP, 13506-900, Brazil. E-mail: amcl@rc.unesp.br. Financial support: CNPq

Most research of Coptotermes havilandi in Brazil has not focused its foraging ecology and population dynamics. The present study was conducted to provide informations about the foraging biology of this pest termite in an urban area of São Paulo state. A heavy infestation of C. havilandi was found in a building of the Universidade Estadual Paulista (UNESP) located in the town of Rio Claro, SP, Brazil (22°21'49S, 47°31'32W). A triple mark-recapture programe was developed to assess the number of colonies present in the area, their territories and foraging populations. Traps of rolled corrugated cardboard were placed in-ground (around the building), on trees (in front of the building) and above ground (inside the building) to determine the trap stations. Termites collected from these stations were fed with filter paper impregnated with Nile Blue and Neutral Red dyes. A weighted mean model was used to estimate the foraging populations and associated standard error. The results showed two colonies (A and B) in the study site with foraging populations of 575,721±9,330 and 737,545±14,834 respectively. The foraging territory of the colony A (red colony) covered an area of about $395m^2$ and involved two urban trees of Caesalpinia peltophoroides. The foraging territory of the colony B (blue colony) covered an area of approximately 10m2 involving only above ground stations inside the building. Marked termites from colony A were recaptured at a maximum linear distance of 30m from their release point while marked foragers from colony B were recaptured at a maximum linear distance of 6.4m only. The mean of individual worker biomass was calculated by weighing eleven groups of ten individuals each. The mean of worker biomass was 3.6mg in the colony A and 3.7mg in the colony B. Foraging biomass was determined multiplying the mean worker weight by the foraging population. The foraging biomass was estimated at 2.1 kg in the colony A and at 2.7 kg in the colony B. Index terms: subterranean termite, colony sizes, foraging territories.
[0941] CORRIDORS FOR MOVEMENT OF BARK BEETLES IN FOREST LANDSCAPE MOSAICS

<u>R. N. Coulson</u>, Dept. of Entomology, Texas A&M University, College Station, TX 77843-2475, e-mail: r-coulson@tamu.edu

Species movement in landscape mosaics is a topic central to the concept of metapopulation dynamics. It is also a subject of considerable importance to forest management practice directed to reducing impact of pest insects. Human-caused fragmentation and natural disturbances create mosaic patterns where the specific arrangement of component ecosystems can influence species movement thereby enhancing or inhibiting herbivory by insects. In this study our goal was to consider how the spatial arrangement of landscape elements influences species movement and hence impact of the southern pine beetle, *Dendroctonus frontalis* (Coleoptera: Scolytidae) on forests. Our specific objectives were (i) to examine southern pine behavior in a landscape ecological context and (ii) to propose a corridor structure that facilitates movement and serves to link habitat targets and spatially subdivided populations of the insect. We illustrate the relation of spatial heterogeneity and species movement through an examination of SPB behavior in pine forest landscape, a three-dimensional corridor structure is proposed. The rational for the structure is framed in the context of specific behaviors associated with the natural history of the insect: host selection, colonization, dispersal capabilities, and adult longevity.

TO ANTIHERBIVORY COMPOUNDS

C. E. Coviella^{1, 2} & <u>J. T. Trumble</u>¹, ⁽¹⁾Univ. California Riverside. Riverside CA. 92521, U.S.A. john.trumble@ucr.edu, ⁽²⁾Univ. Nacional de Lujan, Argentina.

[0942] EFFECT OF ELEVATED CARBON DIOXIDE ON PLANT ALLOCATION

Some recent papers have predicted that plants grown in elevated CO2 should allocate relatively more resources to carbon-based defenses when compared with plants grown in ambient CO2 levels. Conversely, concentrations of nitrogen-based defenses should decline. We tested this hypothesis using a novel system that allowed us to simultaneously assess allocation to carbon-based and nitrogen-based defenses, relating these results with potential impacts on herbivorous insects. We used transgenic cotton plants incorporating a Bacillus thuringiensis (Bt) gene as well as a near isogenic line without the Bt gene, grown in both ambient (370 ppm) and elevated (900 ppm) CO_2 levels. We selected a split-plot design with CO_2 level as whole plots, and including a 2 x 2 factorial analysis for two levels of nitrogen fertilization and two levels of nitrogen-based defenses. The nitrogenbased compound (the Bt toxin) and the carbon-based compounds in cotton (total phenolics, condensed tannins and gossypol) were analyzed and quantified. We also examined the response of the insect herbivore Spodoptera exigua (Hübner) using foliar bioassays. We found that in the elevated CO2 concentrations expected within the next few decades, cotton plants will allocate more resources to carbon-based defenses and less to nitrogen-based This reduction in nitrogen defenses could be partly compensated for if defenses. additional N is made available. However, use of additional N has both economic and environmental consequences. The performance of the hypothesis and the biological significance of the observed changes in defensive compounds are discussed.

Index terms: Spodoptera exigua, Bacillus thuringiensis, herbivory, carbon dioxide

[0943] INFERRING ACTIVITIES AND POPULATION DENSITY FROM INCIDENTAL SOILBORNE SOUNDS OF WHITE GRUBS

R. L. Crocker¹, **M. Zhang²**, **R. Mankin³**, **K. Flanders⁴**, **R. Hickling⁵**, **P. Lee⁶ & J. Brandhorst-Hubbard⁷**, ^{1, 2}Texas A&M Univ. Res. & Ext. Ctr., 17360 Coit Rd., Dallas, TX 75252-6599 USA; ³Ctr. for Med., Agric., and Vet. Entomol., USDA-ARS, 1700 S. W. 23rd Dr., Gainesville, FL 32608 USA; ^{4, 7}The Alabama Coop. Ext. Serv., 208A Extension Hall, Auburn Univ., Auburn University, AL 36849-5629 USA; ^{5, 6}Nat. Ctr. for Physical Acoustics, Univ. of Mississippi, Coliseum Dr., University, MS 38677 USA.

Studies of soil arthropods often are hampered because the "black-box" nature of the soil environment generally necessitates destructive sampling. This is not compatible with repeated sampling, such as is needed in most long-term studies. This research demonstrated that characteristic incidental sounds were produced in the 300-2000 Hz frequency range by the larval stages (white grubs) of rhizophagous scarabacids (Coleoptera). These sounds are classified as digging, positioning, feeding and internal body sounds, which usually can be separated by a practiced listener or by computerized analysis. The circadian distribution of *Phyllophaga crinita* larvae's sounds were monitored under constant and variable temperatures. Daily levels of activity increased with soil temperature under naturally fluctuating temperatures, but showed no pattern at a constant temperature. The spatial distributions of P. congrua, P. crassissima, P. crinita and *Cyclocephala lurida* larvae in the soil were mapped under field, greenhouse, and laboratory conditions. Single-microphone sound samples were compared with conventional soil-core sampling for measuring larval population densities in turfgrass. Paired-microphone analyses made it possible to estimate the total number and approximate location of larvae in a sampled area. Soil moisture influenced the sensitivity of measurements. Sounds could be detected at greater distances in dry soil. This approach promises to be of considerable value for non-destructive sampling of these and other cryptic organisms.

[0944] WHITEFLY *TRIALEURODES VAPORARIUM* (HEMIPTERA: HOMOPTERA: ALEYRODIADE) COMPARED BIOLOGY IN SOYBEAN AND IN FIVE BEAN CULTIVARS

W. B. Crocomo⁴ & O. R. Campos², ^{1,2} Dept. of Vegetable Production - FCA - UNESP -P. O. Box 237, Botucatu - SP - Brazil, 18603-970, E-mail <wcrocomo@fca.unesp.br >

With the development of the greenhouse crops, the whitefly *Trialeurodes vaporarim* has becoming one of the most important pest. With the objective to verify the host effect on the development of this species was studied its biology on bean cultivars IAC - Carioca Pyatã, IAPAR - 57, Jalo Precoce, IAC- Bico de Ouro, IAC - Maravilha and on soybean cultivar Cristalina. The essay was conducted on the Agriculture Entomology Laboratory - FCA-UNESP, under temperature of 25+/-3°C, relative humidity of 80+/-10% and photophase of 14 hours. The biological parameters assessed were duration, viability and instars number of ninphal stage; male and female longevity, oviposition period, egg number per each female and sex ratio; eggs viability and incubation period and total cycle. With the obtained data were constructed fertility life tables to permit a comparative analysis of the cultivars effects on the biological development and consequent populational growth of this species. The results allowed to conclude that bean cultivars IAC- Maravilha and Jalo Precoce influenced negatively *T. vaporarium* development, whereas, the other bean cultivars studied, as well as the soybean cultivar Cristalina, provided better conditions to this pest development.

Index Terms: whitefly, bean, soybean, Trialeurodes vaporarium

[0945] PRELIMIARY EVIDENCE OF GEOGRAPHIC VARATION IN SOCIAL BEHAVIOUR OF HALICTINE BEES FROM HOKKAIDO, JAPAN

A. L. Cronin & M. Hirata, Graduate School of Environmental Earth Science, Hokkaido University, Sapporo 060 Japan. Email: CroninA@ees.hokudai.ac.jp.

Halictine bees are known for the flexible nature of their social behaviour, such that a single species may exhibit different states of sociality depending on the population studied. Previous studies have elucidated examples of intraspecific variation between populations at different latitudes or altitudes. Studies in Japan have indicated that altitude may be important in governing social behaviour, but studies of geographic variation have been limited. In an ongoing study in Hokkaido, North Japan, the social behaviour of several species of halictine bee was studied at several different locations with differing climates. Initial results indicate that populations may vary between solitary and eusocial behaviour depending on locality. The colder climate in Eastern Hokkaido apparently constrains bees to a solitary lifecycle whereas southern and central populations are eusocial. There is also some suggestion that variation in habitat may be important in influencing some demographic factors in populations from similar regions. Index terms: halictine, geographic variation, social plasticity.

[0947] FLIGHT PERIODICITIES IN MIGRANT MOTHS

W. Danthanarayana¹ & H. Gu², ¹School of Biological Sciences, University of New England, Armidale, NSW 2351, Australia; ²Institute of Plant Sciences, Swiss Fed Inst of Technology, CH-8092 Zurich, Switzerland.

Actograph studies of flight periodicities of moths show that there are diel and lunar rhythms of flight activity. Epiphyas postvittana and Helicoverpa armigera exhibit a diel bimodal periodicity pattern with a primary flight peak 2-3 hours after sunset and a secondary peak 2-4 hours after sunsite. Biological significance of this behaviour is discussed based on visual observations on E. postvittana. Flights initiate at twilight. A number of activity periods follow during which moths are engaged in different behaviours, viz. feeding, calling, mating and oviposition. In individual moths each type of activity occurs in bouts separated by pauses, where the animal is resting or is involved in one of the other activities. During the early part of the night virgin moths are engaged in calling and mating. Much of the egg laying activity occurs from sunset to sunrise. Thus postsunset flights are associated with calling, mating and oviposition whereas post-sunrise flights are associated with feeding. There is a sexual dimorphism in feeding behaviour, possibly a time budgeting adaptation to accommodate oviposition and competing with males. The lunar rhythm of flight activity in E. postvittana has a periodicity of 27 days. The "full moon" peak that occurred one day prior to the exact day of full moon during the first lunar cycle shifted forward by 3-11 days in subsequent cycles, but a periodicity of 27 days was maintained over the next 5 lunar cycles. It is relevant to note that the period of the Moon's revolution around the Earth, referred to as the "siderial month", is 27.32 days. The time between successive full moons, referred to as "syzygies", is a little longer than the siderial period at 29.25 days, which is the duration of the synodic or the lunar month. These observations based on actograph studies of E. postvittana will be compared with those based on radar studies of Helicoverpa armigera.

Index terms: Epiphyas postvittana, Helicoverpa armigera, circadian rhythm, lunar neriodicity

[0946] ALLOMETRIC RELATIONSHIPS BETWEEN BIOMASS, VOLUME AND POPULATION SIZE IN COLONIES OF SOLENOPSIS (HYMENOPTERA: FORMICIDAE) INVICTA

C. G. Dall'Aglio-Holvorcem, P. B. Candiani & W. W. Benson, Departamento de Zoologia, IB, UNICAMP, C.P. 6109, Campinas, SP 13083-970, Brasil. E-mail: chris@obelix.unicamp.br

In population studies of the fire ant, Solenopsis invicta, it is important to be able to estimate the biomass, colony volume, and population size of given ant colonies from measures, such as nest height (h), length (l), and width (w), that can be easily made without disturbing the ants. To this end, we measured the aboveground dimensions of 28 undisturbed S. invicta nests and determined their volumes (V, in liters), ant biomass (M, in grams) and worker numbers (N) after excavation in colonies from Campinas, Brazil

(22°47' S, 47°05' W). Of these, 14 colonies were examined during the rainy season of 1996-7, and the remaining 14 during the rainy season of 1997-8. The quantities h, l, and w were combined into a "volume index" $v = (4\pi/3)h(l/2)(w/2)$ (transformed to liters), and relationships between v, V, M, N sought in pair-wise regressions. The main quantitative results are $V=2.13\nu^{0.86}$ (R^2 =0.93), $M=5.51\nu^{0.82}$ (R^2 =0.59),

 $N = 7710v^{0.79}$ ($R^2 = 0.47$), $N = 1110M^{1.05}$ ($R^2 = 0.95$), suggesting that good to excellent estiates of S. invicta colony parameters can be obtained from simple non-destructive nest measurements. The data show that ant biomass per unit volume (M/V) and the mean biomass per worker (M/N) are essentially independent of the size of the colony. In contrast, an analogous study carried out by W.R. Tschinkel found out that in the southern United States mean S. invicta worker biomass increased with colony size. Index terms: Solenopsis invicta, fire ant, colony size, population density

[0948] ARTHROPOD COLONIZATION RATES OF EXOTIC WOODY SPECIES

T.E. DeGomez¹ & M. R. Wagner¹, ¹School of Forestry, Northern AZ Univ., Box 15018, Flagstaff, AZ, USA, 86011, E-mail: ted3@dana.ucc.nau.edu

Commercial forestry worldwide depends upon the use of exotic tree species because of the benefits that can be gained from improved production. However, the use of exotic trees in plantations has been rife with misconceptions from both supporters and opponents of their use. Many foresters tend to discourage the use of exotics predicting that the exotics would have higher numbers of insect pest species than the native trees. However, there are many examples when exotics have had fewer insect pest problems than natives of similar taxon. This study was a comparison of arthropod species data sets for species of woody plants in their native and exotic range. Data sets comprised 26 pairs of arthropod species lists; the paired data sets consisted of the number of arthropod species in the native range of the plant and a corresponding data set from where the plant grows as an exotic. Plants in the study came from many genera such as: Pinus, Robinia, Abies, Chamaecyparis, Cupressus, Picea, Pseudotsuga, Thuja, Tsuga, Prosopis, Tamarisk, Cytisus, and Schinus. Preliminary results indicate that there is greater arthropod species colonization on woody plants in their native range. We further analyzed whether the number of arthropods are influenced by the time a plant species has been growing in a non-native range, and whether the area of plant cover influences arthropod colonization of the native and the exotic plant species. Index terms: novel, native, insect, tree, shrub,

[0949] REPRODUCTION OF *SITOPHILUS SPP.* (COLEOPTERA: CURCULIONIDAE) ON DIFFERENT WHEAT CULTIVARS

L.R. Descamps¹, M.E. Reviriego¹ & <u>A.A. Suarez</u>², ¹Univ. Nac. Del Sur, San Andrés S/N, (8000) Bahía Blanca, Argentina, e-mail descamps@criba.edu.ar; ²E.E.A.INTA Anguil, Ruta Nac. N°5 Km 580, C.C. 11, (6326) Anguil, La Pampa, Argentina; e-mail asuarez@anguil.inta.gov.ar.

Sitophilus spp. is an important stored-grain pest in the cereal growing aerea of Argentina. The objective of this study was to determine the influence of different wheat cultivars on the insect reproduction. The trial was conducted under controlled conditions of temperature ($25 \pm 2^{\circ}$ C) and relative humidity ($67 \pm 3\%$). The wheat cultivars were: Buck Arrayán, B. Arriero, Klein Cacique, Cooperacion Calquín, B. Candil, B. Catriel, K. Centauro, B. Charráa, K. Dragón, Prointa Federal, B. Guaraní, C. Liquén, C. Maipún, C. Millán, C. Nahuel, C. Nanihue, B. Panadero, Prointa Bonaerense Pericón, B. Poncho, P. Pigué and B. Topacio. A randomized complete block design with four replication was used. Total adults insect born on each cultivar were registered. The data obteined were analyzed using PROC ANOVA and means were compared by MEANS / LSD test (P=0.05) (SAS Institute, 1998). Sitophilus spp. reproduction was significantly affected by wheat cultivars. On wheat cultivars B. Arriero and P. Federal insect reproduction was higher than on C. Millán and C. Nanihue cultivars.

Index terms: Sitophilus spp, stored-grain, reproduction.

[0950] RICHNESS AND ABUNDANCE OF LEPIDOPTERAN CATERPILLARS ASSOCIATED WITH CERRADO PLANTS

I. R. Diniz¹ & H. C. Morais², ¹Depto, de Zoologia, E-mail: ivone@rudah.com.br ²Depto. de Ecologia, Universidade de Brasília, 70910-900, Brasília, DF, Brosil.. * Partial funding from CNPq and FAP-DF.

The cerrado, the savanna-like vegetation of Central Brazil, is characterized by an elevated richness of plant species belonging to a flora that is highly exclusive to this biome. The region also presents a great richness of lepidopteran species with an estimated 10,000 species. This study is being developed, since 1991, in preserved cerrado sensu stricto areas of the Federal District (Brazil) (15°30'S - 47°25 W). The climate is markedly seasonal with five months of dry season (May-Sep). The 4 ha study area was divided into quarters, surveyed in rotation. Fifteen to 20 unmarked plants from each species were examined every week, during at least one year. Each individual of a plant species examined on a particular date was considered to be a census, and the proportion of censuses with caterpillars was used as an indication of caterpillar abundance. All external folivorous caterpillars found were collected and reared to adult stage in the laboratory (450 species belonging to 36 families). We made 30,892 consuses of 40 plant species, yielding a low proportion of plants with caterpillar (10%), but this proportion varied from 0.7 to 34% among the plant species. An average of 19 (range 4 to 53) caterpillar species were found per host plant. The most common families (56% of the species) were Gelechiidae, Elachistidae, Pyralidae, Geometridae, Tortricidae and Arctlidae. Of these species, 80% were found on only one host plant family and 20% on two to 23 families. In general, caterpillars are most abundant at the end of the rainy season and the beginning of the dry season (Mar-June) and are very rare at the end of the dry season (Aug-Sep), when the relative humidity of the air falls to 15%, and at the beginning of the rainy season (Oct-Nov), when most plants sprout new leaves. The plants species vary in relation to their growth shape, foliar phenology, leaf pilosity, presence of latex and extra-floral nectaries, number of taxonomically proximate species and through their geographical distribution Variations in the richness and abundance of caterpillars were within the cerrado. examined in relation to these characteristics for 40 species (20 families) of host plants. The richness and abundance of caterpillars are positively and significantly correlated. The variation in the species richness is not explained by the plant characteristics when examined separately. Local richness of herbivorous insect species has been positively correlated with the size, abundance, number of taxonomically related, and geographical distribution of the host plants in temperate environments and, in some situations, in tropical environments. The preliminary results for the cerrado do not show either of these relationships.

Index terms: Elachistidae, Gelechiidae, Pyralidae, host plants, diet

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[0951] PATTERNS OF INSECT ABUNDANCE IN THE CERRADO OF BRASÍLIA AND THE EFFECT OF CLIMATE

I. R. Diniz¹ & F. Pinheiro², ¹Departamento de zoologia; ²departamento de ecologia, universidade de brasília, 70910 900, df, brazil e-mail: ivone@rudah.com.br. Partial funding from FAP-DF.

In the cerrado, insects present large fluctuations in numbers on a seasonal basis. This variability is primary driven by environmental factors such a rainfall, temperature and relative air humidity. The study was carried out in an area of cerrado (savanna like vegetation), in Central Brazil. The seasonal distribution of the relative diversity and abundance of different insect orders were investigated through systematic surveys with regular collections through the wet and dry seasons, employing the simultaneous use of four sampling techniques: Malaise tent, pit-fall trap, Window interception trap, and sweep net. The monthly averages of rainfall and relative humidity, as well as the maximum, minimum, and mean temperatures were used in four different manners: the month of collection, and delayed in one, two and three months totaling 16 variables. For all analyses, monthly averages of insects were used. Multiple regression analyses explained most of the insect abundance fluctuations by association with climatic parameters and insect numbers. More than 830,000 insects of 16 orders were collected during the one-year period. The results obtained showed large variability among, and within insect orders. However, it is possible to recognize four broad categories of insect order abundance patterns in the cerrado: (1) Greater insect abundance after the first rains: Coleoptera, Diptera, Homoptera, Hymenoptera, Lepidoptera, Orthoptera, and Psocoptera; (2) Greater abundance occurring from the mid-rainy season, until the beginning of the dry season for Collembola; (3) Greater occurrence of the end of the dry season, until the beginning of the rains for Hemiptera; and (4) Greater abundance and/or activity in the dry season for Isoptera and Thysanoptera. Among the more numerous insect orders, 10 presented aggregated temporal distributions, and only Hymenoptera was uniform, with a peak in abundance occurring in November. The number of insects begins to decrease well before the end of the rainy season, but there is an increase in the beginning of the dry season with a strong reduction as the dry season proceeds. In the beginning of the dry season hydric stress is not yet accentuated, the intense decreases in minimum temperatures have not yet occurred and there are young leaves available on some plant species. These facts appear to be important in supporting fauna of superior trophic levels in the region. However, the long dry season appears to be stressful for the majority of insect populations in the cerrado. In the wet season one or more climatic factors may act to trigger activity breaking diapause for the majority of species finding food resources quantitatively and qualitatively modified, thereby allowing for reproduction and survival of young. Index terms: central Brazil, dry season, insect orders, wet season

[0952] PHYLOGEOGRAPHY AND ECOLOGICAL DIVERSIFICATION OF CICINDELA LUSITANICA (CICINDELIDAE: COLEOPTERA)

A. C. Diogo¹, A. R. M. Serrano¹ & A. P. Vogler², ¹Depto. Zoologia e Antropologia and Centro de Biologia Ambiental, Fac. Ciências de Lisboa, Campo Grande, Lisboa, Portugal, E-mail adiogo@fc.ul.pt; ²Department of Entomology, The Natural History Museum, Cromwell Road, London, SW7 5BD, UK.

Cicindela lusitanica is the Portuguese component of C. hybrida Group, one of the most widespread and common taxon of the Palearctic Cicindela (s.str.). The C. hybrida group is represented in Portugal by two endemic subspecies whose distribution is restricted to the stabilised dunes of the Atlantic coastline. Both groups are morphologically different and show a markedly distinct North-South distribution. The goal of this work is to test the causes of this geographic patterns which could be due to selection in the face of ecological (habitat) differences or due to a long history of separation between northern and southern populations. To assess the historical context of these differentiated populations, we analysed the pattern of ntDNA distribution, as a way to reconstruct palaeogeographical events and gene flow in C. lusitanica. Four regions of the mtDNA genome (COI, COIII, 16S and Cytb) were sequenced for a total of 74 individuals belonging to 22 Portuguese populations, 8 representatives of other European populations of C. hybrida group and 4 outgroups. In total 13 haplotypes were detected. Although these haplotypes exhibited low levels of genetic divergence, phylogeographic structuring was apparent, clearly separating the populations in three distinct groups. However, these groups are not consistent with the taxonomic recognised entities. Further, we found that the Portuguese populations represent a group deeply separated from the remainder of the European samples, including populations in Central Europe, Russia and Italy. The phylogeographic patterns are interpreted in the light of hypothesis about past geological and climatic events which night have affected the flora and fauna of the Iberian Peninsula. The distributional range of C. lusitanica coincides with the postulated Pleistocene refugia and thus the analysis of these populations gives insight into the history of the colonization pathways in the Palearctic during the quaternary. A comparative analysis of populations existing under different geological conditions along the Portuguese coastline will permit to analyse the processes of ecological diversification in these populations which apparently have persisted over long time periods.

Index terms: mtDNA, speciation, refugia.

[0953] DEPOSITION OF CORN POLLEN ON MILKWEED AND EXPOSURE RISK TO MONARCH BUTTERFLY LARVAE

G.P. Dively¹, J.E. Foster², G.D. Jones³ & T.L. Clark², ¹Dept. of Entomology, Univ. of Maryland, College Park, MD 20742, USA, Email gd7@umail.umd.edu, ²Dept. of Entomology, Univ. of Nebraska, Lincoln, NE 68516-4729, ³USDA, ARS, APMRU, 2771 F&B Rd., College Station, TX 77845.

Exposure risk to the monarch butterfly depends on the amount of Bt corn pollen that falls on its host plant. To address this risk factor, studies were conducted in 1999 to quantify the pollen deposition on common milkweed associated with corn fields. In corn producing areas in Maryland and Nebraska, 1517 leaves at different strata were removed from 652 milkweed plants associated with 86 fields during full anthesis. Distance from each corn field, plant cluster size, and surrounding habitat type were recorded. Plants also were visually examined for monarch butterfly larvae and feeding injury. Pollen deposits were rinsed from leaves, processed, and counted. Pollen deposition was expressed as the number of pollen grains/cm² of leaf area. No monarch larvae were found feeding on any sampled plant. Only adult butterflies and eggs were seen at the end of the sampling period. This indicates that larval activity did not coincide with corn anthesis in the sampled areas. For the Maryland data, the exponential decay relationship of y=3.82 + 32.36*exp(-x/3.85) provided a significant nonlinear fit of the pollen levels (y) as a function of distance (x). The highest pollen level was found inside and at the edge of fields, where the number of pollen grains averaged 56.2/cm² of leaf area. Pollen deposition dropped 61% (21.8 grains/cm2) within the first 5m from the field edge. Pollen deposition averaged 12.7 grains/cm² within 6-10m from field edge. After 10m, pollen levels averaged 7 grains/cm2 or less, and 42% of the leaf samples had no pollen deposit at all. In the Nebraska study, pollen levels dropped rapidly from the field edge and were significantly less than those recorded in Maryland. The exponential decay relationship of $y=0.32 + 5.44^{4}exp(-x/3.03)$ predicted pollen levels of 6 grains/cm² at the field edge compared to 35 grains/cm² predicted by the Maryland data. Differences in pollen deposition due to weather conditions, wind direction, leaf strata, and patch size are discussed. Although wind can move pollen away from fields, these data clearly show that the relatively large pollen grains settled out very rapidly within a short distance. Given provisional "no effect" levels of <150 pollen grains/cm2 and the frequency of pollen deposits found on milkweed, the majority of leaves are safe to monarch larvae, even those that are found inside corn fields.

Index terms: Danaus plexippus, Asclepias syriaca, Bt corn, monarch butterfly, risk assessment

[0954] MIGRATION OF NORTH AMERICA MONARCHS, DANAUS PLEXIPPUS, TO CUBA

C. Dockx, Dept. of Zoology, University of Florida, 223 Bartram Hall, Fl 32611, USA, Email cdockx@zoo.ufl.edu.

The monarch butterfly from eastern North America is known by its annual migration from northern North America to the Oyamel forest located on the Transverse Neovolcanic Belt in Central Mexico. The migratory butterflies are mainly born in the United States and southern Canada where the host plant of the monarch larvae Asclepias sp. is abundant. After the adults emerge, they move southward as the Asclepias sp. decrease in abundance at the end of the summer. During their travel they feed on nectar that will be transformed in lipids. The migraat monarchs arrive in central Mexico, from October through November. During the approximately four months that these monarchs stay in Mexico, they are reproductivily dormant, living from their lipid reserves. In March these butterflies mate and recolonize the southern United States. In contrast with the extensive study of the migrant monarchs in Mexico alternative migration routes like Cuba, and resident populations of the Caribbean have been poorly studied. My research explores the possibility of a migration of North American monarchs to Cuba and the inclusion of their individuals and their genes into the Caribbean, specifically into the Cuban population. In order to adress this possibility, monarchs were collected in November during four years (93,95,96,97) in three different areas in Cuba. These areas were: San Antonio de los Banos, Zapata Swamp and Guanahacabibes Peninsula. In order to know if the butterflies were Cuban resident or migratory, two techniques were used: thin Layer Chromatography (TLC) and Stable Isotops (carbon and deuterio). The fat content of the butterflies as well their reproductive stage was analized too. The results show that some North American monarchs do not migrate to Mexico, and instead go to Cuba. This migration to Cuba occurred during all the four years of this project. The preliminary isotopic results show that North American monarchs that go to Cuba came from a broad geographical range (especially northern and southern United States), in contrast to the 50% of the monarchs that go to Mexico came from the Midwest. The fat content of the butterflies show that North American monarchs that arrive to Cuba, have only 18 mg of lipids in comparisson to 113 mg of the healthy overwintering monarchs in Mexico.Suggesting that the physiological condition of the butterfly can determine their migratory behavior. Some of these North American monarchs were reproductivily active, suggesting that they can hybridize with resident population and staying in the island without retourning to the United States.

Index terms: monarch butterfly, Caribbean, animal migration.

10955] GREEN LACEWINGS OCCURENCE ON WEEDS IN CROP CORN

H. O. S. Dória¹, N. M. M. S. de Albergaria², R. J. Forreira³, A. T. Murata³ & S. de Freitas¹, ¹²Dept. de Fitossanidade, Fac. Ciências Agrárias e Veterinárias, UNESP, Via de Acesso Prof. Paulo Donato Castellane, s/n, 14884-900, Jaboticabal, SP, Brasil, (¹CNPq Fellowship), (²FAPESP Fellowship), ³Dept. de Biologia, Fac. Filosofia, Ciências e Letras de Ribeirão Preto, Univ. de São Paulo, Av. dos Bandeirantes, 3900, 14040-901, Ribeirão Preto, SP, Brasil, E-mail: murataat@asbite.com.br (FAPESP Fellowship)

This work was carried out to evaluate the influence of weeds in the maintenance of green lacewings populations in the corn crop fields. The trial was led at the Research Farm located Universidade Estadual Paulista, Jaboticabal, SP, Brazil. The weed plants were sampled 16 times with intervals from 3 to 4 days. Each time was evaluated the number of eggs, larvae and pupae of green lacewings on 100 weed plants in a crop of corn field. The results showed that 13.4% of the weed sampled was found crisopids. The weeds sampled that presented insects were: Arachis hypogaea L. (60.28%), Acanthospenum hispidium D. C. (23.83%), Cenchrus echinates (2.34%), Ephorbia hetertophylla (2.34%), Amaranthus deflexus L. (1.87%), Bidens pilosa (1.87%), Portulaca oleracea L. (1.40%), Alternanthera tenellacolla (1.40%), Amaranthus spinosus L. (1.40%), Parthenium hysterophorus L. (0.93%), Amaranthus viridis L. (0.47%), Sida santaremnensis (0.47%), Senna obtusifolia L. (0.47%), Brachiaria plantaginea (0.47%) and Cyperus rotundus L. (0.47%). The iarvae occurence on the weeds was rare, representing just 1.46% and 1.15% in Arachis hypogae and Acanthospenum hispidium respectively. The percentage of plants with coccons was 3.7% and it was found 8.1% of parasitism in green lacewing eggs. Index Terms: Crisopids, Neuroptera, parasitsm.

[0956] BIOLOGICAL ASPECTS, POPULATION DENSITY, DAMAGE RATE AND BEHAVIOR OF THE FRUIT-BORER, CONOTRACHELUS SP. (COLEOPTERA: CURCULIONIDAE) ON CUPUAÇU TREE (THEOBROMA GRANDIFLORUM SCHUM.) IN AMAZONIAN REGION, BRAZIL

J.A.Duarte-Aguilar¹ & A.M.Tavares¹, ¹ Embrapa Amazônia Ocidental – CNPq/DCR, Lab. de Entomologia, Rodovia AM-010, Km 29, C.P. 319, CEP 69011-970, Manaus, AM. E-mail sac@cpaa.embrapa.br, ²Embrapa Amazônia Ocidental, Lab. de Entomologia, Rodovia AM 010, Km 29, C.P. 319, CEP 69011-970, Manaus, AM, E-mail adauto@cpaa.embrapa.br.

The fruit-borer (Conotrachelus sp.) has been causing severe economic damage in the cupuaçu tree plantations (Theobroma grandiflorum Schum.) in the Amazon region. In order to estimate the damage of this pest on fruits production, surveys were carried out in areas nearby Manaus, in plants age six years and over, collecting twenty fruits once a week. In each sample of fruit, the number of holes, where the larvae are going out, were counted, and then opened to quantify the larvae in fruits. Biological and behavioral parameters were studied in laboratory, putting the larvae recently emerged from fruits (last instar) into plastic boxes, using as substrate a mixture made of soil and vermiculite in the proportion of 2:1, sterilized at 160 °C and moistened with distilled water. The cultures were kept at room temperature (27 ± 2 °C), relative humidity (80 ± 10%) and photoperiod of 12:00. The intensity of insects on fruits during February to May 1998 and 1999 were 93% and 66%, respectively. Were also observed that 63%; 24% and 13% of the larvae built up their pupal chambers in the soil at depths of 10, 12 and 15 cm, respectively. The emergence time of adults from the soil was 49 to 80 days, with 81,6% of viability. In areas where the fallen fruits were regularly collected from the ground, the extraction process of the fruit pulp were made in an adequate local, including the destruction of the peels, were observed a notable reduction of the insect density to 27 %. The results show that the cultural control was efficient in the reduction of the population of Conotrachelus. Index terms: Tropical pests, cultural control, injury level

[0957] STUDY OF THE PEST OF AN ORGANIC ONION CROP: THEIR POPULATION'S FLUCTUATION, THEIR SPATIAL DISPERSAL AND THEIR NATURAL ENEMIES

<u>A. C. Dughetti</u>, National Institute Technology Agriculture (INTA), Agric. Hilario Ascasubi Exp. Station, Hilario Ascasubi, Bs. As.- 8142, Argentina, E-mail adughetti@inta.gov.ar

In the irrigation area of Colorado's River bonaerense valley, Province of Buenos Aires, Argentina, the organic onion crop is a new activity from five years ago. It is considered a new economic resource to satisfy the demand of the others markets. During the period 1998/1999 was made a list of pest an organic onion crop. In this field was studied the different pests, their densities, their spatial dispersion and their natural enemies. The field was situated in Espié Colony, Hilario Ascasubi, in the Colorado River bonaerense valley. The observations were made in the seed bed and then in the crop using absolutes and relatives methods of counting. The absolute methods were evaluated in 50 onion's plants at random and weekly. The natural enemies of the organic onion pests were made by direct observation of the plants, by the soil's trap (Barber's trap) and by the metal square (0.50m x 0.50m), also by observation weekly. The seed bed was attacked by Delia platura and Delia antiqua, but they weren't very important The onion thrips Thrips tabaci was the most important pest in the definitive crop, also attacked the beetle Conoderus sp. but they were less important. The onion thrips population was two peaks abundance. The first was 02/26/99 with 31.50 thrips/plant and the other was 03/25/99 with 41.6 thrips/plant. The onion thrips spatial dispersal was studied by different index. They were: variance/mean, Southwood and Elliot, David and Moore, Green, Mean Crowding, Patchiness and Morisita. Also was used Taylor's power law, by study the spatial disposition of this insect. Result of evaluation with different index and the Taylor's power law indicated an overdispersed population of *Thrips tabaci*. The main natural enemies were the predators. They were the beetle Eriopis connexa and the spiders.

Index terms: pest, organic onion, population fluctuation, spatial dispersal, natural enemies.

[0958] SPREAD OF A MIGRATORY LOCUST PLAGUE IN MADAGASCAR

J.-F. Duranton¹, A. Razafindratsima², A. Franc¹ & <u>M. Lecoq</u>¹, ¹ CIRAD, Centre de coopération internationale en recherche agronomique pour le développement, TA40/PS2, Boulevard de la Lironde, 34398 Montpellier cedex 5, France, E-mail : nuichel.lecoq@cirad.fr; ² Projet de lutte acridienne, B.P. 1042, Nanisana, Antananarivo 101, Madagascar.

Since 1997, Madagascar has been experiencing an outbreak of the Migratory Locust that is the most severe for about fifty years. In spite of vast control operations, both terrestrial and by air, over three years (with financial support from the international community), gregarious residual populations remain in various localities and control will need to continue for at least several months. This outbreak originated in the locust's gregarious area in the southwestern semi-arid zone, between Toliara and Ambovombe. The first outbreak resulted from a sequence of favorable rainfall events. This phenomenon is well known in Madagascar but, for various reasons, caught the authorities unprepared. The initial outbreak - at that time restricted to well defined and restricted zones in the gregarious area - had been diagnosed from the very start of 1996, but no control measures were undertaken. From this date, the gregarious populations (swarms, hopper bands) progressively invaded northwards and by 1998 the whole island was infested. Observations over the last several years make it possible to provide an outline of this northward progression. The invasion followed a traditional sequence and route, essentially reproducing those of preceding outbreaks - especially those during the periods 1921-29 and 1939-57 (which, however, are much less well documented). The recent data provide a much clearer understanding of how the progression, year by year, relates to the island's ecological zonation. In addition, it seems that recent environment changes have modified some of the invasion routes, with swarms progressing quickly along the east coast (a naturally forested region now subject to deforestation) for the first time. Index terms: Acrididae, Locusta, migration, swarms.

[0959] POPULATION DYNAMICS OF *BEMISIA* SPP. IN WILD HOSTS IN AGRICULTURAL SYSTEM

<u>E. D. Quintela</u>, Embrapa Arroz e Feijão, Caixa Postal 179, Santo Antônio de Goiás, GO, Brazil, 75375-000. E-mail: quintela@cnpaf.embrapa.br.

Many weeds and agricultural crops are colonized by Bemisia spp. Little work has been done on the importance of wild hosts to build up populations before they disperse to cultivated hosts and vice versa. Understanding the population dynamics of Bemisia in different host plants is very important for its management. The objective of this study was to measure relative population levels of Bemisia eggs and adults in wild hosts. From April 1999 through February 2000, plants were selected randomly in a field in Santo Antônio de Goiás GO, Brazil. Plants were also sampled on May and June 1999, in Santa Helena de Goiás, GO, Brazil. The number of eggs and nymphs were counted with a dissecting microscope on the lower surfaces of five top leaves and five lower leaves on main stem of each plant. The plants were sampled weekly or every two weeks. The species sampled were Commelina benghalensis, Ageratum conyzoides, Bidens pilosa, Waltheria indica, Alternanthera ficoidca, Amaranthus deflexus, Emilia sonchifolia, Acanthospermum hispidum, Sida spp., Ipomoea spp., Euphorbia brasiliensis, Cassia tora, Euphorbia heterophylla, Erigeron bonariensis, Sonchus oleraceus, Leonotis nepetaefolia, Acanthospernum australe, Blainvillea rhomboidea, Crotom glandulosus, Stachytarpheta cayennensis. The results showed that population dynamics of Bemisia eggs and nymphs were influenced by the host plant, the intraplant distribution and climate factors. Index terms: Silverleaf whitefly, Aleyrodidae, weed species

[0960] SEEDLINGS AS EPHEMERAL UNDERSTORY IN MANGROVES : IMPACT OF HERBIVORES AND WATER LEVEL ON SEEDLING SURVIVAL

<u>A. Eben, J. García-Franco, M. Martínez & J. López-Portillo,</u> Instituto de Ecología, A.C., Km 2.5 Antigua carretera a Coatepec, 91000 Xalapa, Veracruz, Mexico, E-mail : astrid@ecologia.edu.mx

The impact of herbivorous insects and water level on the establishment of Avicennia germinans and Laguncularia racemosa seedlings was evaluated in two mangrove communities at a coastal lagoon in Veracruz, Mexico. Seedlings of both species were marked along 10 transects in one site ("1"). Type of herbivory and percentage leaf area lost were recorded for each seedling throughout the rainy season. We compared nitrogen content and phenolics in leaves of both species. There was a significantly higher damage by herbivorous insects in A. germinans when compared to L. racemosa. Highest damage was found in transects with higher water level. Herbivore exclusion experiments were conducted at both sites. Seedlings were marked in separate exclusions for both mangrove species. Exclusions and controls were distributed at two locations with different water level at site "1". At site "2", an A. germinans monoculture stand, the same experimental design was used. Presence of herbivores, damage and seedling survival were recorded from the onset of propagules until their establishment. Each species was attacked by one particular herbivore: A. germinans by Junonia evarete (Lepidoptera : Nymphalidae), and L. racemosa by a Psyllidae (Homoptera) species. At site "1", herbivore exclusion did not reduce mortality of A. germinans seedlings, and mortality was significantly lower at locations with higher water level. Survival of L. racemosa seedlings was significantly higher inside herbivore exclusions independent from water level, but overall survival was higher at locations with lower water level. Leaf phenolics were significantly higher in L. racemosa than in A. germinans. Nitrogen content was higher in A. germinans than in L. racemosa. Patterns of herbivory, nitrogen and phenol content indicate that slow growing L. racemosa invest more resources in defenses than fast growing A. racemosa. At site "2", J. evarete larvae decapitated unprotected seedlings, which were able to sprout again. Survival was significantly higher inside exclusions, nevertheless, flooding caused the death of all seedlings at this site. At both sites, survival and establishment of seedlings for both mangrove species was affected by an interaction of herbivore pressure and water level.

Index terms: Avicennia germinans, Junonia evareta, Laguncularia racemosa

[0961] CAN PLANTS USE ENTOMOPATHOGENS AS BODYGUARDS?

<u>S.L. Elliof</u>¹, M.W. Sabelis¹, A. Janssen¹, L.P.S. van der Geest¹, E.A.M. Beerling^{1, 2} & J. Fransen², ¹Section Population Biology, Univ. of Amsterdam, Postbus 94084, 1090 GB Amsterdam, The Netherlands. E-mail elliot@bio.uva.nl. ²Research Station for Floriculture and Glasshouse Vegetables, Linnaeuslaan 2a, 1431 JV Aalsmeer, The Netherlands.

For nearly thirty years, ecologists have been gathering evidence in support of the hypothesis that plants can use insect natural enemies such as predators and parasitoids as bodyguards to protect themselves from herbivory, but entomopathogens have escaped this consideration. We extend the bodyguard hypothesis to ask whether plants can use entomopathogens as bodyguards. We first discuss the evolutionary context of such tritrophic interactions and then categorise possible mechanisms as: (1) maintaining a population of bodyguards on the plant surface, (2) increasing contact rates between insect host and pathogen and (3) increasing the susceptibility of the host. We explore these mechanisms further, examining published studies for evidence for the hypothesis. We then discuss potential costs to the plant of promoting pathogens as bodyguards which may include a reduction in the efficiency of other "bodyguard" species, the incidental promotion of plant pathogens and the risk of entomopathogens developing phytopathogenicity. Aside from our intention to stimulate the testing of the bodyguard hypothesis with entompathogens and to provide a conceptual framework for this, we hope to bring evolutionary ecology and insect pathology closer together.

Index terms: tri-trophic interactions, mutualisms, biological control, plant defence.

[0963] MUTUALISM GONE AWRY? LACK OF HERBIVORE RESISTANCE IN NEOTYPHODIUM INFECTED GRASSES

S. H. Faeth & T.J. Sullivan, Dept. of Biology. P.O. Box 871510, Arizona State Univ., Tempe, AZ 85287-1501, USA.

Systemic endophytic fungi are thought to interact mutualistically with their host grasses mainly by increasing resistance to herbivores, as well as by increasing drought resistance, germination success, competitive abilities and deterring seed predators. However, antiherbivore effects have been documented only for a relatively few grasses, mostly agronomic ones, and mostly on non-native herbivores. There are few studies of the interaction of endophytes in native grass populations and communities. We first show that relatively few native grasses infected with systemic endophytes have strong negative effects on either invertebrate or vertebrate herbivores. Second, our observational studies of Neotyphodium-infected Arizona fescue (Festuca arizonica), a widespread and native grass, show no pattern of increased infection frequency with increased vertebrate grazing as predicted by the mutualistic hypothesis. Third, in field and greenhouse experiments, the presence of the endophyte did not alter preference or mortality of native and non-native invertebrate herbivores, such as leaf-cutting ants (Acromyrmex versicolor) and grasshoppers (Melanoplus femurrubrum and Xanthippus corallipes). Generally, plant genotype swamped the effects of the endophyte on both herbivore and host performance. Since asexual, vertically-transmitted Neotyphodium infections are usually common in natural populations of Arizona fescue, as well as other native pooid grasses, we are testing alternative hypotheses to explain their consistently high, but variable, frequencies. Index terms: Acromyrmex versicolor, endophytes, Festuca arizonica, Melanoplus femurrubrum, Xanthippus corallipes

[0962] INVESTIGATION ON HOST PREFERENCE OF PSUEDODENDROTHRIPS MORI (THYS; THRIPIDAE) ON FOUR VARIETIES OF MULBERRY IN THE FIELD AND LABORATORY

K. Etebari¹, J. Jalali¹, M. Tak sokhan² & E. Hossini², 1.Department of Plant Protection, College of Agriculture, Univ. of Guilan. IRAN, 41335-3179, 2.Research unit of silkworm rearing Co. Rasht, IRAN, P.O.Box 41635-1538.

The mulberry thrips Psuedodendrothrips mori NIWA is introduced as dominant species in the insect fauna of mulberry field in the north of Iran. The insect sucks the sap of the plant and reduces the quality of the leaf fed by the silkworm. The host preference was conducted on a complete randomized plot with four treatments i.e. Kemochi (KM), Kairyo-Nezumigaeshi (KN), Ichinose (I) and Shin-Ichinose, which are improved varieties present in the area. For this purpose, the insects were collected three times with fifteen replications each time. Number of individuals in one cm2 of leaf area was calculated as a density index. The results of statistical analysis with Duncun's new multiple range test (DMRT) indicates that the KM bearing an average of 3.48? 0.3 insects is significantly different from the other treatments at %1 level. Ichinose, bearing 2.2?0.01 stands second while KN and SI varieties each with 1.31?0.06 and 1.07?0.02 insects respectively, stand third. Nonpreference of this insect to different varieties in laboratory with poly choice test was studied. The preference percent of this species in four varieties out of thirteen replications was 38.8, 29.38, 18.96, and 12.73 respectively. The results of statistical analysis in laboratory condition also indicate that the KM is the most preferred variety and stands first while SI with the least preference stands last and the other two varieties are intermediates. Considering combination of the laboratory and field results, the KM variety is the most susceptible one to mulberry thrips while SI shows a relative resistance to this insect species.

Index terms: Psuedodendrothrips mori ; Host preference; Mulberry thrips

[0694] PLANT QUALITY AND GALLING HERBIVORE POPULATION ECOLOGY ON BACCHARIS DRACUNCULIFOLIA

M. L. Faria¹, B.G. Madeira¹, M. Fagundes¹ & G.W. Fernandes¹, ¹Ecologia Evolutiva de Herbívoros Tropicais, DBG/ UFMG. Belo Horizonte, MG, CP 486, 30161-970, BRAZIL, E-mail mlfaria@mono.icb.ufmg.br.

Three-trophic level interactions has been the model that best explains the population We tested two hypotheses in the system Baccharis dynamics of herbivore insects. Neopelma baccharidis (Homoptera: Psyllidae)dracunculifolia (Asteraceae)-Psyllaephagus sp. (Hymenoptera: Encyrtidae). The plant stress hypothesis proposes that plants become physiologically more susceptible to attack by herbivores, while the harsh environment hypothesis predicts that in more stressed habitats galls would suffer smaller attack rates by natural enemies and plant resistance. We collected galls in mesic and xeric habitats, and measured host plant height, width of the crown, xylem water potential, distance between leaves of apical branches, and number of galls found on each plant (n = 60). A sub-sample of galls were collected, weighed and opened for the evaluation of the parasitism rate. In addition, soil humidity was measured in the surrounding of each plant. The abundance of galls was significantly higher on plants in the xeric site (p<0.05). The distance between leaves, taken as an index of plant growth, was negatively related with xylem water potential (r²=0.75, p<0.001), which was negatively related with water content in the soil (r²=0.76, p<0.001). The distance between leaves explained 37% of the variation in gall weight (p<0.001). A multiple model that includes the volume of the plant and distance between leaves explained 16% of the variation of total number of galls in each plant (p<0.05). An average of 1.45 ± 1.29 nymphs of N. baccharidis was found on 1,123 galls dissected. The mean number of nymphs per gall did not vary among habitats, in spite of galls being larger in the mesic habitat (p<0.001). The mean rate of parasitism was 36% and did not vary among habitats. Our results indicate that the nutritional status of the plant is an important factor that determines the attack rates by N. baccharidis and that parasitism in any given habitat can be the result of a combination between environmental stress and the period in which the galls remain vulnerable to the attack by parasites. Index terms: Insect-plant interactions, galling insects, plant stress hypothesis

[0965] THE AGONY OF A HONEYBEE COLONY PARASITIZED BY THE SARCOPHAGID FLY SENOTAINIA TRICUSPIS: TEMPERATURE AND HUMIDITY VARIATIONS

<u>A. Felicioli</u>¹, S. Franceschini² & M. Pinzauti¹, ¹Dept. C.D.S.L., Sect., Agricultural Entomology, Univ., of Pisa. Via S. Michele degli Scalzi n°2, 56124 Pisa Italy E-mail mpinzaut@agr.unipi.it; ² Consorzio Pisa Ricerche, P.zza D'Ancona 1, 56124, Pisa.

This investigation was carried out in a coastal area of central Tuscany, (Italy) during summer and autumn 1999 starting on the 1st August until end of October. Temperature and Humidity were recorded by means of dataloggers (TinyTalk Relative Humidity TK-0302 and TinyTalk Temperature Range H TK-0040) inside and outside a honeybee colony parasitized by the Sarcophagid fly Senotainia tricuspis. All the dataloggers were set in order to take measurements every hour. Senotainiosis diagnosis was outlined by cheking the number of diptera larvae emerging from a sample of 30 bees. 30 bees were captured at the hive entrance and set into a jar. 24 hours after death the emerged endoparasitoid larvae were counted. Samples were taken three times during the investigation period at the beginning of August, on the 15th of August and on the 15th of September. The colony died on the 5th of October. Temperature inside the nest was kept between 30 and 35C° while the external temperature varied between 15 to 40C° from the beginning of the investigation (5th August) to the 30th August then started to decline from 32 to 20C° with an increase of temperature range up to 10C° over a period of 36 days. After such period the external temperature suddenly fell down to 5C° and the colony died. The humidity pattern shows a layout which is the opposite of the temperature pattern. During the first period of investigation (5th August). Afterwords internal humidity was kept by the bees lower (average 50%RH with a range of 10%RH) than external humidity (average 70%RH with a range of 30%RH). Afterwords internal humidity increased up to 28%RH until the bees death.

Index terms: Apis meilifera ligustica, thermoregulation, endoparasitoid.

[0966] RESISTANCE MANAGEMENT OF TUTA ABSOLUTA (LEPIDOPTERA: GELECHIDAE) TO SPINOSAD

M.C. Fernandes¹ & S.A. De Bortoli², ¹Depto. de Biologia, Univ. de São Paulo, 14040-901, Ribeirão Preto, SP, Brasil. ²Depto. de Fitossanidade, Univ. Estadual Paulista, CEP 14870-000, Jaboticabal, SP, Brasil. E-mail: bortoli@fcav.unesp.br.

This work was aimed to evaluate bioassay techniques to show the susceptibility of *Tuta* absoluta to spinosad (Tracer). The trial was carried out in the Biology Lab at University of Sao Paulo State, Jaboticabal, SP, Brazil, under controlled conditions ($T = 25 \pm 3^{\circ}C$, 12:12 (L:D) and RH = $70 \pm 10\%$. The tomatose leaves used were from 'Santa Clara' cultivar and the larvae from a lab population. To the Bioassay 1, tomatoe leaves were treated with 0, 8:16, 25.7, 81.6 and 257 ppm of insecticide solutions, during 5 minutes, and they were left to dry in the air. Two hours later they were put it on Petri dishes with 10 3rd instar larvae. To the Bioassay 2, tomatoe leaves were instated with 10 3rd instar larvae and 10 days later were treated by the same spinosad solutions. The bioassays were evaluated by larvae mortality 24 and 48 hours after the treatments. By the results it is possible to conclude that: spinosad showed high larvae mortality; bioassay 2 was the best to make tests about resistance management to the pest.

Index terms: Susceptibility, Tracer, bioassay

[0967] THE ANNUAL LIFE CYCLE OF AN POPULATION OF *DERALLUS* ANGUSTUS (COLEOPTERA, HYDROPHILIDAE)

L. A. Fernández, Depto. Entomología, Facultad de Ciencias Naturales y Museo, Paseo del Bosque s/11, La Plata, 1900, Argentina, E-mail: liliafer@museo.fcnym.unlp.edu.ar

Derallus is a Neotropical genus with 14 species. Only inmature states of two these species have been described, Derallus rudis y Derallus angustus, but no poblational studies have been accomplished yet, which are significant to understand the functioning of water bodies. The purpose of this research was to study the population dynamics of the species by periodic sampling of a natural population during one year, considering only those stages developing in the water. Derallus angustus is widely distributed from Guatemala to Argentina. The site studied was a permanent water body, located near the locality of Punta Lara (34° 47' S, 58° 01' W; Ensenada, Buenos Aires, Argentina). Punta Lara is at the austral end of "gallery forest" and has a subtropical and tropical floristic composition. The permanent water body was covered by Salvinia rotundifolia, Pistia stratiotes, Spirodela intermedia, Lemna sp., Hydromystria laevigata and Hydrocotyle ranunculoides. Twenty seven samples were taken (approximately two per month). On each sampling date, 20 random sample units of 200 cm² of aquatic vegetation were taken with strainer. Two reproduction periods were observed in this population: the first one by the end of spring and the second by the end of summer. Individuals of third instar larvae and adults were observed during the entire study time, suggesting that didn't hibernate at Punta Lara; this could be related to the fact that the water body is located in the "gallery forest" where environmental conditions are stable. Adults number, disminishing by the end of spring, probably die after reproduction.

Index terms: Derallus angustus, aquatic insects, larvae.

[0968] A STUDY OF MACROINVERTEBRATES IN RIVES ECOSYSTEMS (NW IBERIAN PENINSULA), AFFECTED BY SMALL HYDROELECTRIC DAMS

M. Fernández¹, M. Vidal¹, <u>A. Alonso¹</u>, D. Cuadrado¹, F. Mariño² & J. Garrido¹, ¹Dept. of Ecology and Animal Biology, Univ. of Vigo. E-36200, Spain, E-mail jgarrido@uvigo.cs; ²Ingenieria y Ciencia Ambiental, S. L. Meléndez Valdés, 5, bajo. E-28015. Madrid. E-mail ica@retemail.es.

River ecosystems in Galicia provide habitats for rich and diverse communities of aquatic animals; these communities have an extremely high conservation value as they include endangered species listed in the IUCN Red List of Threatened Animals, some of which are also endemic. Another outstanding feature is the abundance of species of European concern like the otter or the dipper. Stream regulation is known to have considerable impacts on the ecology of catchments, and, in some cases, results in severe environmental consequences for river biota. In general, it provokes a fall of the fauna with evident changes in the composition of the communities. In this sense, this comunication studies the effect of the hydroelectric dams on populations with bentonic macroinvertebratres. Among some effects, these infrastructures mean a problem for the moving of a lot of species, modify the physicochemical features which certain water has, and can affect the hydrological conditions in the rivers. This study expect to increase our knowledge on the biological diversity in the rivers of Galicia through the study of the biology and ecology of animal species and communities, as well as their structure and function. Secondly, we will try to evaluate the response of aquatic animals to river damming, paying special attention to the array of ecological interactions involved. Equally important to our study is to check the suitability of some species for bioindication and monitoring as a proper way to evaluate mitigation and enhancement options. This work takes part in several Vigilance Programmes and Environmental Monitoring carried out by Hidroelectric firms interprises such as San Miguel, S.A. y Aprohiga, S.A., which took place in the Deva and Tuño rivers (Ourense), where there is one hidroelectric minicentral in the first named river and three in the second one.

[0969] DAILY AND SEASONAL ACTIVITY OF HORSE FLIES (DIPTERA: TABANIDAE) ATTACKING REPTILES: *CAIMAN CROCODILUS* (ALLIGATORIDAE) AND *EUNECTES MURINUS* (BOIDAE), IN AN ANTHROPOGENIC CLEARING IN CENTRAL AMAZON, BRAZIL

<u>R. L. M. Ferreira¹, A. L. Henriques¹ & J. A. Rafael¹, ¹Dept. of Entomology - Instituto Nacional de Pesquisas da Amazônia – INPA, Caixa Postal 478 CEP 69.011-970 Manaus-AM, Brazil, E-mail: ruth@inpa.gov.br</u>

Tabanid females are known as hematophages in man and animals, linked to possible mechanical transmission of parasites during interrupted blood sucking. The association between horse flies and reptiles was first known sporadically, but has been gaining more corraboration througt experiments and occasional observation in the tropics. The present study was conducted in a military base (CIGS/BI-2), situated 54 km from Manaus/AM, in an anthropogenic clearing (02º45'S;59º51'W). Observations were made monthly, during April'97 to March'98, during two consecutive days. At the same time, other animals were offered, including humans. However in this paper we will only discuss data obtained on alligator Caiman crocodilus and anaconda, Eunectes murinus, in diurnal observations from 5:30 to 18:30. A total of 254 specimens were collected, 40 from anaconda and 214 from alligator. On the two reptiles four tabanid species were record: Stenotabanus cretatus , S. bequaerti, Phaeotabanus nigriflavus and Tabanus occidentalis. Diurnal activities showed species-specific patterns. althougt the three first species reported above were only found in the second semester which is the season with less precipitation and higher temperatures. T. occidentalis, occured during the whole observation period, and with increased frequency at the end of dry season. Preference in local attack and related defense behavior of the victim are reported.

Index terms: alligator, anaconda, hematophagy.

[0971] SEX, BUTTERFLIES AND BATESIAN MIMICRY: COLOUR PATTERN FORMATION IN THE TIGER SWALLOWTAIL

<u>R.H. ffrench-Constant</u>¹: P. B. Koch & B. Behnecke²,¹ Department of Biology, University of Bath, BA2 7AY UK; ²Department of General Zoology and Endocrinology, University of Ulm, Ulm, D-89069 Germany.

Melanism in lepidoptera, either industrial melanism or melanism involved in mimicry, is one of the most commonly cited examples of natural selection. However, despite extensive studies on the frequency and maintenance of melanic genes in insect populations, there has been little work addressing the underlying molecular mechanisms involved. Nowhere is butterfly melanism more striking than in the Eastern Tigger Swallowtail (*Papilio glaucus*) of North America. In this species females can be either yellow (wild-type) or black (melanic). The melanic form is a Batesian mimic of the distasteful Pipevine Swallowtail (*Battus philenor*) which is also black in overall color. Melanism in *P. glaucus* is controlled by a single Y-linked (female) black gene. Melanic females therefore always have melanic daughters. Melanic females show a replacement of the background yellow with black melanin. Here we show that the key enzyme involved is N- \Box -alanyl-dopanine-synthase (BAS) which shunts dopamine from the melanin pathway into the production of the yellow color pigment papiliochrome and also provides products for cuticle sclerotization. In melanic females this enzyme is suppressed leading to abnormal melanisation of a formerly yellow area and wing scale development is also delayed in the same area. This raises the possibility that either reduced BAS activity itself is preventing scale sclerotization (maturation) or, in contrast, that the delay in scale development precludes expression of BAS at the correct stage. BAS is probably homologous to the product of the *ebony* gene of *Drosophila*, mutants of which show black bedy color.

[0970] PERFORMANCE OF UTETHEISA ORNATRIX (LEP.: ARCTIIDAE) IN TWO SPECIES OF CROTALARIA SP. (FABACEAE) HOST PLANTS

V. G. Ferro & J. R. Trigo, Departamento de Zoologia, UNICAMP, POBox 6109, 13083-970, Campinas, Brazil. E-mail: vgferro@yahoo.com; trigo@obelix.unicamp.br

The moth Utetheisa ornatrix is protected against predation by pyrrolizidine alkaloids (PAs), sequestered from its larval food plants. Larvae are found mainly inside green pods of Crotalaria, where it feed on the seeds. Seeds have the highest PA concentration in relation to the other parts of plant. The objective of this study is try to answer what selective pressure lead to the utilization of this resource (seeds into green pods) for the larvae. Perforate the seeds and feed on highest concentrations of PAs could represent a cost? Or this represent a benefit, since the larva would become mechanical and chemical protection against natural enemies? We try to assess the performance of larvae (larval survival percentage and development time, pupal weight on the day after pupation and the females fecundity during 15 days) in C. juncea and C. pallida. Larvae were submitted to different feeding treatments: leaves, flowers, mature pods with seeds, green pods with seeds, green pods without seeds, green pods with seeds opened, green seeds and mature seeds. The last 4 treatments vs green pods with seed will assess the mechanical cost of pod uses. All U. ormatrix caterpillars reared since the first instar on mature seeds and mature pods with seeds of both plant species died. Larvae reared on flowers and leaves of C. pallida had the highest percentage of survival and green pods without seeds had the lowest. On C. juncea, the percentage of survival was highest for larvae reared on leaves; all larvae submitted to flower and green pods without seeds treatments died. Larvae reared on flowers and green open pods without seeds of C. pallida had development time significantly higher than larvae submitted to all other treatments. On C. juncea, larval development time were not significant. On C. pallida, larvae reared at green seeds developed significantly heavier pupae in comparison to the other treatments. On C. juncea, pupae obtained from larvae reared on leaves had a lower weight when compared with green seeds and green pods with seeds treatments. Female fecundity did not differ significantly in both species. These data indicate that U. ornatrix performance was better on green seeds, green pods with seeds and leaves. In these plant parts (where caterpillars are more commonly find) the percentage of larval survival percentage and the pupal weight were higher and the larval development time was lower; the females fecundity did not was affecting. Between species, C. pallida looked to be better than C. juncea. Though fed of leaves offered highest larval survival, green pods would be utilized because offer higher protection against predators: mechanic due the pods and chemical due PAs. This hypothesis remain to be tested. Index terms: Crotalaria pallida, Crotalaria juncea and resource utilization.

[0972] NECTAR AND POLLEN COLLECTION PATTERNS OF *MELIPONA* BICOLOR BICOLOR (HYMENOPTERA, APIDAE, MELIPONINAE)

A. O. Fidalgo¹, S. D. Hilário², A. M. P. Kleinert¹ & V. L. Imperatriz-Fonseca¹, ¹Dept. de Ecologia, E-mail afidalgo@ib.usp.br; ²Dept. de Zoologia, Univ. de São Paulo, R. do Matão, Trav. 14, n. 321, São Paulo, SP 05508-900, Brazil, E-mail sedilar@.usp.br.

This study describes how the foraging activity of Melipona b. bicolor is influenced by the us study describes now the foraging activity of *Metipona v. bicotor* is influenced by the environment and/or colony state. This bec species, was studied at the Bees Laboratory (Universidade de São Paulo; 23°33'S, 46°43'W) from November/98 to February/99. We used two colonies from Cunha/SP (23°05'S, 44°55'W). These colonies were classified as strong (Colony 1) and intermediate (Colony 2) according to general conditions, population and combs sizes and number of food pots. Flight activity was evaluated by capture of bees at nest entrance. Only bees carrying pollen and/or nectar were considered for the analysis. The pollen loads were counted, removed and saved for further analysis. Nectar was collected with capillary tubes placed between the mandibles while the abdomen was pressed. The volume was noted and the solutes concentration was measured by a pocket refractometer (Atago, BRIX 0-32%). Bees from each colony were captured for 10 minutes every hour from 6am to 7pm. Air temperature and relative humidity were also registered. M. b. bicolor was active from sunrise to sunset. Bees collected more nectar loads than pollen loads all over the day. Daily patterns of nectar and pollen collection was similar. However the collection of pollen and nectar loads were maximum in the early morning, from 6 to 7am. In Colony 2 the collection of pollen loads in the early morning was three times larger than in other times of day. Another peak in nectar foraging activity was observed between 10 and 11 am. Pollen and nectar intake varied strongly among the days studied. In January/99 the number of pollen and nectar loads decreased in both colonies, especially at Colony 2. That may be a consequence of changes in rain pattern in the study area in November/98 and January/99. Temperature and relative humidity showed daily variation in the study area. Temperature was maximum at noon when relative humidity was minimum ($r_s = -0.621$; p < 0.0001). The number of loads increased as relative humidity rose, being maximum between 70-90%. High temperatures had a strong negative influence on the number of loads collected with maximum ranging between 19-22°C. The foraging patterns of M, b. bicolor must be affected by colony state and environmental factors such as temperature and relative humidity.

Index terms: Melipona bicolor, bee, daily foraging patterns, nectar, pollen.

[0973] MAPPING, SURVEYING AND MODELLING INSECTS USING GIS TOOLS. CASE STUDY: CERAMBYX CERDO AND CERAMBYX VELUTINUS (COLEOPTERA: CERAMBYCIDAE) IN ALQUEVA DAM- PORTUGAL

D. Figueiredo¹& <u>R. Raimundo</u>¹, ¹Centro de Ecologia Aplicada, Universidade de Évora, Largo dos Colegiais 7000 Évora, Portugal, E-mail ceaue@uevora.pt.

The purpose of this work is the mapping, surveying and modelling of Cerambyx cerdo L. and Cerambyx velutinus Br. (Coleoptera: Cerambycidae) in the area of influence of the Alqueva dam (Guadiana river, Alentejo, Portugal) using GIS tools. The GIS was built using vector and raster approaches. Analysis of the spectral information in satellite imagery (Landsat TM, July 1997) and aerial photography interpretation supply information about land use and vegetation and was used to produce a habitat classification. Preliminary information of insects was stored in a relational database and managed using SQL (Structure Query Language). This methodology was used to produce the graphic outputs presented in this work. The Alqueva dam is one of the biggest dams in the Iberian Peninsula, and is projected to support a water volume of 4150 millions m³ at maximum level of 152m. The total submersed area will be about 29.000 ha and will include Holm and Cork oak stands. The Guadiana River is an important landscape element of the eastern part of Alentejo. Cerambyx cerdo is a threatened species in Europe, whose population has been decreasing at the same level of their habitats (holm and cork oaks) witch have been replaced by others land uses. This species is often mistaken by a 'sibling' species Cerambyx velutinus. Bait traps are used to catch the insects. This work allowed us to compare the two populations of those species in this area and to conclude that Cerambyx velutinus is much more abundant than Cerambyx cerdo (only one was found in this area). This confirms that this species is still rare in this region and needed some protection. We also tried to find some variables that could provide useful information in order to maintain these sustainable populations. In other areas (this area will be submersed soon), this may be done by using or maintaining the traditional land-use systems or even create new areas with adequate management. Future developments will help to create a good predictive model of the distribution of the two species in Alentejo region.

Index terms: Cerambyx cerdo, Cerambyx velutinus, GIS, conservation.

0975] INTERACTIONS BETWEEN FEMALES OF MANUELIA POSTICA AND COMPARISONS OF ITS NESTS WITH THE NESTS OF MANUELIA GAYI (HYMENOPTERA: ANTHOPHORIDAE)

L. Flores¹, <u>E. Chiappa</u>² & A. Alviña¹, 1 Inst. of Entomology, mailbox 147, Santiago, Chile. 2 Fac. of Sciences. Univ. of Playa Ancha, 34-V, Valparaíso, Chile. E-mail echiappa @upa.cl.

In the framework of field studies of biology of the three species of chilean genus Manuelia, behavioral records on interactions between females of M. postica are provided, Females exhibit three kinds of owner- intruder interactions at the nest: a) owner - intruder at the nest entrance (frequency= 87.9%); b) intruder 1 - intruder 2 at the nest entrancy (frequency= 6%); c) intruder entering the nest - owner (frequency= 6%). In adding, the nest architecture of M. gayi and M. postica was compared. The cells of both species were urnshaped, that of the nests of M. postica were arranged linearly in stems of Chusquea sp., (Gramineae: Bambuseae) and the cells of M. gayi were most irregularly distributed in larger stems of Persea lingue (Lauraceae). The size of the cells of M. gayi is significantly higher than in M. postica, as much the lenght (t = 5.75 p < 0.01) as the maximum diameter (t= 3.25 p<0.01). In both species the completed cells were always closed by partitions, which are more compacted in M. gayi, the thickness of partitions of M. postica was significantly smaller than in M. gayi (t= 16 p< 0.01). The mean value of the number of individuals in the aggregation of nests of M. gayi was 241, and in M. postica the mean was 10 individuals / nest. Both species overwinter as adults, the sex allocation was different, 1.36 females : 1 males in M. gayi, 1,6 females : 1 male in M. postica, probably the difference is caused because the nests of M. gayi were collected in the month of June only with adults inside, and the nests of M. postica were collected in the month of december with larvae, pupae and adults. The high value of number of cells in the nest of M. gayi, the proximity of the nests entrances and the interactions observed between females of M. postica, suggests the possibility of primitively social behavior, that should be corroborated with experimental studies.

0974] FLIES UNDER STRESS: A TEST OF FLUCTUATING ASYMMETRY AS A BIOMONITOR OF ENVIRONMENTAL QUALITY

K. D. Floate & A. S. Fox, Agriculture and Agri-Food Canada, Lethbridge Research Centre, P.O. Box 3000, Lethbridge, AB, Canada, T1J 4B1, E-mail: floatek@em.agr.ca.

Fluctuating asymmetry (FA) has been proposed as a measure of environmental quality. The premise is that increased levels of environmental stress (e.g., chemical pollutants) are reflected by increased levels of FA within populations of organisms developing at the site. We test this premise by examining the relationship between stress, fitness, and FA among laboratory populations of house fly (Musca domestica L.). Exposures from 0.00 to 1.00 ppm of the pesticide, ivermectin, during egg to pupal development caused up to 18-fold differences in levels of stress (measured as percent pupation), and up to 18-fold differences in levels of fitness (measured as the average number of first-instar larvae produced by each female in the starting population) among populations. However, no differences were detected among population levels of FA for five wing traits examined. Power analyses estimated that the accuracy of the image analysis method used to obtain measurements would have detected a 10% difference in average FA among populations 95% of the time. Hence, the results of this study do not support the use of FA as a method for monitoring changes in environmental quality. The absence of a treatment effect on levels of FA may reflect the development of surviving flies in 'refuges', thereby minimizing or avoiding their contact with ivermectin (the 'refuge' hypothesis). Alternatively, flies surviving exposure to ivermectin may represent a 'robust' subset of the starting population whose symmetries are relatively unaffected by the effects of stress (the 'differential mortality' hypothesis). These two hypotheses have received little attention in the literature, yet may have important implications for interpreting the effect of environmental stress on FA.

Index terms: Musca domestica, bioassay, ivermectin, image analysis, environmental contamination

[0976] EFFECT OF TEMPERATURE ON THE SEX RATIO AND WEIGHT OF CHRYSOPERLA EXTERNA ADULTS OBTAINED FROM LARVAE FED ON SCHIZAPHIS GRAMINUM

<u>A.R. Fonseca¹</u>, C.F. Carvalho¹, B. Souza¹ & C.C. Ecole¹, ¹Dept. of Entomology, Federal Univ. of Lavras, Caixa Postal 37,CEP. 37200-000, MG, Brazil, E-mail rsjorge@ufla.br

The aphid Schizaphis graminum is one of the main pests of the sorghum culture, damaging the plant by the suction of the sap, injection of toxins and viroses transmission. Among the enemies of this aphid, Chrysoperla externa stands out, which is of natural occurrence in that Gramineae. Due to its great potencial in the biological control of that aphid, this work aimed to study the effect of temperature on the sex ratio and the weight of C. externa adults, recently emerged, originating from larvae fed on S. graminum, in growth chambers, at 15, 18, 21, 24, 27 and 30 °C, UR of 70 \pm 10 % and photophase of 12 hours. The experimental design was entirely randomized, with six treatments and fifteen replications. It was observed that adults coming from the temperatures of 18, 21, 24 and 27 °C presented the highest weights (6.62; 5.86; 6.31 and 5.84 mg, respectively), in relation to those obtained at 15 °C (5.22 mg), which presented intermediate weight. Adults kept at 30 °C presented lower weight (3.97 mg). Between 18 to 27 °C, C. externa adults presented higher performance in relation to weight. The sex ratio obtained in the six tested conditions were 44.1; 50.0; 45.4; 46.1; 54.5 and 57.1 %, respectively. Index terms: green lacewing, aphid, sorghum, predator.

[0977] PHENOTYPIC PLASTICITY IN *DEOIS FLAVOPICTA* - VARIATION IN THE DRY SEASON DORMANCY AMONG FAMILIES AND AMONG GEOGRAPHICALLY ISOLATED POPULATIONS

E. M. G. Fontes¹, E. R. Sujii¹ & C. S. S. Pires¹, ¹Embrapa Recursos Genéticos e Biotecnologia, PqEB, Final Av. W3 Norte, C.P. 02372, 70849.970 Brasilia, DF, Brazil.

The grass feeding spittlebug Deois flavopicta (Hom.: Cercopidae) is the most abundant species in cultivated pastures, in Brazil. In the Central-west and Southeast regions, populations of this insect are widely distributed; moreover, they consistently differ in abundance and in some traits such as adult coloration and markings, and voltinism. The display of phenotypic variability in physiological traits is expressed by the ability to enter egg diapause. With a gradual increase in the fraction of offspring entering diapause and varying the degree of diapause among a family of progeny to promote hatching variation, D. flavopicta performs a phenotypic plasticity by diversifying its offspring to survive in variable environments. We raised the question whether these variations were genetically related. To examine whether the two traits vary among families within populations we observed the hatching pattern of individual, field collected females from each of the three annual generations. Different hatching patterns and duration of diapause were observed among families from the same generation, and among the three generations. Some females laid nondiapause eggs only, others laid only diapause eggs and others laid a mix of diapause and nondiapause eggs. Moreover, diapause eggs of the same family displayed wariable hatching patterns. The variation in the proportion of diapause eggs among geographically isolated populations was examined by observing the patterns of egg hatching in the progeny of third (April) generation females collected along an East-West transect in parallels 15[°] and 20[°] S. Sample locations were established at each 2.5[°] from longitudes 40 to 50[°] W. A third transect followed the Northern direction on longitude 47[°] W from parallel 16 to 7[°] S. A total of 24 locations were sampled. Females were collected and placed in cages for oviposition. The eggs were transferred to plastic dishes and hatching was recorded each two-three days. D. flavopicta was the predominant species of pasture spittlebug along transects 20'S and 47' W but it was not found in the locations sampled along parallel 15°S. It was observed great variability in the proportion of diapause eggs, as well as in the duration of diapause in eggs laid by females from the different populations. We concluded: 1. traits associated with the diapause syndrome in D. flavopicta are probably genetically related; 2. There probably has three different genotypes underlying the proportion of diapause eggs; and 3. the two traits studied are probably genetically correlated.

Index terms: genetic of diapause, Cercopidae, spittlebug, phenology

[0978] VELVETBEAN CATERPILLAR PREFERENCE TO SOYBEAN AND PENUTS VARIETIES

<u>P. Fortes¹</u>, L. Vieira¹, G. Bissolli¹, S. A. De Bortoli¹ & A.T. Murata², ¹Dept. de Fitossanidade, Univ. Estadual Paulista, CEP 14884-900, Jaboticabal, SP, Brasil. ²Dept. de Biologia, Univ. de São Paulo, CEP 14040-901, Ribeirão Preto, SP, Brasil (FAPESP Fellowship), E-mail: murataat@asbyte.com.br.

Lately it has been increasing the reports about the attack of velvetbean caterpillar, Anticarsia germatalis in peanut crops causing economic damage. This work was carried out to study the preference of caterpillars to soybean (cv. Foscarin and Br 37) and peanut (cv. Tatu), under laboratory conditions $(25 \pm 2 \,^{\circ}\text{C}, 40 \pm 10\% \,\text{RH}, 12$ hours photophase). The trials used 5th instar larvae and multiple and two choicetests with 20 replications and 10 insects per replication, in arenas of 60 cm diameter. Around the arenas were placed pots with 2 plants of each variety (dual and multiple tests). It was evaluated the number of larvae per plant and the time expend to the larvae reach the plants. By the results could be verified that cv. Foscarin was the favorite substrate with 3.95 caterpillar followed by BR 37 (2.7) and peanut (1:15). The caterpillar took an average of 38", 1' 27" and 1' 15" to reach the cultivars Foscarin, BR 37 and Tatu, respectively. It can be conclude that larvae of A. gemnatalis showed preference to soybean, being cv. Foscarin the most attractive.

Index terms: Anticarsia gemmatalis, choice tests, attractively

[0979] BEETLE ASSEMBLAGES (COLEOPTERA) IN THE PARQUE ESTADUAL XIXOVÁ-JAPUI, SÃO VICENTE-PRAIA GRANDE, SÃO PAULO

<u>R. B. Francini</u>¹, I. B. Francini¹, R. G. Cedro², E. C. Francisco² & H. E. Alves², ¹ Museu de História Natural, FAFIS, Univ. Católica de Santos, Rua Euclides da Cunha, 247, 11065-902, Santos, SP, Brasil, E-Mail francini@unisantos.com.br, ² Curso de Licenciatura em Ciências Biológicas, FAFIS, UniSantos. Financial support: IPEC-UniSantos.

The Parque Estadual Xixová-Japui is an area of hills between the cities of São Vicente and Praia Grande (24°00' S - 46°24' W). These hills are formed by Precambrian rocks isolated by coastal plain Quaternary sediments. The park includes an area of approximately 900 ha. with the hills of Japuí, Xixová and Itaipú and the beaches of Itaquitanduva, Paranapuã, Prainha and Battalion, and rocky shores facing Atlantic Ocean. The original vegetation was rain forest (Atlantic forest core area), almost all substituted today by secondary forest in various regeneration phases including edges. The study area we inside the Fortaleza do Itaipú (of the Brazilian Army). Beetle samples were collected along a quasi-linear transect marked every 10 m interval unchanged during all the study period. Techniques included manual collecting, standardized litter samples (1 m², 10 samples each 20 m; Winkler extraction) and two Flight Intercept Traps (FIT). The data from June to December 1999 showed the presence of 420 morphospecies of beetles belonging the 46 families. Curculionidae represented 23.6% of the species followed by Staphylinidae (18.6%), Nitidulidae (6.0%), Scarabaeidae (5.7%), Chrysomelidae (5.5%), Cerambycidae (4.3%) and Carabidae (3.8%). Other families totaled 32.5% with 8.8% not identified. In the standardized 60 litter samples 102 morphospecies were collected with the most abundant, appearing in 20 samples; 55 morphospecies appeared in only one sample. The species accumulation curves for 60 standardized litter samples showed no stabilization after the sixth month of sampling. Beetle richness versus 6 habitat characteristics (mass, volume and moisture content of litter, terrain inclination, degree of canopy cover using fish-eye photography and relative level of illumination) in each point (60 samples) was relatively low (beetles x volume; Spearman R=0.559868;t=5.14594; p<0.000003). The data on beetle diversity was compared with the data from habitat diversity calculated using Brillouin's equitability index for each sample. The results showed a weak correlation between the two series of diversity estimates. A PCA made on the joint matrix (beetles + habitat) showed that the factors mass and volume of litter were important in the determination of the variance species diversity.

Index terms: species richness, winkler samples, flight intercept trap.

[0980] BIOLOGICAL AND ECOLOGICAL STUDIES ON OMASPIDES TRICOLORATA (COLEOPTERA: CHRYSOMELIDAE: CASSIDINAE)

F. A. Frieiro-Costa¹ & <u>J. Vasconcellos-Neto</u>², ¹ Curso de Pós-Graduação em Ecologia.Universidade Estadual de Campinas - Inst. Biologia - Depto. Zoologia. Campinas, SP, Brazil, 13083-970.² Universidade Estadual de Campinas - Inst. Biologia - Depto. Zoologia. Campinas, SP, Brazil, 13083-970. E-mail: jvascont@obelix.unicamp.br.

We studied a population of Omaspides tricolorata Boh. 1854, a species with maternal care at Serra do Japi, Jundiaí, São Paulo state, Brazil (23º 11' S; 46º 52' W) during almost three years (1988-1990). The life cycle of this species is closed tied to seasons and the fenology of its host plant, Ipomoea alba (Convolvulaceae). Adults appeared in October (spring) and remained active until April, when entered diapause, and remained hidden during the dry winter season; and the next reproductive cyle started again in the next spring. The first egg cluttches were found in October (1988) or November (1989), showing two peaks of egg-clutches abundance, one in December and other in February. The last egg clutches were observed in April (1989) and March (1990), and the females and theirs offsprings need at least two months to complet their life cycle. At this time (May) starts the cold dry season and the host plant shows old leaves, wich fall during the winter. The egg-clutch size varied form 28 to 80 egss with an average of 55.1 ± 12.2 eggs (n = 56 clutches). The incubation period of the egg stage was $15.5 \pm 4.4 \text{ days} (n = 120 \text{ clutches})$; the mean duration of larval stage, containing five instars, was $28.0 \pm 5.2 \text{ days} (n$ = 86 larval groups) and the pupal stage lasted 13.7 ± 5.3 days (n = 48 pupal groups). The imature life cyle lasted 57.3 \pm 5.7 days (n =48) and during these two months the female take care its offspring. All these biological dates were obtained in field conditions The females fed only during larval development of theirs offsprings or before laid eggs. One female can take care only two generations each reproductive period. Maternal care and cycloalexy are important behavior against natural enemies.

[0981] NEST DYNAMICS OF POLYGYNE COLONIES OF THE SOUTHEASTERN YELLOWJACKET

G. N. Fritz, S. Stewart & A. J. Deets, Dept. of Biological Sciences, Eastern Illinois Univ., 600 Lincoln Ave., Charleston, IL, 61920, E-mail: cfgnf@eiu.edu.

The yellowjacket, Vespula squamosa, is the only ensocial wasp that commonly has two social forms, has annual and perennial nests, facultatively usurps the nests of conspecifics, and parasitizes other vespine species. Thus, V. squamosa is ideally suited to study ecological determinants of social behavior and kin selection dynamics. Twenty annual and perennial nests of V. squamosa were collected from counties in Georgia and Florida. USA. All perennial nests had multiple gynes (12 - 46) whereas annual nests had single queens. Gyne number varied between perennial nests and nearly all individuals had spermatazoa and mature eggs (n = 143). The number of workers in perennial nests varied from 675 to over 65,000 individuals. Single queens had significantly more mature eggs per ovariole than gynes from perennial nests (7.0 ± 1.0 eggs/ovariole versus 2.0 ± 1.1 , respectively; p < 0.001). Gynes from perennial nests (p < 0.02), but workers were significantly larger eggs than those in single queens from annual nests (p < 0.02), but workers were significantly larger eggs that the latter nests (n = 268, p < 0.001). Data suggest that perennial nests are truly multiple queen colonies. Furthermore, supernumerary eggs and larvae suggest that cell number is a limiting resource in multiple queen colonies. Index terms: Vespula squamosa, polygyne, mongyne, kin selection

[0983] SOURCE-SINK RE-COLONISATION: A POSSIBLE STRATEGY OF INSECTS LIVING IN TEMPORARILY SUITABLE HABITATS

J. Frouz¹, P. Kindlman², II. H. Tulke³ & K. Frank³, ¹Inst. Soil Biology ASCR, Na sadkach 7, Ceske Budejovice, CZ-37005, Czech Republic, E-mail: frouz@upb.cas.cz; ²South Bohemian Univ. Fac. Biol. Branisovska 31, CZ-37005, Czech Republic; ³UFZ, Dept. Ecosyst. Modelling, Permostigerstr. 15, D-04318 Leipzig, Germany.

Continual colonisation and re-colonisation is critical for survival of species living in temporarily suitable habitats. Habitats included in this re-colonisation process are usually assumed to be self-sustainable in terms of species survival. However, some animals may occur also in sub-optimal habitats where population density is maintained by immigration from more suitable (source) habitats and is going extinct when this immigration is stopped (sink habitat). In this study the hypothesis that re-colonisation of permanent sink habitats from a temporary source habitat can increase the probability of metapopulation persistence was tested using a simple mathematical model. Two groups of source habitats recolonising each other were compared, each source habitat being either alone or accompanied by a sink habitat. Inclusion of a sink habitat increased the probability of metapopulation persistence in situations when availability of sources was synchronised or when colonisers were poor migrants or both. This effect depends on the relation between source and sink habitat growth rates and is well pronounced in high growth rates. When growth rates are low, survival probability strongly depends on the proportion of source to sink and sink to source migration rates and in some proportion of migration rated results in a decrease of survival probability. Field data about terrestrial chironomid species, Smittia aterrima, were used to test the model predictions for one patch source-sink system similar to those described above. S. aterrima is specialised in pioneer open habitats in initial stages of succession, which provide good quality food for the larvae and most of offspring are produced here. The optimal habitat, however, is sensitive to summer desiccation, which often results in almost complete extinction of the summer larval population in a large area. It is shown that re-colonisation from less suitable, but more stable "sink" habitats in the surrounding landscape enables population persistence in landscape. The field data correspond well with model outputs, which indicates that re-colonisation of source habitats from sink habitats is one of the reasons for persistence of the latter. Index terms: population ecology, modelling, metapopulation

[0982] SURVEY OF INSECTS IN WEEDS DURING THE OFF-SEASON OF CORN CULTURE

M.R. Frizzas¹, S. Silveira Neto¹ & N.M. Martinelli², ¹Dept. de Entomologia, Fitopatologia e Zoologia Agrícola, Univ. de São Paulo (ESALQ/USP), C. Postal 9, CEP 13.418-900, Piracicaba, SP, Brasil, E-mail mrfrizza@carpa.ciagri.usp.br; ²Dept. de Defesa Fitossanitária, Univ. Estadual Paulista (UNESP), CEP 14.870-000, Jaboticabal, SP, Brasil.

Weeds are considered undesirable plants because they can compete with cultivated crops as well as host insect pests and pathogens. Furthermore, they can also serve as refuges for insect pest during a crop off-season period. Therefore, the management of the abundance and compositions of weeds during the crop off-season period can greatly influence the pest infestation in a cultivated crop mainly in tropical regions. Based on these facts, the objective of this work was to study the insect species associated with weeds during the corn off-season period. The experiment was conducted at Experimental Station of Universidade Estadual Paulista in Jaboticabal, SP, Brazil, during the period between May to September of 1997 and 1998. Insect sampling on weeds were performed weekly by using light traps, Malaise traps and colored trays. After screening the samples, data were subjected to an faunistic analysis. The following index were estimated: constancy, dominance, abundance and frequency. Ninety nine different insect species were collected during the experimental period. Fourteen species were considered predominants: Aphodius sp.; Diabrotica speciosa; Epitragus similis; Paederus sp.; Condylostylus sp.; Alydus sp.; Pangaeus sp., Ophion sp., Anticarsia gemmatalis, Cirphis latiuscula, Elasmopalpus Ignosellus; Leucania humidicola; Spodoptera frugiperda and Chrysoperla externa. From the predominant species, the most frequent ones were E. lignosellus and Aphodius sp. Among the insects collected during the corn off-season period, most of them were insect pests and some of them with a great relevance in corn. A few natural enemies were also collected during this period.

[0984] THERMOREGULATION OF NEST OF WOOD ANT FORMICA POLYCTENA

J. Frouz, Inst. Soil Biology, ASCR, Na sadkach 7, Ceske Budejovice, CZ-37005, Czech Republic, E-mail: frouz@upb.cas.cz.

The factors affecting daily a seasonally pattern of temparature fluctuations and thermal loss from ant nest were studied. Patterns of temperature fluctuation and mechanisms of Two extreme thermoregulation change substantially along nest moisture gradient. situations can be distinguished. In dry nest (moisture of nest material c, 10 %) daily temperature fluctuation is characterized by slow decrease of internal nest temperature during night and increase during daytime. Seasonal changes are characterized by slow The thermal loss of these nests, increase of internal nest temperature during spring. during period of activity, is low (about 2w per nest) and the thermal flow is less homogeneous over the nest surface. In contrast the daily fluctuation of moist nest (moisture 35% and more) is characterized by increase of nest temperature during night and lower temperature during day. Seasonal fluctuation is characterized by step increase if temperature during spring. The thermal loss is higher in comparison with dry nest (c. 35w) and concentrated mostly to top part of the nest. The thermal loss of moist nest is so high that it can not be explained by ant metabolic heat production. In moist nest microbial activity increase and thus microbial metabolic activity may serve as additional source of heating in wet nest. The implications of this shift in thermoregulation for ecology of wood ants are discussed.

[0985] CONNECTIVITY AND HABITAT PREFERENCE OF SPASSALUS CRENATUS (COLEOPTERA: PASSALIDAE) IN THE LUQUILLO EXPERIMENTAL FOREST, PUERTO RICO

A. Galindo-Cardona & A. Sabat, Dept. of Biology, Univ. of Puerto Rico, P.O.Box 23360, San Juan, PR 00931-3360, E-mail: is973083@rrpac.upr.clu.edu

Connectivity between patches, in metapopulations, influences their demographic and genetic structure. Other factors influencing population dynamics, in metapopulations are local extinction rates and anthropogenic or stochastic disturbances. Animals inhabiting ephemeral patches, such as fallen tree trunks and ponds, have characteristics that match the assumptions of a classical metapopulation model: low vagility, few generations per patch, and reproduction in one or few patches during the adult lifespan. Bees-beetles (Coleoptera: Passalidae) inhabit fallen tree trunks where they establish a colony and spend their entire life cycle, which includes some parental care during egg and larval development. After attaining sexual maturity, adults disperse and colonize new trunks. In this study I addressed the following questions: 1) What is the colonization rate of the patches? 2) What is the effect of dispersal distance, trunk species and state of decomposition on colonization rate? To answer these questions an experiment was performed at El Verde Field Station (Luquillo Experimental Forest, Puerto Rico). Four 20 m x 1.5 m experimental plots were constructed by enclosing them with a 0.7 m barrier. In each plot, four stems were placed at 2 m, 6 m, 12 m and 18 m from the edge of the plot, for total of 16 trunks per plot. The trunks ranged from 60-70 cm in longitude, and 20-30 cm in diameter. The trunk species were Cecropia spp. and Ormosia krugii fallen down by Hurricane Georges (October 1998), and Swietenia macrophylla fallen down by hurricanes Hugo (September 1989) and Georges. Groups consisting of 3 or 4 bees-beetles individuals were released at the corner of each plot. The individuals were permanently marked by cutting small pieces of elytra. Trunks were checked after 24 hrs, 8 days, and then weekly for three months. Preliminary results indicate that of the 16-groups released on October 1999, three successfully established a colony, and two solitary individuals were found after 14 weeks. All three colonies were established in decomposed stems of S. macrophylla fallen down by Hugo, and located at 6 m from the release point.

Index terms: Colonization, dispersion, wood density, and decomposition level.

[0986] IMPLICATIONS OF HOST-PLANT CARBON UPTAKE PATTERNS AND LEAF SIZE ON THE PERFORMANCE AND ABUNDANCE OF A CYNIPID GALLFORMER

<u>P.S.Galusky</u>, J.R.Ott & R.J.Reynolds, Southwest Texas State Univ., San Marcos, TX, USA, 78666-4615, E-mail: pg34960@swt.edu.

Gallformers ovinosit at the site of larval development thus promoting selection for linkage between oviposition preference and larval performance. The host vigor hypothesis (HVH) predicts linkage on host tissues that attain relatively large size as a result of high growth rates. We examined preference-performance linkage and tested the HVH by documenting the within-canopy distribution of leaf galls induced by Belonocnema treatae (Cynipidae: Hynemoptera) on its host plant, Quercus fusiformis. Over 2 consecutive gallformer generations, 16 trees were sampled according to previously documented within canopy patterns of carbon uptake (upper > mid > lower and SE > SW = NE > NW) which, along with abiotic correlates, are known to influence phytophage habitat suitability. At each of the 12 strata x direction sites/tree, ovipuncture density, initiated gall density, gall size, and gall-former performance (# mature galls/ovipunclure) were estimated from a random sample of 100 leaves (total 1200 leaves per tree). Three-way ANOVA was used to test for main and interaction effects of direction, strata, and host plant on ovipuncture density, initiated gall density, gall size, and performance. Leaf area was estimated for all second year leaves attacked by B. treatae and correlated with gallformer performance and abundance to test the HVH. Gall and ovipuncture densities were highest in the low stratum. Conversely, performance was highest in the upper stratum. Tissue level performance and abundance were not consistently correlated with each other or leaf size. These results suggest that larval performance is enhanced on more physiologically active regions within host canopies, but preferred oviposition sites are not linked to larval performance and neither is influenced by tissue size. Observed patterns may result from spatially constrained gallformer attack strategies.

Index terms: *Belonocnema treatae* (Cynipidae: Hymenoptera), within-plant distribution, host vigor, preference-performance linkage

[0987] APHIDS: NOT ONLY A PEST INSECT

S.Ganassi¹, <u>A.M.Pagliai¹</u>, A. Moretti², A. Logrieco², B.Fratello¹& M.A. Sabatini¹, ¹Dept. Biologia Animale, Univ. Modena e Reggio Emilia, 41100 Modena, Italy, E-mail: sabatini@unimo.it ²Inst. Tossine Micotossine, CNR, Bari, Italy.

Aphids are considered major pests of crops, as they are sap sucking insects that can induce great damage by nutrient drain or other mechanisms, including virus transmission. Of the organisms proposed for biocontrol of pest insects, fungi producing bioactive metabolites are considered promising candidates, and aphids are considered a very good organism for testing their insecticidal properties. Aphids have parthenogenetic reproduction and short generation times that allow rapid increase in population size, and their colonies have numerous individuals that are closely related genetically. Moreover, due to heteromorphism, with wingless and winged morphs, they represent pest insects with different ecological value. Some fungal species produce toxins, and aphids present characteristics that make them excellent test organisms for verifying the toxic activity against target and non-target organisms. The sap-sucking behaviour allows them to be used to evaluate crops contaminated by toxigenic fungi. Furthermore, due to the peculiar feature of "telescopic generations" it is possible to treat and observe the effects of mycotoxins on two-or-three generations at a time. Aphids are in symbiotic mutualistic association with intracellular prokaryotes, permitting the simultaneous treatment of eukaryotic and prokaryotic organisms and identification of toxic effects on both of them. We used Schizaphis graminum, a cereal pest, as organism to test the effects of two formulations of the fungus Fusarium proliferatum and the effects of two toxins (fusaproliferin and beauvericin) from the same fungus. Treatment of aphids with the two mycotoxins, assumed via feeding on plants, affected their reproductive fitness, in particular with a significant decrease in newborns and increase in aborted embryos and newborns found dead. The large amounts of DAPI and Feulgen positive material in the symbionts of some bacteriocytes in third generation treated aphids suggests an interaction between toxins or their metabolites and nucleic acids. This interaction might affect the numerous exchanges between prokaryotes and their host, leading to anomalies in the aphid life cycle, particularly in reproduction and development. We hypothesise that toxin effects, starting from the first treated generation might also extend to the second and third generation due to telescopic generations. The outcome is an additive pathogenic activity most evident in the third generation. Another possibility is that the target embryos were in a developmental phase particularly sensitive to the bioactive metabolites applied. Second generation embryos, already present in newborns at treatment time, might have passed through the most sensitive phases before treatment and thus be less influenced by the metabolite. Instead, third generation embryos could be submitted to the toxic activity at an earlier developmental stage, and thus possibly be more sensitive.

Index terms: Schizaphis graminum, test organism, mycotoxin, bacteriocytes

[0988] INTRAGUILD PREDATION BETWEEN APHIDOPHAGOUS PREDATORS AND ERIGONID SPIDERS IN CEREALS

A. Gathmann & H.-M. Poehling, Inst. of Plant Diseases and Plant Protection, Univ. of Hannover, Herrenhäuser Str. 2, D-30419 Hannover, Germany, E-mail gathmann@mbox.ipp.uni-hannover.de,

In cereals, polyphagous predators are among the most numerous predators of insect pests. One of the most abundant predators in cereals are erigonid spiders. They can reach abundance of hundred or more individuals per square meter. However, most polyphagous predators can also feed on beneficial arthropods, which may affect the population dynamics of insect pests. Field studies in cotton revealed that intraguild predation (IGP) by hemipteran bugs can reduce the predation rate of lacewing larvae on aphids, but less is known about interactions between aphidophagous and polyphagous predators in cereals. In microcosm experiments we examine the intraguild predation between *Erigone atra*, *Chrysoperla carnea*, *Coccinella septempunctata*- and *Episyrphus balteaus*-larvae. 15 oneweek old wheat seedlings were infested with 20 alatiforme fourth instar larvae of the cereal aphid *Sitobion avenae* and 1 female or male of *Erigone atra* or the other mentioned aphidophagous predators were added, single or in combination. First results showed that spiders could reduce population size of aphids, but are less effective than coccinellid or syrphid larvae. Intraguild predation between spiders and the other predators occured but not very frequently.

Symposium and Poster Session

$\left[0989\right]$ TRAP-NESTING BEES AND WASPS AND THEIR NATURAL ENEMIES AS BIOINDICATORS

A. Gathmann¹ & T. Tscharntke², ¹Inst. of Plant Diseases and Plant Protection, Univ. of Hannover, Herrenhäuser Str. 2, D-30419 Hannover, Germany, E-mail gathmanu[@]mbox.ipp.uni-hannover.de, ²Inst. of Agroecology, Univ. of Göttingen, Waldweg 26, D-37073 Göttingen, Germany, E-mail ttschar@gwdg.de.

Results from our field studies show that communities of trap-nesting bees and wasps and their natural enemies are promising bioindicators for ecological change or habitat quality. These small and easy to handle communities can be analyzed with respect to (i) species richness and related parameters, and (ii) ecological functions or interactions. The communities comprise Hymenoptera (Apidae, Sphccidae, Eumeninae, Pompilidae) and natural enemies belonging to many insect taxa. Traps consisted of 150-200, 15-20 cm long reed internodes, put into tins or plastic tubes of 13-15 cm diameter and wooden posts with 2-10 of such reed-filled tins were exposed in the target habitat. The sensitivity of this bioindicator system profits from the fact that evaluations rely not only on presence or absence of species, descriptive population attributes or diversity indices, but also on interactions or ecological functions. Monitoring ecological responses or multitrophic interactions, and their relationship to species diversity is rarely done but much needed. Ecological functions include e.g. the percentage mortality of trap-nesting bees and wasps due to parasitcids and predators, which was correlated with species richness of these natural enemies, seed set of allogamous plants due to successful pollination by trapinstitute the second se be easily characterized by simple parameters. Taxonomy and biology are well known and quick evaluations can be done using the close correlation between the number of occupied nests and species richness. Species richness of trap-nesting bees and wasps was closely correlated with that sampled by sweep nets. Further criteria of the indicator method are (i) sampling over the whole vegetation period (ii) reproduction and not presence or absence of a species, thereby excluding short term visitors or tourists (iii) possibility of experimental manipulation of parameters such as orientation of nests and diameter of nest holes.

[0991] THE NESTING BIOLOGY OF EUFRIESEA VIOLACEA (HYMENOPTERA: APIDAE) IN TRAP-NES'TS

A. L. Gazola¹ & C. A. Garófulo², Faculdade de Filosofia Ciências e Letras de Ribeirão Preto – USP, Dept. de Biologia, Av: Bandeirantes 3900, CEP: 14040-901, São Paulo, Brasil, E-mail: ¹algazola@usp.br ²garofalo@ffclrp.usp.br

The nesting behavior of Eufriesea violacea was studied on the campus of the University of São Paulo, Ribeirão Preto, SP, Brazil, from October to December 1998. Trap-nests consisted of bamboo canes, which were cut so that the nodal septum closed one end of the cane. The canes were placed horizontally along two shelves in a shelter built near the laboratory. The bees (n=16) nested in bamboo canes ranging from 14.8 to 25.9 cm in length and from 0.9 to 1.8 cm in diameter. Space occupied by the nest within the trap was filled with small pieces of barks, firmly fused to one another with resin, and the cells were moulded within this substrate. The trips to collect construction material (barks + resin) lasted 2 to 45 min (n = 127), and the time spent by the female to deposit the material within the cavity ranged from 0.6 to 3.0 min (n=37). After the cell is built the female collects resin which is used to line the inner cell wall. Larval food (pollen + nectar) collecting trips lasted 50 to 160 min (n=41), and the food discharge into the cell lasted 0.9 to 3.5 min (n=69). The duration of cell provisioning ranged from 4 to 15 days (n=29), but 59% of cells were provisioned from 4 to 8 days. After finishing the provisioning, the female oviposits and immediately seals the cell by constructing the cell partition. After finishing the construction of the cell partition, the female repeats the same procedure until all the brood cells are built. The period in which a female remained nesting in the area ranged from 13 to 54 days and it was significantly correlated with the number of cells built (r=0.638; P< 0.05; n=15). The number of brood cells in each nest ranged from 1 (n=5) to 6 (n=1) arranged in a linear serie. Of the 16 nests obtained, 4 nests produced only females, 4 nests had only males, 3 nests both sexes, and in 1 nest the inimature was dead. Of the 4 remaining nests, dead immatures were found in nests that produced females (n=2), males (n=1) and both sexes (n=1). Of the 33 brood cells built in the 16 nests, 28 produced adult bees and 5 contained dead immatures from unknown causes. The sex ratio of 28 individuals emerging from the nests was 35.7% female to 64.3% male which is not significantly different from a 1:1 sex ratio ($x^2 = 1.75$; P> 0.05) In the nests that produced both sexes, males always emerged before females. The egg-to-adult period ranged from 311 to 345days for females (n=9) and from 303 to 341 days for males (n=16) indicating the occurrence of a single generation per year.

Index terms: Euglossini, bee, behavior.

[0990] MORPHOLOGICAL CHARACTERIZATION OF TWO PASSIFLORA SUBEROSA FORMS AND INFLUENCE ON HOST PLANT SELECTION BY HELICONIUS ERATO

<u>E. A. B. Gauer</u> & G. R. P. Moreira, PPG Biologia Animal, Depto de Zoologia, Inst. de Biociências, Univ. Federal do Rio Grande do Sul. Av. Paulo Gama, 40. Porto Alegre, RS, Brasil, Cep. 90.046-900, E-mail grpm@if.ufrgs.br

In South Brazil, there is a strong phenotypic variation within populations of Passiflora suberosa (Passifloraceae), as for example on leaf color, trichome density, toughness and shoot growth rates. Contrary to plants located under shade situation, which are green, those established in open areas are violet, grow slower and have tougher leaves, and greater trichome density. The latter form is apparently avoided for oviposition by females of Heliconius erato phyllis (Lepidoptera: Nymphalidae), to whose larvae P. suberosa is one of the preferred host. Thus, phenotypic variation in this passion vine populations could be caused at least in part by local changes in light intensity, and be associated with herbivory exclusion by H. erato phyllis, which are examined in this study. We grow P. suberosa under two light regimes (light and shadow), characterize the resulted phenotypic forms, and test the corresponding response by H. erato phyllis. The study was conducted under laboratory and insectary conditions with field collected adults of H. erato phyllis and transplanted plants of P. suberosa from populations of Porto Alegre County, Rio Grande do Sul State. To produce the shadow condition, potted plants were individually covered with a 50% plastic screen. Every 14 days during the summer, plants under light and shadow situations were compared regarding growth rates of shoots, and variation on leaf color, size, toughness, and on trichome density. Sequential and simultaneous choice experiments were performed under insectary conditions to determine the oviposition preference regarding the two P. suberosa forms. Under laboratory conditions, larvae were reared on green and violet shoots to evaluate the corresponding feeding consequences on growth rates and adult size. We confirmed field observations concerning the effects of light intensity on changes of P. suberosa phenotype from a typic green to a violet form. Also, H. erato phyllis females preferred to oviposit on green to violet shoots on both sequential and simultaneous choice trails. However, there was no effect on larval performance. Thus, the ultimate causes for the corresponding oviposition choice remain undetermined. Additional studies indicate there is no significant differences among these forms regarding their nutritional value for H. erato phyllis larvae. Also, that females select the two forms according to color, within the human visible spectrum, and that the violet aspect of leaves is related to presence of antocionins.

Index terms: phenotypic plasticity, host plant selection, oviposition preference

[0992] CHANGES IN THE DEVELOPMENT OF MOSQUITOES OF THE CULEX PIPIENS COMPLEX CAUSED BY HORMONES, TEMPERATURE AND POPULATION DENSITY

I. Gelbic¹ & J. Olejnícek², ¹Institute of Entomology AS CR, ²Institute of Parasitology AS CR, Branišovská 31, 370 05 Ceské Budejovice, Czech Republic, E-mail: gelbic@entu.cas.cz

Developmental changes were found in the laboratory populations of mosquitoes of the *Culex pipiens* complex - autogenous *C. p. molestus* Forskal and anautogenous *C. p. quinquefasciatus* Say. In both species reared in the water containing different concentrations of analogs of insect hormones (methoprene, hydroxycedysone) exhibited dose dependent toxic effects , effects on the delevelopment of larvae and malformations of pupue and adults. Analog of juvenile hormone caused prolongation of larval development. In various strains of *C. p. quinquefasciatus* and *C. p. molestus* of various geographical origin different sensitivity to the action of tested compunds was found. Developmental changes caused by insect hormones were accompanied by changes in hemagglutination activity in gut., namely in the adults obtained after application of JHA on the larvae of *C. p. quinquefasciatus*. Various strains of the same subspecies can significantly differ in the response on various temperature and density during the preimaginal development. They can maintain these discaracters for several years even if they are reared for long time in constant laboratory conditions. That is why, we can teoretically have a situation when two different populations of the same species can coexist in the field in the same locality, adults of which need not meet.

Index terms: Culex molestus, Culex quinquefasciatus, toxicity, vector, autogeny, anautogeny, development, hemagglutination activity

[0993] LIVING AT THE EDGE OF ICE: CARABID BEETLES IN AN ALPINE GLACIER FORELAND

B.-A. Gereben-Krenn¹ & H.W. Krenn¹, ¹Institute of Zoology, Univ. of Vienna, Althanstr. 14, A-1090 Vienna, Austria, E-mail Barbara-Antina. Gereben@univie.ac.at

Based on the alternating periods of climatic cooling and warming over geological time, the attendant changes of glacial advances and retreats can be determined. Most glaciers in the European Alps have been retreating since the maximum postglacial extension in the middle of the 19th century, although occasionally interrupted by short advances. The dramatic retreat of glaciers in the last ten years has opened up new area for the colonization of animals and plants. Glacier forelands are suitable for the study of colonization in expanding high-altitude habitats, their primary succession and the underlying factors and mechanisms. In the Hornkees glacier foreland (Zillertal Alps/Austria) the first investigation of the succession of the arthropod fauna dates back to the middle of the 20th century. These studies showed that carabid beetles are one of the major epigean arthropods. In a second phase of investigation, between 1986 and 1988, distribution patterns of carabid beetles were assessed in more detail for this particular glacier foreland. Among the Carabidae, species of the genus Nebria are found to be the first colonizers of new alpine area after glacier retreat. The six Nebria-species, which were dominant within the ground beetle assemblage of the Hornkees glacier foreland in both the number of species, as well as in the number of trapped individuals, provided an excellent opportunity to investigate the co-existence of taxonomically closely related carabid beetles in the high-mountain region. The study focused on aspects of habitat and microhabitat use of the adults and larvae, phenology and diel activity. Each of the Nebria-species was most active, both as adults and larvae, in different areas within the glacier foreland characterized by distinct geomorphological and ecological conditions. The most recent investigation in the Hornkees glacier foreland were carried out in the year 1999. The glacier has retreated more than 100 m in the last ten years. The youngest ice-free area is limited by a characteristic end moraine. Five Nebria-species co-exist in an area immediately below this end moraine but only two Nebria-species were found in the newly exposed area above the end moraine. Comparative investigation of the distribution patterns and environmental factors in the various areas within the Hornkess glacier foreland allow us to conclude that habitat selection seems to be a major mechanism for the colonization and co-existence of carabid beetles of new alpine areas

Index terms: Nebria, Carabidac, co-existence, colonization

109941 AGE-SPECIFIC LIFE TABLE OF LIPAPHIS ERYSIMI (HOMOPTERA: APHIDIDAE) UNDER FIELD CONDITIONS

K. B. Godoy¹ & F. J. Cividanes¹, ¹ Dep. de Fitossanidade. Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, s/n. Jaboticabal, São Paulo, Brazil. 14870-000, Email karlla@fcav.unesp.hr, CNPq Fellowship.

This work was developed in the experimental area of the Departamento de Horticultura, Faculdade de Ciências Agrárias e Veterinárias, Universidade Estadual Paulista, Jaboticabal, SP, Brazil, during the winter (August 13th, 1998 – February 22th, 1998) and summer (February 15th, 1999 – March 3th, 1999). The aphid *L. erysimi* was reared in kale, Brassica oleracea L. var. acephala, aiming the development of age-specific life tables, which are fundamental for to understanding the population dynamics of this insect pest. The results showed that the net reproductive rate (Ro) was larger in the winter (53.50) than in the summer (40.99), the same being observed with the mean generation time (T), which was 13.85 days for the winter and 7.57 days for the summer. The intrinsic rate of natural increase (r_m) and the finite rate of increase (λ) were 0.29/1.34 and 0.40/1.63 for winter and summer, respectively. The doubling time (DT) observed in the winter (2.39 days) was larger than the one observed in the summer (1.41 days).

Index terms: Insecta, ecology, population dynamics, Brassica oleracea

[0995] THERMAL REQUIREMENTS AND PREDICTION OF POPULATION PEAKS OF LIPAPHIS ERYSIMI (HOMOPTERA: APHIDIDAE)

K. B. Godoy¹ & <u>F. J. Cividanes¹</u>, ¹Dep. de Fitossanidade. Univ. Estadual Paulista, Via de Acesso Prof. Paulo Donato Castellane, s/n. Jaboticabal, São Paulo, Brazil. 14870-000, Email karlla@fcav.unesp.br, CNPq Fellowship.

The kale (Brassica oleracea L. var acephala) is attacked by several aphids species and Lipaphis erysimi is one of the most important of them. The determination of thermal requirements of pests provide a better understanding of the population dynamics of insects by allowing the prediction of population under field conditions. This work was developed at the laboratory of Insect Ecology of the Departamento de Fitossanidade and at the experimental area of the Departmento de Horticultura, Faculdade de Ciências Agrárias e Veterinárias, Universidade Estadual Paulista, Jaboticabal, SP, Brazil, during the period from October 1998 to August 1999. The aphid was reared in kale aiming to estimate its thermal requirements. For this, L. erysimi was studied under laboratory conditions, using incubators adjusted to 10, 15, 20, 25 and 30°C, 14 hours photophase and 70±10% RH. The lower developmental thermal threshold found was 3.04°C and the thermal constant 132.21 degree-day. The prediction of adult occurrence in the field was done using the triangulation method and the results showed that the predicted populational peak occurred 0-1 day before the observed dates in the field.

Index terms: Insecta, temperature, degree-day, thermal threshold, Brassica oleracea

[0996] INSECTS AS BATS' PREY: A CASE STUDY ON KUHL'S PIPISTRELLE (PIPISTRELLUS KUHLII)

U. Goiti, P. Vecín, I. Garin, J. R. Aihartza & M. I. Saloña, Dept. Zoología y Dinámica Celular Animal, Fac. Ciencias, Univ. País Vasco - Euskal Herriko Unibertsitatea, Apdo. 644 - Leioa, 48080 Bilbao, España, E-mail zopsabom@lg.ehu.es

Insects are known as basis of the diet of many bat species. Recently, several studies have pointed out specificity and seasonal changes of diet (Vaughan, 1996). This study has focused on *Pipistrellus kühlii*, a species of subtropical origin, which shows a southern distribution in Europe. This work was carried out from May to October 1999 on a breeding colony roosting in our university campus. Previous surveys of this species delimited 2 main activity areas for this colony: the campus itself and a reservoir close to the University. In both areas, we used Malaise traps every month during one night to collect insects and determine prey availability. The next day, faecal pellets were picked up on the floor beneath the nursery: 20 drops were selected randomly for analysis. Cuticle fragments found in them were compared with insects collected in the activity areas and identified, at least, to order level. Preliminary results of this research show that diet changes monthly and it seems to be not related with prey availability. Diptera are the most abundant insects collected by Malaise traps, especially Chironomidae, Cecidomyiidae and Psychodidae (moth flies mainly in May and June). Nevertheless the main groups identified in faceal pellets during the whole period were Lepidoptera and Diptera (mainly Culicidae). However, the presence of a species of a Coleoptera Scarabeidae (*Rhyzotragus* sp.) was remarkably predominant in May drops. Oth , taxa that appeared also, but in lower abundance, were Hymenoptera (Aphidiidac), Neuroptera (Hemerobiidae), Psocoptera (Stenopsocidae), Heteroptera (Acanthostomidae), Trichoptera (Beraeidae) and and Ephemeroptera. Other Arthropoda have been found although sporadically in bat drops such as isolated mites, probably parasites of fed diptera and of bats themselves ingested while grooming, and spiders.

Index terms: trophic, phenology, prey selection, Chiroptera

Symposium and Poster Session

[0997] DO INSECTS CONTRIBUTE TO LENGA (NOTHOFAGUS PUMILIO) DECLINE? A STUDY IN TIERRA DEL FUEGO, ARGENTINA

<u>C. A. Gomez</u>, Patagonian Andes Forest Research and Extension Center (CIEFAP), P.O. Box 14, 9200 Esquel, Chubut, Argentina, E- mail: cecilia@ciefap.cyt.edu.ar carabell@teletel.com.ar

Lenga is the most important ecological and economic native forest species in the patagonian region of Argentina. However, timber exploitation is mainly affected by the occurrence of white and brown rots in the heartwood that determine a poor sanitary condition as they decrease the stability of trees, their quality and wood value. Primary insects also contribute to the loss of vitality in trees. To improve the knowledge on the relationship between insects and fungi, the role of insects in diminishing the vitality of lenga was studied. 39 trees were selected, 18 of them unhealthy and 21 healthy, according to their external good commercial qualities. As no intense defoliations were registered in the study area, every branch were examined in detail looking for sapsuckers and phloem and wood horer insects. Sections of attacked branches were left in the field under caged conditions to report the emergence of adults. It was characterized the length, form, position and direction of the founded galleries just as colour, form and structure of the sawdust. Although primary insects and phloem borers were not registered on crowns, we could characterize aspects of the biology of Microplophorus magellanicus, a cerambycid boring beetle in rot wood, which was registered on 72% of studied crowns. The larvae of this species live within the brown rotted heartwood, following fungi in the colonization process. These rots define the extent of galleries that generally are related to dead branches and wounded bark, as it occurs with fungi.

Index terms: *Microplophorus magellanicus*, brown rot, fungus-insect relationship, loss of vitality.

[0999] DO HOST PLANT TRAITS AND GALLING INSECTS AFFECT THE ABUNDANCE OF ISSUS SP. ON COLLIGUAJA ODORIFERA ALONG AN ALTITUDINAL GRADIENT?

W. L. Gonzáles¹, R. Fernández² & H. M. Niemeyer¹, ¹Laboratorio de Química Ecológica, Departamento de Ciencias Ecológicas, Facultad de Ciencias, Univ. de Chile, Casilla 653, Santiago, Chile, willy@abulafia.ciencias.uchile.cl, ²Laboratorio de Ecofisiología, Area de Biodiversidad Animal, Facultad de Ciencias Naturales y Matemáticas, Univ. Nacional Federico Villarcal, Lima-Perú, rosariofi@hotmail.com

The common shrub Colliguaja odorifera is distributed between 600 and 1200 meters above sea level, and is scarcely attacked by folivorous insects but strongly attacked by gall makers. Previous work has focused on different aspects of the relationship between galling insects and C. odorifera, emphasizing the relevance of plant traits and the influence of altitudinal gradient. However, a common jumping hemiptera, Issus sp. closely associated to C. odorifera, has been poorly studied. In this work, the pattern of abundance of Issus sp. on C. odorifera growing at two contrasting sites was evaluated in relation to plant traits (fruits, flowers, buds, plant size and cover) and galling insect abundance. Two contrasting sites, at low (850 m.a.s.l.) and high (1150 m.a.s.l.) altitudes, were studied. At the low site, the number of fruits and buds, cover and plant size were larger (t-test, p < 0.05, for each trait) than in the high site. The number of galling insects and isids was higher in the low site. The ratio of isids to galls was not significantly different in low and high sites. The ratio of fruits to isids was significantly larger in the low site (t- test, p < 0.05) than in the high site. Using multivariate approaches to each site, plant cover was significantly (F2.97 =4,89, p<0.01) and positively associated with isid abundance in the low site, whilst at the high site the number of fruits was significantly ($F_{3,36}$ = 3.18, p < 0.05) and positively associated with isid abundance. The effects of plant phenology and presence of galls on isid abundance are discussed in terms of population dynamics of the insect species envolved.

Index term: Issus sp, Colliguaja odorifera, herbivores, altitudinal gradient

[0998] EFFECT OF CATERPILLARS AND DEFOLIATION IN OVIPOSICION OF PLUTELLA XYLOSTELLA

A.H.R. Gonring¹, M. Picanço¹, R.N.C. Guedes¹ & A.L.B. Crespo¹, ¹ Dept. de Biol. Animal, Univ. Fed. de Viçosa, CEP 36571-000, Viçosa, MG, Brazil, E-mail: gonring@alunos.ufv.br.

This greenhouse work was led in the Federal University of Viçosa, at Viçosa, State of Minas Gerais from May to June, 1999. During the experimental period the temperature ranged between 25.5 \pm 3.5°C, 75 \pm 5% of relative humidity and 10 hours photofase. Twenty four hours before the installation of the bioensay hybrid Astrus cabbage plants were infested with 2, 4, 8 and 16 caterpillars of Plutella xylostella (Lepidoptera: Yponomeutidae) of he fourth instar/leave, to produce different rates of defoliation. The experimental design was in blocks randomized with 10 treatments and four repetitions. The treatments were established in factorial outline 2 x 5 (caterpillars presence or not x defoliation levels). In leaves with three 4th instar caterpillar placed/leaf. Initial levels of defoliation ranger between 0 and about 1.60, 2.54, 4.61 and 7 cm²/leaf. The experimental portion was constituted by a glass of 200ml sealed with cotton and parafilm containing cabbage leaf with submerged peciole in water. Each block was constituted by wood cage 1.0 x 0.9 x 0.5m covered with organdy cloth. The portions were distributed equally distant from each other inside each cage. For the bioensay installation 300 non sexed adults of P. xylostella up to three days of life, raised in laboratory were released in the cage. The counting of P. xylostella eggs on cabbage leaves took place 24 hours after exposure to this insect. After the bioensay the contour of the defoliation was copied in paper white A4 of 72 g/m^2 density. Contours were cut out and their areas were measured three times in portable apparel of measurement of areas. The average of these evaluations was taken as the defoliated area. Experimental data was submitted to the covariance analysis and of regression p < 0.05. Larger number of eggs of P. xylostella cabbage leaves was verified with the increase of the rate of defoliation caused by this insect (p < 0.0001; $R^2 = 0.4335$; n = 40). The effect of caterpillars was not detected on the oviposicion of this species after 24 hour defoliation (F = 0.24; p = 0.6292).

Index terms: Insecta, behavior, diamondback, Brassica oleraceae var. capitata.

[1000] COMPARISON OF SENSITIVITY TO COLD IN SOUTH AMERICAN FRUIT FLY AND MEDFLY (DIPTERA: TEPHRITIDAE)

M.C.Gramajo¹, G.Gastaminza¹, <u>E.Willink¹</u>, A.R.Salvatore¹, M.B.Carrizo¹ & A.Macián¹, ¹Estación Experimental Agroindustrial Obispo Colombres, C.C.n^o 9, Las Talitas, (4101) Tucumán, Argentina. E-mail: saneeaoc@tucbbs.com.ar.

The presence of the South American fruit fly Anastrepha fraterculus and the medfly Ceratitis capitata in citrus groves in Argentina has imposed trade restrictions on the commercialization of fresh fruit to countries free of those pests. Such countries demand the implementation of measures to avoid the introduction of the fruit flies into their territory. Exposure to cold is one of postharvest treatments most often used to eliminate fruit fly immatures in citrus fruits. The USDA has determined the number of days at different low temperatures necessary to satisfy quarantine requirements for various fruit fly species. At a temperature of 1,66°C fourteen days are required to eliminate *C.capitata*, 22 days for A.ludens and 17 for other Anastrepha species. However, no cold sensitivity tests have been made for A. fraterculus. The objective of this research was to compare the cold sensitivity of A. fraterculus and C.capitata in oranges in northwestern Argentina. Third instar larvae were used in the tests because they are the life history stage which best tolerates low temperatures. The larvae were obtained by rearing in the laboratory. Each test included 10 different exposure time treatments of 8 inoculated fruits, and was repeated 3 times. Eighty eight Valencia Late orange fruits were inoculated with 35 larvae each, kept for 24 hours at 25°C, and then placed in a cold chamber at 2±0,5°C, to which 12 noninoculated fruits with sensors were added in order to verify the flesh core temperature. The cold treatment started when more than 6 sensors showed 2°C or less. Eight fruits were The cold from the cold chamber after 4,6,8,10,12,14,16,18,20 and 22 days, respectively. These were left for 48 hours at 25°C, and then were evaluated for live and dead fruit fly larvae. The mortality data were analysed using the Probit method, establishing the lethal time (LT) 50 and 99, with their respective confidence intervals. The overlap of the LT 50 confidence intervals shows that there is no significant difference in tolerance to cold between the 2 fruit fly species. The same occurs for the LT 99 confidence intervals. After 20 days exposure to cold no live larvae of either species were found. It is thus evident that the cold treatment currently used for C.capitata also guarantees total elimination of A fraterculus.

Index terms: Anastrepha fraterculus, Ceratitis capitata, quarantine.

[1001] PLANT PATCH SHAPE AND SURROUNDING VEGETATION AFFECT THE POPULATION DYNAMICS OF PREDATORY AND HERBIVOROUS INSECTS

A. A. Grez¹ & E. Prado², ¹Facultad de Ciencias Veterinarias y Pecuarias, Universidad de Chile, Casilla 2, Correo 15, La Granja, Santiago Chile, E-mail agrez@abello.dic.uchile.cl; ²INIA La Platina, Santiago, Chile, E-mail eprado@platina.inia.cl. Funded by FONDECYT 1970853

We assessed the effect of plant patch shape and surrounding vegetation on the density, emigration, and immigration of predatory coccinellids, and on the density of their prey, Brevicoryne brassicae. Between spring 1997 and fall 1999, we set up square and I-shaped patches of Brassica oleracea surrounded by Medicago sativa or Allium porrum. Medicago sativa was considered more permeable to coccinellids than A. porrum based on the former's greater use by coccinellids. We used a factorial (2 shapes x 2 surrounding vegetations) randomized block design, and evaluated the density of coccinellids and aphids every 10 d. We also evaluated emigration and immigration of adults coccinellids through mark-recapture experiments. We quantified the population increase of aphids, and the final weight of plants. All insects were more abundant in patches surrounded by A. porrum than in those surrounded by M. sativa, and coccinellids were occasionally more dense in square patches than in I-shaped ones. Coccinellids emigrated less from square patches, either surrounded by A. porrum or M. sativa, and immigrated more to patches surrounded by A. porrum, particularly square ones in the case of E. connexa. Aphids had a higher population increase, and plants of B. oleracea ended to be heavier in patches surrounded by A. porrum, particularly in I-shaped patches. Surrounding vegetation and plant patch shape seem to have a direct effect on the density of coccinellids by modifying their immigration and emigration patterns, but also seem to have an indirect effect resulting from changes in plant growth and its effect on herbivorous recruitment.

Index terms: Eriopis connexa, Hippodamia variegata, Brevicoryne brassicae, patch geometry, edge permeability.

[1002] RESPONSES OF AQUATIC INSECTS TO AN ENVIRONMENTAL STRESS GRADIENT

C. M. Gualdoni[†] & <u>M. del C. Corigliano[†]</u>, ¹Dpto. Ciencias Naturales, Universidad Nacional de Río Cuarto, Ag. Postal 3, X5804 BYA - Río Cuarto, Argentina. E-mail: mcorigliano@exa.unrc.edu.ar.

Lotic communities structure changes from the headwaters to the mouth of river systems in response to physical, chemical and hydraulic conditions of natural or anthropogenic origin. Organic pollution generally reduces insect diversity. However, since some species benefit from the increased supply of food, the numbers of macroinvertebrates may increase. The aim of this study was to analyze the benthic and drifting insects response to organic contamination, in a fluvial system which receives a sewage discharge. Along the Chocancharava river basin (Córdoba, Argentina) benthos and drift were sampled at 10 sites, for two years in high and low water level conditions. Application of the TWINSPAN program to the data set suggested that benthic and drifting fauna was distributed in characteristic groupings of rhithron, foothill and potamon reaches, where insects showed the higher densities and species richness. Baetis sp.1, Camelobaetidius penai, Paracloeodes sp., Leptohyphes sp., Tricorythodes sp. and other less frequent Ephemeroptera species contributed with more than the 75% of insect fauna. A gradual change in community structure and composition was observed until the sewage discharge site, where abrupt changes were produced. Immediately downstream from the release, the abundance of Chironomus sp., Nematoda, Nais variabilis and Limnodrilus hoffmeisteri increased, while non-Diptera insects were absent. Downstream of the polluted stretch Chironomidae was dominant in benthic community, the densities of Nematoda and Oligochaeta decreased and Ephemeroptera incremented again. Besides, in the drift fraction the contribution of non-insect groups continued being important. Abundance and composition of both fractions were similar in two flow conditions, except in the perturbed reach, where there were alterations during low water flow periods. The environmental stress produced by sewage effluent limited the insect densities and favored the population expansion of tolerant organisms to low oxygen concentrations. However, the disturbance only affects few kilometers. Although the abundance of insects drift decrease at the impact site, there is a fraction that surpassed it, demonstrating that drift would be an adequate mechanism to transpose ecological barriers such as polluted stretch. Recuperation of benthic community would be favored by the energy subsidy produced by the increment of organic material and by the recolonization mechanisms like drift and migrations from hyporreos.

Key-Words: Baetis sp.1, Camelobaetidius penai, Paracloeodes sp., Leptohyphes sp.

[1003] PHENOLOGICAL INTERACTIONS BETWEEN THE WEEVILS EXAPION SPP. AND LEPIDAPION SPP. AND THE GENISTEAE IN CENTRAL SPAIN (SW EUROPE)

<u>P.Gurrea¹</u>, M. J. Sanz² & Y. Jiménez¹, ¹Dept. de Biología, Univ. Autónoma de Madrid, Cantoblanco, 28049 Madrid, Spain, E-mail pilar.gurrea@uam.es; ²Fac. de Biología, Univ. Internacional SEK, c/. Cardenal Zúñiga, 12, 40003 Segovia, Spain.

Larvae and adults of weevils belonging to genus *Exapion* and *Lepidapion* (Coleoptera, Curculionoidea) feed on different parts of their host plants. Adults are leaf-eaters whereas larvae feed on seeds and flowers. In this work different behaviour patterns of eight weevils species (*Exapion compactum*, *E. fuscirostre*, *E., laufferi*, *E. putoni*, *Lepidapion argentatum*, *L. cretaceum*, *L. gallaecianum* and *L. squamidorsum*) are shown, which have been found on seven species of Genisteae in the Iberian Peninsula (*Genista florida*, *G. cinerascens*, *Adenocarpus complicatus*, *Echinospartum barnadessi*, *Retama sphaerocarpa*, *Cytisus scoparius* and *C. oromediterraneus*). By studing the insects phenology we have found that adults have two annual population maxima, one of them in spring time and the other one at the end of the summer. The species whose larvae are flower-eaters have the first population maxima at the beginning of the spring, whereas in the species whose larvae are seed-eaters this peak takes place in the middle of the spring. When we compare the insects phenology to their host plant phenology we find a narrow relationship between both. Index terms: Curculionoidea, seed-eaters, flower-eaters, host-plant

[1004] SPATIAL DISTRIBUTION OF INMATURE STAGES OF THE SWEETPOTATO WHITEFLY (BEMISIA TABACI) IN SESAME (SESAMUM INDICUM)

H. E. Laurentin¹ & <u>C.J. Pereira</u>², ^{1,2} Departamento de Ciencias Biológicas. Decanato de Agronomía. Universidad Centroccidental "Lisandro Alvarado". Apdo. 400. Barquisimeto, Lara, Venezuela. E-mail: helauren@yahoo.com entm96@hotmail.com

To estimate within plant distribution of eggs and nymphs of *B. tabaci* on six sesame genotypes, field studies in Turen, Portuguesa state, Venezuela were established in 1998 and 1999, using complete randomized block designs, four times replicated. Treatments consisted of all combinations of genotypes, three plant sampling strata (apical, medium, and basal), six sampling dates, and two years of evaluations. After natural infestations of experimental plot by *B. tabaci*, five leaves per stratum were weekly removed from each experimental plot during six consecutive weeks. Leaf area, number of eggs (H), and number of nymphs (N) were recorded for each leaf and transformed using a log transforming factor [In (x+1)] to conduct statistical analyses. A significant genotype x stratum interaction (P < 0.01) was detected for H and N, indicating differential variability of these forms in each stratum along genotypes. A three way significant interaction (genotype x stratum, likewise, in all combinations the basal stratum, showed greater values of N than the basal stratum, likewise, in all combinations the basal stratum showed greater values of this variable than the apical stratum on sesame plants, which indicates what leaves should be taken to estimate its population in sesame.

Index terms: Bemisia tabaci, Sesame, Within plant distribution.

[1005] COMPARATIVE BIOLOGY OF ANAGASTA KUEHNIELLA (LEPIDOPTERA, PYRALIDAE) FED ON THREE DIFFERENT DIETS BASED ON WHEAT GRAINS

M. E. M. Habib¹ & <u>F. Cabral²</u>, ¹ Dept. Zoology, IB, University of Campinas (UNICAMP), SP, 13083-970, Brazil; ² Dept. Parasitology, IB, University of Campinas (UNICAMP), SP, 13083-970. E-mail: fcabral@obelix.unicamp.br.

Biological informations about insect pests are necessary to develop successful IPM strategies. Like all the other animals, insect reproduction and development are directly influenced by the quality, as well as the quantity, of the available dict. The present study was conducted to, comparatively, study the biology of Anagasta kuehniella, reared on three distinct diets, all based on wheat grains: whole meal flour, grain germ and bran. The mated adult activities, investigated in 40 pairs per diet, included reproductive performance, longevity and duration time of its different phases. Concerning the unmated adults (n = 80), only longevity of both sexes was determined. The biology of the immature stages was undertaken investigating 250 individuals in each diet. The whole meal flour, utilizing the different biological indicators, showed to be the most adequate for the development of the immature stages. While the germ dict occupied an intermediate position, the bran one showed to be the worst. Under 25° C, 70% RH and 12 kr photo-period, the larval stage lasted an average of 29.41 ± 0.121; 37.38 ± 0.1.13 and 71.21 ± 1.72 days for whole meal flour, germ and bran diets, respectively. For these diets, and in the same sequence, the prepupal stage lasted 2.45 \pm 0.06; 1.86 \pm 0.06 and 7.16 \pm 0.25 days. The pupal one completed its development after an average of 11.35 \pm 1.16; 17. 40 \pm 0.63 and 17.30 \pm 0.07 days, respectively in the same sequenced diets. The natural mortality during the larval stage of the individuals reared on bran was more than 3 times higher than that of those reared on the other two diets, possibly due to its physical structure or hardness. In spite of its high energetic value, the bran inadequacy resulted also in the lightest pupae weight, in comparison with the other dists. The unmated adult longevity was shown to be higher that that of the mated ones, independently of sex or larval diet. In all cases, the male longevity showed to be higher than the female one. The number of eggs deposited per female, showed to be a good biological indicator to evaluate the efficiency of larval diets. While the adults, emerging from bran diet, deposited an average of 55.97 ± 7.68 eggs / female, those from the whole meal flour and germ diets produced an average of 175.9 ± 12.14 and 158.0 ± 3.96 eggs per female, respectively.

[1006] EL NINO, LA NINA AND BROWN LOCUST PLAGUES

<u>S.A. Hanrahan</u>, Dept. of Animal Plant & Environmental Sciences, Univ. of the Witwatersrand, WITS 2050, South Africa. E-mail shirley@gecko.biol.wits.ac.za

Rainfall is a key factor in the factor in the hatching of grasshopper and locust eggs. The brown locust, Locustana pardalina appears to have a regular cycle of swarming and nonswarming events. These have been recorded since 1910. The recording of actual locust numbers has never been attempted. The number of swarms destroyed have been recorded for each magisterial district. The records were kept to repay farmers and others for swarm control. The government provided the poison and paid for mileage. Swarming behaviour develops as the drought periods common to this country began to wane. L. pardalina is particularly well adapted for living in dry conditions. For example, females will lay eggs in dry soil where most other species require damp soil, the eggs can with stand high levels of desiccation and are capable of surviving long periods in a quiescent state. L. pardalina seems to be constantly ready to exploit favourable conditions. It has been shown that southern Africa has a rainfall pattern that is influenced by the Southern Oscillation . The central Karoo region, a semi-arid area where drought periods alternate with above average rainfall is the outbreak area of the brown locust. Southern Oscillation variations here are linked to El Nino cycles but the connections are tenuous. During the El Nino years southern Africa experiences drought or below average rainfall in the low phase of the Southern Oscillation. During the high phase above average rainfall would be expected . It yould seem intuitive that locust outbreaks or irruptions and recessions would link with La Nina and El Nino events. A simple comparison of locust outbreaks as measured by number of magisterial districts recording swarm destruction and lull periods with no locust activity shows a strong correlation with the timing of La Nina and El Nino events. Index terms: Locusta pardalina, brown locusts, swarming, El Nino,

[1007] ADAPTIVE CASTE MANIPULATION BY A POLEMBRYONIC PARASITOID WASP

<u>LA. Harvev^{1,2}</u>, Laura Corley¹ & M.R. Strand¹, ¹Department of Entomology, University of Wisconsin-Madison, Madison, WI 53706 USA; ²Centre for Terrestrial Ecology, Netherlands Institute of Ecology, P.O Box 40, 6666 ZG Heieren, The Netherlands, E-mail harvey@cto.nioo.knaw.nl

One of the most important transitions in insect life history evolution has been a shift from a solitary to a social lifestyle, where groups of specialized individuals (or castes) live together but perform different functions. Among caste forming insects, some individuals reproduce whereas other castes produce few or no offspring, but instead adopt worker functions, such as foraging and defense. Caste formation occurs in a diverse range of inzect groups, from ants and termites to thrips, aphids and polyembryonic wasps. The evolution of specialized castes is determined by natural selection acting at the both the level of the individual and the colony. Consequently, investment into different castes is predicted to be influenced by a range environmental factors, including resource availability, predation and competition. However, at present only limited evidence in the occurrence of adaptive shifts in caste ratios has been obtained. This is partly because it is difficult to manipulate factors influencing caste development, and also because workers of some eusocial species may switch tasks in response to short-term emergencies. Unlike other caste-forming species, the castes of polyembryonic wasps develop clonally, meaning that the increased production of one caste likely results in decreased production of the other. Because of their ability to manipulate the restricted host environment, combined with the absence of task switching, polyembryonic wasps make excellent subjects for studies of caste ratio evolution. Here, we report that the polyembryonic wasp, Copidosoma floridanum, is able to facultatively adjust caste ratios in response to competition by a solitary endoparasitoid, Microplitis demolitor. Our results reveal a classic trade-off between reproduction and defense, and further suggest that polyembryonic wasps like C. floridanum possess the ability to adaptively adjust caste ratios.

Index terms: Copidosoma floridanum, Microplitis demolitor, Pseudoplusia includens, parasitoid, caste induction

[1008] TOP-DOWN AND BOTTOM-UP CONTROL OF INSECT POPULATIONS: INTRODUCTION TO THE PROBLEM

B. A. Hawkins, Department of Ecology & Evolutionary Biology, University of California, Irvine, CA 92697, USA, E-mail: bhawkins@uci.edu

The issue of the relative impacts of foodplants and natural enemies on herbivorous insect populations has a long history in pest management. Biological control in particular is founded on the presumption that top-down effects are strong and widespread, and successes in biological control are commonly used to support the hypothesis that natural enemies are primarily responsible for the regulation of insect populations. However, this is true only if biological control and 'natural control' are synonymous. In this introduction to the symposium I will sketch a brief history of the problem and will assess the evidence that biological control actually reflects a reestablishment of the 'natural balance' that is thought to be lacking in pest situations.

Index terms: Biological control, natural enemies, natural control

[1009] DISPERSAL OF AN ERIOPHYID MITE, THE WHEAT CURL MITE, AND ITS IMPORTANCE IN DISEASE EPIDEMIOLOGY

G. L. Hein¹ & J. A. Thomas¹,¹Univ. of Nebraska, Panhandle Research & Eztension Center, 4502 Ave. I, Scottsbluff, NE 69361, USA, E-mail: GHEIN1@UNL.EDU.

The wheat curl mite Aceria tosichella transmits two viruses to wheat in the Great Plains of North America. These viruses, wheat streak mosaic virus and high plains virus, form a complex that is the most important disease problem to wheat in the western plains. The mites colonize winter wheat through most of the growing season. However, the key to disease epidemiology is the over summering period from wheat harvest in summer until emergence of the winter wheat in the fall. For disease problems to develop, mite populations must survive this period on over summering hosts. The most serious host for developing disease epidemics is volunteer wheat resulting from hailstorms. Hail shells out mature wheat from the heads, and it rapidly germinates and grows. This volunteer wheat provides a perfect 'green bridge' for the mites and virus to survive through the summer. Control of this volunteer is the major management objective in managing this disease. Other summer hosts are present in the region including crops such as corn, foxtail millet, spring wheat and barley and a number of grass hosts that include grass weeds and range and pastures grasses. Because of the tiny size of these mites, extensive study of their behavior and ecology has been limited. The objective of our research has been to try to understand the population dynamics of the wheat curl mite and its potential for dispersing into wheat from various over summering hosts. The mite has mostly been considered capable of dispersing only short distances (i.e. field to field). However, our recent surveys of virus diversity indicate virus variation between locations (counties) within a state is not great enough to detect differences in virus types, thus indicating population mixing. Host plant and genetic data indicate that regional (state to state) differences exist in mite populations. Studies on the survival of mites when held off the plant indicate relatively short survival (<24hrs), but at lower temperature and higher humidity conditions they can survive up to 3-4 days. These survival levels indicate potential for greater than field to field dispersal activity. Studies on the initiation of mite movement from wheat hosts show movement to be a function of the number of mites present rather than plant condition; however, as plant condition worsens the proportion of mites moving increases. The extent of movement from host plants depends on mite survival on the host plant, the growth patterns of the host plant, and the seasonal population dynamics of the mite in the agroecosystem. These factors make rotational and cropping systems important to the epidemiology of this disease complex.

Index terms: Aceria tosickella, wheat streak mosaic virus, high plains virus, movement

[1010] DISTRIBUTION OF THE HORSE-CHESTNUT LEAFMINER, CAMERARIA OHRIDELLA (LEPIDOPTERA, GRACILLARIIDAE) IN THE REGION SOUTH-TYROL – TRENTINO (NORTH EASTERN ITALY)

K. Hellrigl¹ & <u>P. Ambrosi</u>², 'Ripartizione Foreste Provincia Autonoma di Bolzano, Via Brennero 6 I-39100 Bolzano, Italy; 'Istituto Agrario di San Michele all'Adige, Via E. Mach 1 I-38010 S. Michele a/Adige (TN), Italy; E-mail: paolo.ambrosi@ismaa.it.

The horse chestnut leafmining moth (Cameraria ohridella Desch. & Dimic 1986), recently introduced in Central Europe, was observed for the first time in Italy in 1995 in South-Tyrol and Julian-Venctia. Over the last five years, this pest has invaded an area in north Italy about 50.000 Km². Its occurrence causes heavy defoliation on the main host, horse chestnut (Aesculus hippocastanum L.), with serious consequences on plant health and the environment. A survey on the present distribution of C. ohridella, in Italy and in Europe is shown. The progression of the distribution in the region of South Tyrol - Trentino is reported. In the province of Bozen-South Tyrol, between 1995 and 1999 the moth has spread in all three main valleys (Eisacktal, Pustertal, Etschtal). In Trentino province, local attacks began only in 1998, near Trento and Riva del Garda, but spread over the entire Etschtal/Adige Valley in 1999. While in South Tyrol C. ohridella was introduced from the north (North Tyrol), the introduction into Trentino occurred from the south (Verona). At present the attacks in Trentino have a relatively low impact and are serious only in the city of Trento and Riva del Garda. So far, the attacks are limited in a range of altitudes from 70 to 700 m a.s.l. In South Tyrol, attacks are more damaging in a range from 250 to 900 m a.s.l., while they decrease between 1,000 to 1,230 m. A survey was taken in the region and attack intensity and other parameters are given. The number of generations per year depends on climatic conditions: in lower altitudes, usually three generations develop in a year, but in higher altitudes, 800 to 1,100 m, only two generations; in the climatically favoured area around the Garda Lake a partial fourth generation appears possible. The question of host plants (Aesculus sp., Acer sp.) and the larval parasitism of C. ohridella is discussed. The parasitism of the larvae, principally by Eulophidae (Hym., Chalcidoidea), was ascertained already in the first years of attack. In South Tyrol, sixteen species of parasitodes are present, and eight in the Trentino, but only two species were dominant: Minotetrastichus sp. and Pnigalio sp. The level of parasitism reached was relatively low, comparable to other Central European countries.

Index terms: biology, Aesculus sp., parasitism.

[1011] SOUTHERN CORN ROOTWORM: BIOLOGY AND MANAGEMENT IN PEANUT

D. A. Herbert, Jr.¹ & R L. Brandenburg², 1Virginia Polytechnic Institute and State Univ. Tidewater Agric. Res & Ext. Ctr. 6321 Holland Rd. Suffolk, VA 23437 USA; 2North Carolina State Univ. Dept. of Entomol. Raleigh, NC 27695 USA

The southern corn rootworm (SCR), Diabrotica undecimpunctata howardi Barber, is a primary pest of peanut, Arachis hypogaea L., in the United States, especially in Virginia and North Carolina, and occasionally in South Carolina, Georgia, Alabama and Texas. Larvae injure peanut by feeding on developing pods causing direct yield loss, or cause indirect loss by allowing entry of secondary pathogens. Pod yield losses in Virginia have been reported to range from 100 to 500 kg/ha and exceed 1000 kg/ha (30% of total yield) been reported to range from two to so right and exceed two kgrint costs of total yield) in extreme cases. Current management is based on preventive application of soil insecticides (chlorpyrifos, phorate) against larval populations. The development of alternative management strategies has been difficult as SCR undergos several overlapping generations each year, adults feed on hundreds of different host plant species, and larvae which feed underground are difficult to detect and current soil sampling procedures are too labor intensive to be adopted by producers. Also, by the time large numbers are detected, it is essentially too late to apply remedial insecticide treatments. Therefore, producers must make insecticide treatments as 'preventives' with little knowledge of actual pest abundance or likelihood of crop loss. Efforts to monitor or control adults using traps baited with female sex pheromone (10-methyl-2-tridecanone), TIC (1,2,4-trimethoxybenzeae, indole and trans-cinnamaldehyde) or attractants impregnated with carbaryl as a toxicant have not proyen successful. Efficacy is poor and pod damage is unaffected compared with standard larval insecticide treatments. A risk index has been developed that predicts level of pod damage and the relative need for insecticide treatments using factors that affect SCR survival and ability to inflict pod damage: soil texture, soil drainage class, variety, planting date, and field history of crop damage. Field validations from 1989-1999 in producers' fields show that the index can reduce the need for insecticide without loss of vield.

Index terms: Diabrotica undecimpunctata howardi, Arachis hypogaea, IPM

[1012] CIRCADIAN RHYTHMS ON NECTAR AND POLLEN COLLECTION BY FORAGERS OF *MELIPONA BICOLOR BICOLOR* (HYMENOPTERA, APIDAE, MELIPONINAE)

S. D. Hilário¹, <u>A. O. Fidalgo²</u>, V. L. Imperatriz-Fonseca² & A. M. P. Kleinert², ¹Dept. de Zoologia, E-mail sedilar@.usp.br; ²Dept. de Ecologia, Univ. de São Paulo, R. do Matão, Trav. 14, n. 321, São Paulo, SP 05508-900, Brazil, E-mail afidalgo@ib.usp.br.

The aim of this study is to investigate an occurrence of rhythmic frequencies in nectar and pollen collection by Melipona bicolor bicolor. This species, was studied at the Bees Laboratory (Univ. de São Paulo; 23°33'S, 46°43'W) from November/98 to February/99. We used two colonies from Cunha (23°05'S, 44°55'W). These colonies were classified as strong (colony 1) and intermediate (colony 2) according to general condition, population and comb sizes and number of food pots. Nectar and pollen loads were counted for 10 minutes every hour from 6am to 7pm. The sixteen days of observation were separated in four groups of four days. This data were analyzed in chronological order to verify the occurrence of a circadian rhythm. Circadian rhythms were detected in pollen and nectar collection, except when pollen collection was scarce (Jan/99, for both colonies; Feb/99, for colony 2). Although pollen and nectar collection were more conspicuous in the early morning, pollen collection acrophases occurred earlier than nectar collection acrophases, except in Feb/99 - colony 1. The acrophases of nectar collection occurred earlier in the strong colony than in the intermediate one. Pollen collection not showed the same pattern. The results for nectar collection were expected, because foragers from strong colonies usually collect food earlier than bees from intermediate or weak colonies in the same species. In relation to pollen collection, our observations were strongly influenced by climatic changes.

Index terms: Melipona bicolor, bee, circadian rhythms, nectar, pollen.

[1013] MORTALITY ASSESSMENT OF PESTS WITH OVERLAPPING GENERATIONS: THE USE OF LIFE TABLES IN BIOLOGICAL CONTROL

M. S. Hoddle, Department of Entomology, Univ. of California, Riverside CA 92521, USA. E-mail: mark.hoddle@ucr.edu.

Assessing and quantifying the impact natural enemies have on target pest populations is essential if the success of a biological control program is to be determined. One method of assessing natural enemy efficacy against the pest of interest is through the use of life tables. Life tables tabulate pest numbers entering and dying in each life stage, and where possible assignment of mortality factors responsible for death in each stage is made. Multidecrement life tables partition total mortality observed in a stage amongst contemporaneous mortality agents and this approach is extremely powerful for determining which factors have the biggest impact on the target pest's population growth. Assessing the impact natural enemies have on specific life stages of pests with overlapping generations is difficult. Several techniques have been developed to quantify survivorship rates and advancement to subsequent life stages and these include: 1) stage frequency analysis, 2) recruitment analysis, 3) death rate analysis, and 4) growth rate analysis. Each of the preceding systems has its own set of particular shortcomings. One powerful technique that can be used for pests with overlapping generations to accurately quantify advancement to subsequent developmental stages is the use of artificially constructed pest cohorts. Individual survivorship and mortality within these cohorts is monitored over time. Construction of multi-decrement life tables from artificial cohorts can provide extremely useful insight into mechanisms regulating pest population growth. The use of a photographic technique for following artificial cohorts of whiteflies in the presence and absence of aphelinid parasitoids has been used to identify important factors affecting the success of biological control of Bemisia argentifolii on greenhouse grown poinsettias. The results of work assessing the efficacy of varying parasitoid release rates in greenhouses will be used to illustrate the usefulness of life tables in assessing the efficacy of biological control agents against pests with overlapping generations.

Index terms: Eretmocerus eremicus, Bemisia argentifolii, poinsettias, greenhouses

[1014] DENSITY-DEPENDENT GROWTH OF MONOCLONAL APHID COLONIES AND ITS CONSEQUENCES FOR CLONAL FITNESS

D.I. Hodgson¹, ¹Inst. of Virology and Environmental Microbiology, Mansfield Rd., Oxford OX1 3SR, United Kingdom. Email: djhod@ceh.ac.uk.

All aphid species undergo parthenogenetic multiplication for at least part of the clonal life cycle. Many species also have highly aggregated distributions. Aphis fabae forms large colonies on individual host plants: individual members of such colonies may compete for food resources. Density-dependent colony growth is implied by evidence for a dispersal response to crowding, but is difficult to prove empirically. Two experiments were performed to manipulate the dispersal of aphids from monoclonal colonies. The first demonstrated that few aphids dispersed from colonies before peak colony size was reached (early dispersers). Replacing the few aphids which did disperse early had no impact on the total number of dispersers produced over the entire lifespan of a colony. This demonstrated a growth-then-dispersal pattern of colony development. If colony growth is density-dependent, the release of early dispersers should relieve competition on the host plant and lead to greater longevity of the colony and increased total disperser-production over the colony's lifespan. Increased early dispersal was mimicked in the second experiment by harvesting adult aphids from growing colonies. The results confirmed the predictions for density-dependent colony growth. Disturbance controls in both experiments showed that differences in disperser-production were not due to alarm responses to manipulation. If natural aphid colonies are monoclonal and densitydependent, then natural selection should favour prudent resource use and early dispersal strategies. I discuss ecological explanations for the apparent sub-optimality of the unmanipulated aphid colony dispersal strategies in these experiments. Index words: Aphis fabae, dispersal, harvesting

[1015] BIOLOGICAL NOTES ON THE NEOTROPICAL MUD-DAUBER WASP, TRYPOXYLON MANNI (HYMENOPTERA: SPHECIDAE)

A.W. Hook, Dept. of Biology, St. Edward's Univ., Austin, TX, USA, 78704-6489

Trypoxylon, one of the largest sphecid genera, is most diverse in the neotropics with over 120 species recorded here. Unfortunately few species have been studied in this region even though many appear to nest communally. This report details results obtained from 46 nests collected in Trinidad, W.I. between 1996-1999. Most nests were found attached to exposed rootlets suspended under overhanging dirt banks that bordered sides of trails and roads. Nests contained up to 64 cells and as many as 10 females. There was a significant positive relationship between nest size and the number positive relationship between female size and its ovarian condition (r-squared = 0.38). Parasites reared from nests include members of the following groups: Ichneumonidae, Chalicidae, Chrysididae, Mutillidae, Sarcophagidae and Rhipiphoridae. Nest included members of these groups: Sphecidae, Megachilidae, Halicidae, Colletidae, Bethylidae and Lepidoptera. Nest Structure/contents, ovarian analysis, parasites

[1016] COMMUNITY OF INSECTS FROM PAEPALANTHUS BROMELIOIDES: A NEW PHYTOTELMATA PLANT

<u>M. A. P. Horta¹</u>, J. E. C. Figueira² & R. P. Martins¹, ¹Lab. of Ecology and Behaviour of insects, ICB, Univ. Federal de Minas Gerais, E- mail mahorta@mono.icb.ufmg.br; ²Lab. of Plant Population, ICB, Univ. Federal de Minas Gerais.

Phytotelmata are aquatic microecossistems formed by plants. These plants provide conditions to the accumulation of water and resources forming communities whose organisms develop and complete their lifecycles. Paepalanthus bromelioides is an Eriocaulaceae species from the highlands of Serra do Cip6, a chain of mountains located in the state of Minas Gerais, Brazil. The architecture of *P. bromelioides* is similar to that of bromeliads in its ability to impound water among the leaves. The aquatic contents is formed by water which comes from rainfall and a fluid secreted by the plant itself. Although the very dense medium and the acid nature of the liquid, individuals of the Culicidae (Diptera) and Helodidae (Coleoptra) families have been found inhabiting *P. bromelioides*. The reservoir contains a sediment rich in organic matter supplied by arthropod pieces and vegetal parts which are used by the inhabiting organisms. The reason by which these organisms are colonizing such habitats is still unknown. Although the low diversity found the nature of the aquatic medium appear not to be a limiting condition for some species, that might be using these ecossistems as an avoidance of competition or predation.

Index terms: Phytotelmata, Paepalanthus bromelioides

[1017] A POSSIBLE CASE OF MIMICRY BETWEEN AN INSECT AND A TADPOLE

M. A. P. Horta¹, A. L. Melo², J. Bertoloci³ & J. Cassimiro³, ¹Lab. of Ecology and Behaviour of Insects, ICB, Univ. Federal de Minas Gerais, E- mail mahorta@mono.icb.ufmg.br; ²Lab. of Taxonomy and Biology of Insects, ICB, Univ. Federal de Minas Gerais; ³Lab. of Herpetology, ICB, Univ. Federal de Minas Gerais.

Mimicry is a widespread phenomenon in which a palatable or unpalatable species dupe predators resembling an unpalatable species that often display aposematic colouration. This study presents a case where two immature species were found to have the same pattern of shape and colour and both were found in the same places. *Limnocoris* are heteroptera insects of the family Naucoridae that inhabits streams and are effective predators like all members of the family. *Scinax machadoi* is a treefrog of the family Hylidae whose tadpoles are also found in streams and obtain food by scraping stones and sediment of the stream. The observations took place in Serra do Cipó, a chain of mountains in the state of Minas Gerais, Brazil. Serra do Cipó presents a typical vegetation of highland savannas and a large number of rivers, streams and ponds. The naucorids and tadpoles are found in many streams of Serra do Cipó living close to each other in large numbers of individuals. Both present a rounded black body with a yellowish transversal stripe. Hypothesis about the processes involved are discussed.

Index terms: mimicry, Naucoridae, Hylidae, Serra do Cipó

[1019] FLIGHT PATTERNS OF AN ASIAN AMBROSIA BEETLE, XYLOSANDRUS CRASSIUSCULUS, IN TREE NURSERIES IN GEORGIA AND NORTH FLORIDA, USA

W. Hudson¹ & R. Mizell², ¹Dept. of Entomology, Univ. of Georgia, P.O. Box 1209, Tifton, Georgia, 31793, USA, E-mail wghudson@uga.edu; ²Univ. of Florida, NFREC-Monticello, Rt. 4 Box 4092 USA

The Asian ambrosia beetle (AAB), Xylosandrus crassiusculus, has become a serious pest for nurseries across the southern USA in recent years. While nurseries throughout the region have suffered losses each season, the number of locations experiencing severe problems has varied greatly from year to year. The beetles have proven difficult to control with the usual barrier sprays used in the industry for prevention of damage from other types of borers such as clearwing moths and long-horned beetles. Pesticide screening trials demonstrated that pyrethroid insecticides were more effective at controlling the beetles, but timing of the sprays was important for optimal results. Beginning in 1994, traps were operated at ornamental plant nurseries in north Florida and Georgia to gather data on beetle activity and attacks on nursery stock. Trap data provided some information about seasonal occurrence of adult females, but no clear pattern emerged that would allow prediction of where an outbreak would occur and how severe it night be. The patterns of flight activity were consistent among locations for a given year, but varied considerably from year to year. There was an effect of winter weather on both the number and timing of adults caught the following year, with colder winter temperatures followed by fewer beetles flying later in the season the following spring. There was no significant correlation between degree-day accumulation and date of first flight. Beetles were caught every month of the year (but not in all months every year), with two clear generational peaks in March and May. First activity was delayed by ca. 1-2 weeks in central Georgia compared to north Florida and south Georgia, a distance between traps of about 150 km to the north. Although a significant number of beetles were active in April and May, virtually no nursery stock was attacked after the spring flush of leaves was completely expanded. Attacks on stressed trees in landscape plantings, as well as pecan and peach orchards, can occur anytime from spring until cold weather arrives, sometime in November in these climates. Trapping data offer no explanation for this observation.

Index terms: integrated pest management, ornamental plant pests, beetle traps

[1018] PRELIMINARY STUDY OF LIFE HISTORY OF TORTOISE BEETLE, ASPIDOMORPH MILIARIS (COLEOPTERA: HRYSOMELIDAE)

W. F. Hsiao & H. J. Tsai, Department of Biological Resource, University of Chaiyi, Chiayi, Taiwan, 60083

Life history of Tortoise beetle, Aspidomorph miliaris (Fabicius) was conducted under laboratory in the incubator set at 25°C, 12L:12D. About 200 larvae and 100 adults were collected from sweet potato field ,20 km near Chiayi city and brought back and reared with the same food plant as the stock culture. Around 100 newly hatch larvae were randomly chosen to start the following experiment. Egg mass was laid on the undersurface of the leaf. Each brownish egg mass composed of 10-15 pieces sheath and each sheath contained 2-4 eggs. Eggs were longitudinal. The length of egg was 0.15cm with stage of 12.68 day. Larvae are oval, flat and bear two forked processes at posterior end of the body to which was attached cast skin, excrement, or debris. The color of larva was yellow and fringed with blackish spine. Larval stage has five instars, first two were colonized and started to disperse until fourth instar. The body length of five instars was in the following orders: 0.12, 0.26, 0.38, 0.57 and 0.75 cm, respectively. The duration of larvae was in the following orders: 4.26, 4.96, 5.2, 5.0, and 8.19 day, respectively. The survival rate of larvae were in the following orders: 100%, 100%, 100%, 99% and 99%, respectively. Larvae have been found devoured the leaves of sweet potato and wild morning glory that had caused a serious damage of this two host plant. The morphology of prepupae was similar to fifth instar larvae. The head of pupa and adult was largely and completely concealed from above. The duration of prepupa and pupae were 3.21 and 7.96 days, respectively. Adult was broadly oval, with body expanded and flattened, resembling a tiny turtle. It took several minutes to hours to complete the mating. Female has mated for several times throughout the life. The preovipotion period was ranged from 17-30 days. Female adults produced 1-2 egg mass per day. The life span of adults was ranged from two months to one year.

Index terms: Aspidomorph miliaris (Fabicius), life history. Sweet potato.

[1020] USE OF THE FUNGUS METARHIZIUM ANISOPLIAE TO CONTROL LOCUSTS IN AUSTRALIA

D. M. Hunter¹, R. J. Milner² & J. C. Scanlan³, ¹Australian Plague Locust Commission, AFFA, GPO Box 858, Canberra, ACT 2601, Australia. E-mail david.hunter@affa.gov.au ²Division of Entomology, CSIRO, GPO Box 1700, Canberra, ACT 2601, Australia. ³Robert Wicks Research Centre, Queensland Department of Natural Resources, P.O. Box 318, Towoomba, Queensland 4350, Australia.

In Australia, locusts are managed through a programme of preventive control where treatment begins with the small bands and swarms that form early in outbreaks. Such programmes have relied on the use of chemical insecticides but increasing constraints on insecticide use have led to the search for biological alternatives. Work by LUBILOSA in Africa and CSIRO in Australia has shown that the fungus Metarhizium anisopliae is a most promising candidate for the biocontrol of locusts. During intensive studies in the past two years, Metarhizium has been applied by aircraft to local infestations of the migratory locust, *Locusta migratoria* (L.) and the Australian plague locust, *Chortoicetes terminifera* (Walker). At a dose of 75-100 g/ha (3-4 x 10^{12} conidia/ha), there was >90% mortality of migratory locusts in treated sorghum crops or open grassland. Decline was less at lower doses. With the Australian plague locust, >90% mortality resulted even at a dose of 25 g/ha (1 x 1012 conidia/ha). Mortality was high both during the moderate temperatures of spring and during high summer when maximum temperatures were 36-42°C. Nymphs hatching a few days after treatment and bands invading treated areas also died suggesting Metarhizium persisted on the vegetation for some days. Persistence was confirmed by feeding locusts vegetation from the treated blocks: there was 50% mortality of locusts fed vegetation collected from the treated blocks 5-7 days after treatment. In areas where bands were treated with Metarhizium, mortality was evident in 7-10 days during the hot summer and in 10-14 days at moderate temperatures of spring. The efficacy of Metarhizium at quite low doses means that it is price competitive with chemical insecticides and will be used as part of programmes of preventive control in the coming vear.

Index terms: Biological control, Locusta migratoria, Chortoicetes terminifera

[1021] MAJOR PESTS OF SOURSOP (ANNONA MURICATA) IN BRAZILIAN CERRADOS REGION AND THEIR NATURAL ENEMIES

<u>I. M. Icuma¹</u>, M. A. S. Oliveira¹ & T. Asayama², ¹Embrapa/Centro de Pesquisa Agropeucária dos Cerrados (CPAC), Caixa Postal 08223 CEP 73301-970 Planaltina, DF, Brazil, E-mail icuma@cpac.embrapa.br; ² Kitahonjigahara-cho 2-143 Owariasahi-shi, 488-0043, Japan.

The soursop Annona muricata is a crop with a high economic potential in cerrados region, not only for its fresh fruit consumption but for its importance in the food processing market, because it has the exotic smell, flavor and consistence gives them an important role as source for industries of juice, ice-cream and consumption of fruits in natural. However, fruit production is limited by the attack of various insects and the phytosanitary problems, especially the pests have been discouraging the commercial plantations. The major insect pests were observed and collected in orchard of EMBRAPA-CPAC area, and the damage were registered. Insects and plant parts attacked were conducted to laboratory to be analyzed. The insects were mounted, identified and deposited in the CPAC Entomological Collection. Major insects pest observed in anonacean plants found in Brazilian Cerrados region were stem borer (Cratosomus bombina bombina and Eurypages pennatus (Coleoptera: Curculionidae)), stern base borer (Heilipus catagraphus (Coleoptera: Curculionidae)), fruit borer stem base borer (Heilipus catagraphus (Coleoptera: Curculionidae)), fruit borer (Cerconota anonella Lepidoptera: Oecophoridae: Stenomatinae)) and seed borer (Bephratelloides pomorum (Hymenoptera: Eurytomidae)). The fruit borer is the most serious pest of soursop. Damages caused by this pest may vary from 70 to 100% of the fruit production. It was observed that the larvae of C. anonella are parasitized by braconid Apanteles sp. and by ichneumonidae Xiphosomella sp., and the pupas are parasitized by chalcid Brachymeria annulata and by eulophid Trichospilus diatraeae.

Symposium and Poster Session

[1023] THREATENED JAPANESE BUTTERFLIES LISTED BY THE ENVIRONMENT AGENCY OF JAPAN IN 2000

<u>M. Ishii¹</u> & Y. Nakamura², ¹Entomol. Lab., Graduate School of Agr. and Biol. Sci., Osaka Pref. Univ., Sakai, Osaka 599-8531, Japan, E-mail ishii@plant.osakafu-u.ac.jp, ²Japan Wildlife Res. Center, 2-29-3 Yushima, Bunkyo-ku, Tokyo 113-0034, Japan, E-mail ynakamura@jwrc.or.jp.

Although none of circa 240 butterfly species distributed in Japan has become extinct so far, 2, 5 and 40 butterfly taxa were listed as endangered, vulnerable and rare, respectively, in the Red Data Book (RDB) published by the Environment Agency of Japan (EAJ) in 1991. Out of the total of 47 taxa listed, 13 and 14 occur in detached islands and high mountain regions, respectively, and of the rest 20 taxa, 3, 10 and 7 occur in evergreen and deciduous forests, and grasslands of mainlands, respectively. EAJ began to revise the list from 1996 on the basis of new Red List Categories of IUCN (1994), and prepared a revised list, which will be publish in the spring of 2000. In the revised list, the number of threatened butterfly taxa has increased to 74: 29 were added and 2 excluded. Out of the 74 taxa listed, 12, 21 and 41 were listed as (critically) endangered, vulnerable and near threatened, respectively. Numbers of taxa in detached islands (12) and high mountain regions (17) were almost similar, while those in mainlands (45) have largely increased as compared with RDB 1991. Especially, butterfly taxa inhabiting deciduous forests and grasslands have increased by 7 (70%) and 19 (270%), compared with RDB 1991. Main threats to these butterflies are considered to be the degradation and destruction of secondary forests and grasslands of earlier successional stages which have been maintained by human intervention through coppicing and grass-cutting for fuels, manure and other materials.

Index terms: threatened butterfly, Japan, Red Data Book, the Environment Agency of Japan.

[1022] *BELOSTOMA* (HETEROPTERA: BELOSTOMATIDAE) FROM THE STATE OF RIO DE JANEIRO, SE. BRAZIL

J. R. Inacio Ribeiro^{1,2,3} & J. L. Nessimian², ¹Depto Parasitologia, ICB, Universidade Federal de Minas Gerais, P. O. Box 486, 31270-901, Belo Horizonte, MG, Brasil, E-mail zribeiro@ig.com.br; ²Depto Zoologia, IB, CCS, Universidade Federal do Rio de Janeiro, P. O. Box 68044, 21994-970, Rio de Janeiro, RJ, Brasil, E-mail nessimia@acd.ufrj.br. ³Supported by CAPES, CNPq, FAPERJ, FUJB

During a revisional study of *Belostoma* from southeastern Brazil it was possible to record fourteen species from the State of Rio de Janeiro: *Belostoma anurum*, B. aurivillianum, B. candidulum, B. costalimai, B. dentatum, B. dilatatum, B. foveolatum, B. micantulum, B. oxyurum, B. plebejum, B. ribeiroi, B. sanctulum, B. stollii, and B. testaceopallidum. Of them, six species are newly recorded for the first time from this State: B. aurivillianum, B. candidulum, B. dilatatum, B. oxyurum, B. ribeiroi, and B. sanctulum. In this way, synonym lists, diagnosis, notes on the biology, and distribution maps are given. Index terms: *Belostoma*, Belostomatidae, taxonomy, Rio de Janeiro State, southeastern Brazil. [1024] POPULATION DYNAMICS OF COSMOCLOPIUS NIGROANNULATUS (HEMIPTERA, REDUVIDAE) IN NICOTIANA TABACUM

S. M. Jahnke, L. R. Redaelli & L. M. G. Diefenbach' Dep. Fitossanidade, Univ. Federal do Rio Grande do Sul, Av. Bento Gonçalves, 7712, Porto Alegre, CEP: 90046-900, Brasil, E-mail smjahnke@yahoo.com.

The effect of natural enemies upon phytophagous insects is important to keep their populations at low levels and so decrease the damage done to the cultures. Therefore, the knowledge about the bioecology of predators insects mainly population dynamics is essential to establish their role in biological control programs. The tobacco culture represents an important issue either in economical as in social terms in Rio Grande do Sul State. Previous studies in the same area registered the presence of a predator complex of the Reduviidae acting upon Corecoris dentiventris (Hem. Coreidae) population, a bug that cause the wilting of the tobacco leaves due to its sucking habit. The present work aimed to investigate the spatial distribution and population changes of Cosmoclopius nigroannulatus, a predaceous reduvid, along one cycle of the tobacco culture. The study was carried out in an experimental area of the Departamento de Fitossanidade, Universidade Federal do Rio Grande do Sul, in Porto Alegre (30°01'S; 51°13'W) with 270 tobacco plants (cult. Virginia, var. K 326). The sampling initiated in August, 1999, and 3 times a week all plants of the plot were inspected and the adults found were captured, marked, counted and liberated at the same place. Data was analyzed by the Fisher-Ford method. The beginning of the colonization of the experimental area was considered on September 19th when the first female was found on the tobacco culture. The second generation was registered approximately 76 days after this date. The sex ratio was 0,45 until the second generation, considering the number of adult individuals marked in the sampling occasions. Until the present moment, the adults daily survival rate is 96% and the population peak registered was 57 individuals in December 24th. The data fitting to Poisson and Positive Binomial distributions applying the dispersion index (I) resulted in 11,43% of occasions with random distribution, 50% with regular and 38,57% with clumped.

Index terms: Insecta, Spatial distribution, Predator, Tobacco

[1025] LIFE TABLE AND DEMOGRAPHIC PARAMETERS OF THE SOUTH AMERICAN FRUIT FLY (DIPTERA: TEPHRITIDAE)

H.E. Jaldo¹ & <u>E. Willink¹</u>, ¹Estación Experimental Agroindustrial Obispo Colombres, C.C.n^o 9, Las Talitas, (4101) Tucumán, Argentina. E-mail: saneeaoc@tucbbs.com.ar.

Anastrepha fraterculus, the South American fruit fly, is considered the second most important economical fruit fly species in Argentina. No life table or demographic analysis has been made for this species. Research of these parameters are useful to establish the baseline to plan action programmes to control or eradicate the pest. The objective of this tesearch was to study the life table of A. fraterculus under laboratory controlled conditions and analyse the most important population parameters that characterise this species. The material used came from the A. fraterculus rearing at the Estación Experimental Agroindustrial Obispo Colombres. The life cycle at a constant temperature of 24°C was: 2 days for the egg, 3 days for the first instar larvae, 3 days for the second instar larvae, 9 days for the third instar larvae, 14 days for the pupae, and 10 more days for the preoviposition period. The mortality was 8% for the eggs, 24% for the larvae, 32% for the pupae and 10% for the preoviposition period. The gross reproductive rate was 962.98 while the net reproductive rate was 313.12. The mean generation time was 61.7 days, the mean age of a stable population is 7.23 days and the time in which the population duplicates is 7.44 days. The intrinsic rate of increase was 0.093. The data obtained shows that the biotic potential of A. fraterculus is quite lower than Ceratitis capitata. Index terms: Anastrepha fraterculus, life cycle, demography

[1026] POPULATION DYNAMICS OF ADULTS CORECORIS DENTIVENTRIS (HEMIPTERA; COREIDAE) IN A TOBACCO EXPERIMENTAL PLOT

C. R. Jesus¹ & H. P. Romanowski², ¹Progr. Pós-grad. Biol. Animal, ² Depto. of Zoology, ^{1,2}Univ. Federal do Rio Grande do Sul, Av. Paulo Gama s/n⁰, Porto Alegre, CEP: 90046-900, Brazil, ¹E-mail crjesus@vortex.ufrgs.br.

To understand the processes shaping a population, knowledge on the yearly and seasonal fluctuations on its size, nad the movements and survival rates of its members are needed. Beyond its own theoretical importance, information on this aspects is crucial for management and control of "pest" species. The population dynamics of *Corecoris dentiventris* adults was investigated in a tobacco experimental plot in Porto Alegre, Brazil (30° 01'S 51° 13'WGR), using the mark-release-recapture method. In an area of ca. 300 m², 365 tobacco plants were grown; each plant was identified by alpha-numeric coordinates. From August/97 to February/98, all plants were inspected weekly. Adults were captured by hand, marked and released in the same plant they were caught. Data was analysed by the Fisher-Ford method. 273 bugs were marked in 45 sampling occasions. Recapture rates were about 41 and 40% for females and males respectively. Daily survival rate estimates were above 96%. Population size was about 200 individuals. Mean minimum longevity was 25.19 ± 2.21 and 22.9 ± 3.54 for females and males respectively. Dispersion indexes k and I were estimated: out of the 16 occasions in which sample sizes were large enough (n >= 10), 15 revealed an aggregated pattern of distribution. Index terms: grey-tobacco bug, mark-release-recapture, dispersion, distribution,

[1027] IS A LIMITED DISPERSAL PROPENSITY THE REASON FOR THE RARITY OF THE BEETLE OPLOCEPHALA INAEMORRHOIDALIS IN NORTHERN EUROPE?

M. Jonsson, M. Jonsell, & G. Nordlander, Dept. of Entomology, Swedish Univ. of Agricultural Sciences, P. O. Box 7044, SE-750 07 Uppsala, Sweden, E-mail: Mattias.Jonsson@entom.slu.se.

A large number of insect species are dependent on dead wood. In northern Europe many of them have become threatened due to human activities. One possible reason for this is that the dispersal propensity of the species limits colonisation of substrates that have become more sparsely distributed in the modern managed landscape. Knowledge about the dispersal propensity of wood-living insects is however very limited, and the data available primarily concerns pest species. It has been argued that rarity of insects is generally not due to a low dispersal propensity in managed boreal forests, but to an absence of suitable substrate. Comparing both the substrate demands and the dispersal propensities between rare and common wood-living insects with a similar biology could be one way to evaluate this. Fruiting bodies of wood-decaying fungi constitutes a well defined and species rich part of the dead wood. We have studied the two tenebrionid beetles Oplocephala haemorrhoidalis and Bolitophagus reticulatus, which both are monophagous on fruiting bodies of the wood-decaying fungus Fomes fomentarius. O. haemorrhoidalis is considered threatened in several European countries, whereas B. reticulatus is usually common where the host fungus is present. We studied the substrate demands of the species, the effects of forest history on the occurrence of them, as well as the genetic differentiation between their populations. O. haemorrhoidalis was strongly restricted to localities with a long continuity of dead wood, whereas *B. reticulatus* was not affected by this parameter. The substrate demands of *O. haemorrhoidalis* was somewhat narrower than those of *B.* reticulatus, but still broad enough to indicate that suitable substrate should be rather common at many localities where the species is absent. Populations of O. haemorrhoidalis showed a significant correlation between genetic and geographic distance, whereas no such correlation was found between populations of B. reticulatus. Based on these results we suggest that the main reason for the rarity of O. haemorrhoidalis in northern Europe is a weak dispersal propensity, which hinders colonisation of new patches although suitable substrate is abundant. To further evaluate this, a study of the duration of flight in flight mills is planned for the summer of 2000. Results from that study might be presented as well at the conference.

Index terms: conservation, saproxylic beetles, substrate demands, genetic differentiation, dispersal propensity

[1028] DIVERSITY AND TEMPORAL CHANGE IN THE EFFECTIVE POLLINATORS OF GERANIUM THUNBERGII

<u>L. Kandori¹</u>, ¹Laboratory of Entomology, Faculty of Agriculture, Kinki University, Nakamachi, Nara, 631-8505, JAPAN, E-mail kandori@nara.kindai.ac.jp.

Assessing the relative contribution to seed set for each of a plant species' floral visitors provides an indication of the relative influence of these visitors on the plant's reproductive success. This study examined pollinator activity and seed set in a population of Geranium thunbergii, an insect-pollinated perennial wild herb. This plant species was visited during the two years of the study by 41 insect taxa belonging to four orders. Of 21 main visitor taxa, 14 taxa consisting of eight bees, one wasp, one ant, two hoverflies, and two butterflies acted as effective pollinators. The main contributors to seed set changed largely between two year. The top five contributors in each of the first and second year were, 1: Coelioxys acuminata (bee), 2: Megachile tsurugensis (bee), 3: large Lasioglossum (bee), 4: Zizeeria maha (butterfly), 5: Ceratina spp. (bee) / Betasyrphus serarius (hoverfly), and 1: Apis cerana (honeybee), 2: M. tsurugensis (bee), 3: large Lasioglossum (bee), 4: Chalicodoma spissula (bee), 5: Sphaerophoria macrogaster (hoverfly), respectively. At the level of orders, Hymenoptera alone contributed to more than 80 % of seed set during the experiment, and the rest by Diptera and Lepidoptera. Meanwhile, the nectar/pollen robbers, which were defined as the frequent visitors with little seed set per one visit, were also mostly Hymenoptera (4 out of 5 robbers). Interestingly, smaller visitors were less efficient in setting seeds per one visit, and thus tended to act as the nectar/pollen robbers for this plant. The reason will be discussed from the point of behavioral difference in collecting nectar or pollen on the floral surface by different sized visitors. Seasonal visiting patterns of the main contributors were divided into four types, i.e., type 1: concentrated mass visits on the mid flowering season at its peak blooming (honeybee), type 2 and 3: concentrated visits in the early or late flowering season (one and two taxa, respectively), and type 4: normal visits throughout the flowering season (five taxa). Diurnal visiting patterns were divided into two types, i.e., type 1: one peak of visits around noon (five taxa), and type 2: two peaks of visits before and after noon (four taxa). In conclusion, G. thunbergli may well be considered as bee-pollinated. However, important pollinators, or contributors, among bee taxa could change largely year by year. Therefore, this plant is not specialized to a certain pollinator, though some specialization to mediumsized bees could occur in this study site. Since this plant has taxonomically diverse, potentially effective pollinators, it will successfully reproduce in spatio-temporally heterogeneous habitats.

Index terms: Geranium thunbergii, seed-set, pollination effectiveness, generalization, foraging behavior

[1029] THE DYNAMICS OF SEXUAL SELECTION AND THE EVOLUTION OF NOVEL ACOUSTICAL SIGNALING IN HAWAIIAN DROSOPHILA

<u>K.Y. Kaneshiro</u>, Center for Conservation Research & Training, Univ. of Hawaii, 3050 Maile Way, Gilmore 406, Honolulu, Hawaii 96822, USA, E-mail kykanesh@hawaii.edu.

It has been suggested that sexual selection and the dynamics of sexual selection have played a critical role in the evolution of the tremendous speciation of Drosophilidae in the Hawaiian Islands. During periods of small population size, there is strong selection for females that are less choosy in mate selection which results in an increased frequency of less choosy females in subsequent generations of small population size. It is suggested that such conditions result in a shift in gene frequencies toward the genotypes of the less choosy female. Perturbation of the balanced genetic system results in a destabilized genetic condition and the break-up of co-adapted genetic elements, which in turn, promotes the generation of novel genetic recombinants previously not present in the population. These novel genetic elements then provide the raw material upon which natural selection or sexual selection can operate in the population's ability to adapt to the new habitat or to changing environmental conditions. Some selection experiments involving morphological characters will be used to illustrate the pleiotropic effect of the sexual selection system and this model will be used to explain the four different mechanisms of acoustical signaling observed among the Hawaiian Drosophila species. While wing vibrations are known to produce acoustical signals among dipteran species, several species of Hawaiian Drosophila also produce sounds by vibrating two pairs of muscles that adjoin the thorax and abdomen. Other species produce a high frequency sound which is beyond the sensitivity level of the typical receptor found in Diptera, i.e. the arista. Still other species are able to modulate the frequency of their wing vibrations resulting in a much more complicated set of signals previously unknown for dipteran species. It is suggested that the novel acoustical signaling mechanisms in the Hawaiian Drosophila are pleiotropic results of shifts in the sexual selection system during founder events or during population bottlenecks.

Index terms: mate choice, small population size, speciation, founder event, genetics

[1031] BEHAVIORAL AND ECOLOGICAL FEATURES OF HOST PLANT SELECTION AND INFLUENCE ON LOCAL SPECIALIZATIONS BY HELICONIUS ERATO

S.M. Kernel¹ & G.R.P. Moreira², ¹PPG Ecologia, Univ. Federal do Rio Grande do Sul, Av. Bento Gonçalves 9500, 91540-000, Porto Alegre, RS, Brasil, E-mail solmk@bol.com.bt; ²Depto. de Zoologia, Instituto de Biociências, Univ. Federal do Rio Grande do Sul, Av. Paulo Gama 40, 90046-900, Porto Alegre, RS, Brasil. E-mail grpm@if.ufrgs.br

There is considerable interspecific variation in host plant (Passifloraceae) use among Heliconius erato phyllis (Lepidoptera: Nymphalidae) larval populations. The causes for the corresponding local differences are unkown. They could be based on either ecological or behavioral mechanisms that take part in their interaction with passion vines, regarding both larval and adult stages. The main objective of this study is, by adopting a behavioral ecology approach, to identify the mechanisms involved in *H. erato phyllis* local specializations concerning use of host plants. The study was conducted under laboratory or insectary conditions with a populations of H. erato phyllis of Porto Alegre County, Rio Grande do Sul State, using two preference host plants (Passiflora suberosa and Passiflora misera). Feeding preference and respective induction in relation to P. suberosa and P. misera were evaluated for all instars through choice tests using leaf disks. To evaluate Hopkins' effect, larvae were individually reared on either P. suberosa or P. misera. Under insectary conditions, females were tested for oviposition choice in relation to the two passion vine species. For testing conditioning of oviposition preference, field collected females were used. Shoots of either P. suberosa or P. misera were offered for these female during periods of 3, 7, 11 or 15 days (conditioning times). After, they were also tested for oviposition choice. To quantify density effects, intact shoots were offered for oviposition (six treatments), varying in number from zero to five. To the evaluate importance of presence of intact terminal bud on oviposition, field collected females were tested under four situations, which resulted from the possible combinations between presence of intact and/or damaged shoots of *P. suberosa* and *P. misera*. Both larvae and adult of *H. erato* phyllis showed preference for P. misera compared to P. suberosa, under laboratory and insectary experiments. Larval feeding preference could not be induced, the Hopkins' effect was not detected and oviposition choice could not be conditioned. Females alternated use of host plant species as a function of variation in either density or presence of terminal bud on shoots. Thus, data indicate host plant preference in H. erato phyllis is not learned but innate. Therefore, local use of host plant results in this butterfly from quali- and quantitative variation of passion vines, to which females respond.

Index terms: passion vines, induction of preference, Hopkins' effect, conditioning.

[1030] MIGRATORY SPECIES, INDIVIDUAL VARIATION IN MIGRATORY TENDENCY: CORRELATIONS WITH RESOURCE STORAGE AND MOBILIZATION

J. W. Kent Jr.¹, K. J. Min¹, J. L. Plunkett¹ & M. A. Rankin¹, ¹Integrative Biology Section, School of Biological Sciences, The Univ. of Texas at Austin, Austin, TX 78712 USA, E-mail: jwkent@mail.utexas.edu.

The North American migratory grasshopper Melanoplus sanguinipes exhibits heritable variation in migratory tendency. Although both migrants and non-migrants of this species are fully winged and capable of flight, some individuals are predisposed to make long flights in response to appropriate environmental cues. This predisposition can be measured on a tethered-flight apparatus in the laboratory, and the measure is repeatable. We are investigating the physiological differences between migrants and non-migrants, particularly with regard to mobilization of energy reserves. Migrants and non-migrants do not differ in magnitude of lipid reserves at rest, even though these reserves are used to fuel long flights. However, migrants mobilize more lipid than non-migrants in response to equal doses of adipokinetic hormone (AKH). Both migrants and non-migrants mobilize lipid when mounted on a tethered-flight apparatus, but the magnitude of adipokinesis is greater in migrants. Migrants have a greater content of total protein in the thorax, per unit of body size, than non-migrants. Thorax protein appears to be mobilized during flight, a phenomenon that has been indicated in migratory birds. Endocrine mechanisms of resource mobilization, and the physiological significance of protein mobilization, will be discussed.

Index terms: Melanoplus sanguinipes, migration, adipokinetic hormone, AKH

[1032] COMPARATIVE ANT SPECIES DIVERSITIES IN INTACT AND LOGGED AMAZONIAN RAINFORESTS

S. M. Ketelhut & A. Y. Haradn, ¹, ¹Museu Paraense Emílio Goeldi, Depto. Zoologia, Entomologia. Cxp 399 - 66040-170. Belém, PA, Brazil. E-mail: sktelhut@inpa.gov.br

A comparative study of ant fauna communities was made in a primary forest and in two kinds of logging systems (Managed and Traditional) located in a tropical rainforest area, near Paragominas, Pará state, Brazil. In each area, ants were sampled using pitfall traps during December 1997 and March 1998 on six 200 m transects, separated from each other by 100 m. Differences in ant fauna diversity among the sites were tested using diversity indexes (Shannon, Simpson and Fisher's Alpha) and richness estimates protocols (e. g. Colwell & Coddington 1994). Species composition was evaluated through affinity analysis (Scheiner 1992) and similarity indexes (Jaccard and Morisita-Horn). A total of 134 ant species belonging to seven subfamilies and 42 genera could be identified in the entire area. Of these, 90 species were found in primary forest, 90 in managed and 84 in the traditionally logged forest. Differences between habitats could be detected comparing diversity and similarity indices among different transects. There were no differences in indexes when absolute values were compared for each site. Results from richness estimates protocols also indicate that ant faunas were similar between sites and suggest that ant faunas were still underestimated. The richness and abundance of ants were different between the months, and it does not affect the diversity patterns in the areas as a whole. High mosaic diversity could be detected using affinity analysis, and it is suggested that the communities were composed by very complex gradients. Thus, differences in ant

composition would be due to heterogeneity at smaller scales. Index terms: Logged systems, Hymenoptera, Formicidae, Biodiversity, Amazon, Estimates.

[1033] STRUCTURE OF THE CROP IN THE ADULT QUEEN BLOWFLY, PHORMIA REGINA

J. Kinkorova¹. M. Jokes³, M. Carcupino³ & J. Stoffolano⁴, ¹Dept. of Zoology, Charles Univ., Prague-2, CZ 128 44, Czech Republic, E-mail kinkor@prfdec.natur.cuni.cz; ²Res. Inst. of Plant Prod., Prague-6, CZ 161 05, Czech Republic; ³Dept. of Zoology and Anthropology, Univ. of Sassari, Italy, E-mail carcupin@ssmain.uniss.it; ⁴Dept. of Entomology, Univ. of Massachusetts, USA, E-mail stoffolano@ent.umass.edu.

The majority of studies on the crop of adult dipterans focuses on the distribution of various nutrients fed upon and not on how it is regulated for intake or emptying. Evolution of the crop, a liquid storage organ in the adult queen blowfly, is essential for feeding on various nutrients, both proteins (for egg development) and carbohydrates (for energy), both of which are patchily distributed and often not readily available in the environment. The ability to store large quantities of liquid when encountered give adults greater dispersal capabilities. Thus, it is surprising that no known definitive study has been done on its structure, both at the SEM and TEM levels. The crop is a diverticulum connected to the esophagus by a duct and is a bilobed sac capable of considerable distention. Its ability to retain liquids for long periods of time following removal is attributed to sphincters that keep fluid from leaving the crop duct and also to its cuticular, impermeable lining. Circular and longitudinal, visceral muscles produce the contractions of the crop and crop duct. Recent studies show that these muscles are regulated by two peptides (one inhibitory and the other stimulatory). Fluorescent antibody probes reveal that the neurons releasing these peptides produce a net-like covering over the crop lobes and duct. TEM studies reveal a large number of trachea also cover and are located between the two muscle types. TEM studies also show that the neurons delivering these peptides usually follow the course of and are usually associated with the trachea. In addition to acting as a storage organ, the crop plays a significant role in terminating feeding once it reaches its maximum volume.

[1035] THE ROLE OF LEARNING AND MEMORY IN LEAF-CUTTING ANT FORAGING ECOLOGY

J. J. Knapp¹, T. Legg¹, L. Farnham¹ A. Shaw¹, A. Tonhasca Jr.² & Dr A. Eiras², ¹Division of Biodiversity and Ecology, School of Biological Sciences, Univ. of Southampton, Bassett Crescent East, Southampton SO16 7PX, UK. ²Crop Protection Laboratory, CCTA, Universidade Estadual do Norte Fluminense, Campos, RJ, Brazil. Email: jjk@soton.ac.uk.

Leaf-cutting ants of the genera Atta and Acromyrmex are known to cut and transport a wide range of fresh plant material as a substrate for their symbiotic fungus. The ants are selective. It has been shown that colonies harvest plant material which provide a suitable substrate for the growth of the fungus and avoid cutting plants which contain compounds that are deleterious to the fungus. Thus the relationship between the ants and the fungus is a close and complex one. It has been shown that the decisions involved in selecting plant material can involve a range of different behavioural responses some involving learning and memory. While some plant material is recognised upon first contact as unacceptable other plant material is not, it must first be harvested and only when negative consequences for the fungus result does the colony learn to reject the plant. This process has been termed delayed rejection and the negative conditioning involved has been shown to have long term consequences for substrate selection in laboratory and field colonies. The colony as a whole will continue to reject the deleterious material when presented even though only a few individual ants have been exposed to it in the first instance. Attempts to unravel how the ants first detect the deleterious effect, the mechanism by which they associate the correct plant with the effect and how this information is passed onto the other members of the colony have been difficult. Using fungicide baits made from a matrix of a normally highly acceptable plant species, citrus, we begin to illuminate the role of the different worker castes in making the decision to accept and/or reject a particular plant. Based on our results behavioural mechanisms which enable the 'message' to be spread throughout the foraging workforce are proposed. In addition the extent to which delayed rejection could be transferred from the bait to the plant itself was investigated in the lab and field. Results indicate that such transferral is possible. The significance of delayed rejection in the ecology of attine host-plant selection and the wider implications for control strategies will be discussed.

[1034] INVASION SUCCESS AND BREEDING SYSTEMS: A COMPARISON OF INBREEDING AND OUTBREEDING BARK BEETLES BREEDING IN PALM SFEDS (CURCULIONIDAE, SCOLYTINAE)

L. R. Kirkendall, Univ. Bergen Dept. Zool., Allégaten 41, N-5007 Bergen, Norway. Email: lawrence.kirkendall@zoo.uib.no.

On the Canary Islands, the endemic *Dactylotrypes longicollis* (outbreeding) and the cosmopolitan *Coccotrypes dactyliperda* (inbreeding) breed in palm seeds: 1 will present comparative data on their life histories and genetic variation (isozymes, mtDNA, cuticular hydrocarbon profiles), and discuss the phylogeography of populations of these two species, in the context of the role of genetic variability in colonizing success. I will also use the genetic data to attempt to disentangle the relative roles of historical vs. contemporary dispersal, in understanding current patterns of population subdivision. (See also the more general presentation in this same volume, for Session 21-Symp. Index terms: *Coccotrypes, Dactylotrypes*, biogeography, dispersal, Canary Islands

[1036] BEE-PLANT-RELATIONS OF MASS-FLOWERING TREES IN A SOUTH BRAZILIAN ARAUCARIA FOREST OF THE MATA ATLÂNTICA

A. Köhler^{1,2} & W. Engels^{1,2}, ¹LPB, PUCRS, 90619-900 Porto Alegre, RS, Brazil, e-mail: andreas@pucrs.br, ²Zool. Inst., Uni. Tübingen, 72076 Tübingen, Germany.

In contrast to the mostly anemogamous trees in temperate forests, zoogamous trees dominate tropical rain forests, with insects being the principal pollinators. We studied insects visiting mass-flowering trees in an Araucaria forest reserve of 4,500 ha, located at 900 m altitude on the Serra Geral of Rio Grande do Sul. In addition, the structure of inflorescences and the phenology of antheses were recorded for 51entomophilous tree species. About 2/3 of the flower visitors were bees. Syrphid flies were also frequently recorded in addition to other hymenopterans, coleopterans, dipterans and lepidopterans. The highest α -diversity was monitored for halictid bees. The most abundant foragers, however, were workers of stingless bees and the introduced Africanized honey bee. The pollen and nectar sources were quantified, including measurements of the sugar content. The period of tree blossom varied between 2 and 10 days. Of the melittophilous taxa, the family Myrtaceae contributed the maximum with 17 species, all exhibiting the massflowering syndrome, with anthesis occurring early in the morning. Pollen exploitation patterns and pollinator guilds are discussed regarding the impact of bees within the reproductive web of the subtropical Araucaria rain forest ecosystem. Index terms: Araucarian forest, flower visitors, bees, hoverflies, blooming time.

[1037] ABUNDANCE-REGIONAL DISTRIBUTION RELATIONSHIPS IN NORTHERN EUROPEAN CARABIDS (COLEOPTERA: CARABIDAE)

D. J. Kotze¹, J. Niemelä¹, H. Turin² & R.B. O'Hara¹, ¹ Dept. of Ecology and Systematics, PO Box 17, FIN-00014, Univ. of Helsinki, Finland. E-mail: johan.kotze@helsinki.fi² Esdoorndreef 29, 6871 LK RENKUM, The Netherlands.

Considered as one of the most basic patterns in ecology today, the abundance-range size relationship hypothesises that, for a given taxonomic assemblage, there is a positive interspecific relationship between abundance and range size. In other words, locally abundant species tend to be geographically widespread, while locally rare species tend to be geographically restricted. Although this relationship is well established in the ecological literature, little consensus exists on what causes it. For example, there are currently eight mechanisms that can explain this relationship, but none of these have unequivocal support. These mechanisms can be divided into two categories: artefactual (sampling artefact and phylogenetic non-independence), and biological (range position, resource breath, resource availability, habitat selection, metapopulation dynamics and vital rates). Using allas data, we investigated abundance-regional distribution relationships of ground beetles for Belgium, Denmark and the Netherlands. The aim here was to identify shared beetle characteristics along the abundance-range size distribution relationship in these three countries. For example, we investigated which set of characteristics make a species locally rare and narrowly distributed, and which set makes a species abundant and widespread. Three basic carabid beetle characteristics were investigated; wing form (macropterous, dimorphic, brachypterous), body size (a log2 gradient from < 3 mm to > 16.9 mm), and habitat specificity (a five-step gradient from stenotopic to eurytopic). A significant positive relationship was found between abundance and range size for all three data sets. There was, however, considerable scatter around the regression lines. Species with residuals greater than two standard deviations from the fitted lines were selected as outliers. In other words, carabid species narrowly distributed but locally abundant, and species widely distributed but locally rare were identified. Outlier species were not the same in different countries. The beetle characteristics; wing form, body size and habitat specificity, showed a significant relationship with beetle range, for the three countries investigated. For example, dimorphic beetles had a significantly larger range than either macropterous or brachypterous species, for all three countries investigated. Also, larger species, and eurytopic species were widespread, while smaller species, and stenotopic species tended to be more restricted. The results here are discussed in light of the eight proposed abundance-range size relationship mechanisms.

Index terms: ground beetles, wing morphs, body size, habit specificity

[1039] INCREASED INCIDENCE OF BOREAL FOREST PEST OUTBREAKS: HERALD OF GLOBAL CHANGE?

M. V. Kozlov¹ & A. V. Selikhovkin², ¹Sect. of Ecology, Univ. of Turku, Turku FIN-20014, Finland, E-mail mikoz@utu.fi; ²Dept. of Forest Protection, Forestry Academy, Institutskij 5, 184018 St. Petersburg, Russia, E-mail selichovkin@mailbox.alkor.ru.

We analyzed data on 133 forest pest outbreaks that have occurred during 1956-1998 in the Russian part of the Barents Sea region, approximately within the limits of 61-69°N and 31-57°E. Most of the records concern pests of Scots pine (74) and Norway spruce (31). The most extensive damage (average outbreak area >5,000 ha) was imposed by the European pine sawfly *Neodiprion sertifer* (12 outbreaks), the autumnal moth *Epirrita* autuninata (8), the larch bud moth Zeiraphera diniana (3) and the sawfly Cilpinia hercynae (3). The number of outbreaks reported in 1989-1998 was 3.5 times higher than in 1956-1965 ($\chi^2 = 9.20$, P = 0.002), and the intensity of forest damage increased by a factor of 2.1 ($\chi^2 = 6.89$, P = 0.009). Since the information on outbreaks collected during the past 20 years is less complete than the information for the period from 1956 to 1975, the true increase in outbreak frequency may be even higher than that reported here. Neither the annual nor the winter mean temperatures in our study region have demonstrated significant changes during 1955-1997. However, significant increase in winter precipitation may result in rarer inversions, and thus exclude low temperature extremes, which are dangerous for insects which overwinter above the snow cover. If these species are analyzed separately, both the annual number of outbreaks and the intensity of forest damage changed in species hibernating above the snow cover (r = 0.71, n = 43 years, P = 0.0001and r = 0.57, n = 28, P = 0.002, respectively) but not in species which overwinter beneath the snow (r = 0.23, n = 43, P = 0.13 and r = 0.04, n = 30, P = 0.83, respectively). The increase in the spatial extent of an outbreak was also much clearer in species directly exposed to short-term temperature fluctuations during the wintertime (r = 0.64, n = 43, P =0.0001) than in species protected by the snow cover (r = 0.35, n = 43, P = 0.02). Although our data point to an increase in low temperature extremes as a plausible explanation of the increased incidence of forest pests, the contribution of other factors (CO2, UVB, pollution) cannot be excluded, and the evaluation of causal links by means of our data set is therefore not really possible. Nevertheless, our findings indicate that forest protection measures should form an important part of strategies for the mitigation of and adaptation to Global Change impacts in the Barents region under the premise of achieving sustainable development in the European North.

Index terms: hibernation, minimum winter temperatures, Barents Sea region.

[1038] ECOLOGICAL ADAPTATIONS AND CONSERVATION OF THREE PAPILIONID SPECIES LIVING ON THE *ARISTOLOCHIA* SPECIES IN ULUDAG, BURSA, TURKEY

<u>B. Kovanci</u>¹, O.B. Kovanci¹ & N.S. Gencer¹, ¹ Uludag Univ., Fac. of Agriculture, 16384, Görükle, Bursa, TURKEY. E-mail: bkoruma@uu20.bim.uludag.edu.tr

There are three papilionid species, which feed on the Aristolochia spp. as larvae, in Mount Uludag located in Bursa. These species are Archon apollinus, Zerynthia polyxena and Allancastria cerisy. In IUCN Red Data Book, A. apollinus and Z. Polyxena is listed as vulnerable in Europe and A. cerisy is localised but common species in Turkey. In Uludag according to our studies, there are three landscapes where these species live. Two landscapes are small and one of these is modified for the agricultural production whereas the second is altered by urbanisation. The third one where all the three species live within an area of 2-3 km in diameter, have been disrupted by man's activities for the agricultural purposes. The studies were carried out essentially on this landscape where Aristolochia pallida and Aristolochia bodame, the larval foodplants, occur either side by side or mixed each other. The main aim of this study is to determine the landscape structure, composition, interactions and the characteristics of the ecological adaptations of three papilionid species and thus to obtain a sound data regarding their conservation. The study was based on the weekly counts and observations along the fragmented biotopes of the species in 1997 and 1998. Each of the species gives one generation in a year and overwinters as diapausing pupal stage. All species were monitored during the period from the first adult emergence in spring to the next pupal stage. Their behavioural ecology, lifehistory style and developmental stages were also examined. The first A. apollinus and Z. polyxena adults emerged on the same dates within April according to the climatic conditions. On the other hand, A. cerisy adults appeared 2-3 weeks later compared to the other species. Although the larvae of all species can feed on both foodplants as indicated above, Z. polyxena have a strong preference for A. pallida in nature whereas A. apollinus and A. cerisy feed primarily on A. bodame. A. apollinus lay eggs in groups but in other two species eggs are laid singly. In addition, A. apollinus larvae roll the upper leaves and feed inside them. In conclusion, it is possible to conserve these species by stopping the fragmentation and modification of the third landscape and by preserving hedgerows and as many biotopes as intact possible. Also of great importance are the restoration of some sites and sustainable utilisation of the landscape. In addition, beneficial aspects of insect conservation should be emphasized. Archon apollinus, Zerynthia polyxena, Allancastria cerisy

AND MAGNITUDE OF DENSITY FLUCTUATIONS IN SUBARCTIC FOREST MOTHS M. V. Kozlov¹, S. Koponen², J. Kouki³, P. Niemelä³ & P. W. Price⁴, ¹Sect. of Ecology,

[1040] LARVAL FOOD AND FEEDING HABIT CONTRIBUTE TO PERIODICITY

M. V. Kozlov', S. Koponen', J. Kouki', P. Niemelâ' & P. W. Price', 'Sect. of Leology, Univ. of Turku, FIN-20014 Turku, Finland, E-mail mikoz@utu.fi; ²Zoological Museum, Univ. of Turku, FIN-20014 Turku, Finland; ³Faculty of Forestry, Univ. of Joensuu, FIN-80101 Joensuu, Finland; ⁴Dept. of Biol. Sci., Northern Arizona Univ., Flagstaff, AZ 86011-5640, USA.

Density records of 232 species of Lepidoptera spanning 26 years (total catch amounts to ca 230,000 specimens), obtained by continuous light-trapping in Kevo, northernmost Finland, were used to quantify temporal variability of moth abundance's. Annual catches of 190 'rare' species fluctuated below or close to the doubled detection limit of our method (0.5 specimen/trap x year), and the maximum annual catches of 132 of these species never exceeded 1 specimen/trap x year. Catches of the remaining 42 'abundant' species accounted for ca 97 % of the total number of individuals, with mean densities ranging from 0.78 to 1716 specimen/trap x year. Moths with detritophagous or moss-feeding larvae, species hibernating in the larval stage, and species pupating during the first half of the growing season were over-represented among abundant species. Magnitude of density fluctuations in species whose larvae pupate early in the season (the character generally associated with hibernation in the larval stage) was 1.7 times higher than in species pupating late in the season. Magnitudes of density fluctuations in species with endophagous larvae were significantly higher than in species with exophagous larvae. Average coefficients of density variation were as follows: leaf onewers - 74 %, leaf rollers - 106 %, stem/root borers - 120 %, leaf miners - 188 %. Moths with herbivorous larvae generally demonstrated periodic density fluctuations whereas densities of species with larvae feeding on other substances usually fluctuated stochastically. Periodicity in density fluctuations was mostly recorded among species of Macrolepidoptera, whereas species from less advanced lepidopteran clades usually demonstrated stochastic density changes; however this conclusion presumably reflects size differences more than phylogenetic constraints. We concluded that some of life history traits are linked with temporal variability of moth abundance; quantitative approaches to population variability which forms a continuum from latent to eruptive species, rather than classification as 'outbreaking' and 'other' species, should be preferred in studies emphasizing an evolutionary perspective.

Index terms: Lepidoptera, life histories, population cycles, rarity, temporal variability.

[1041] SOCIAL EVOLUTION IN THRIPS: LACK OF REPRODUCTIVE SKEW IN A GALL FORMING THRIPS WITH 'SOLDIERS'

B. D. Kranz, T. E. Wills & <u>M. P. Schwarz.</u> School of Biological Sciences, Flinders University, GPO Box 2100, Adelaide S.A. 5001, Australia. Email: Michael.Schwarz@flinders.edu.au

One or two origins of eusociality have been inferred for the gall-inducing Australian thrips living on Acacia species in arid Australia. The existence of eusociality in these thrips was based on the coincidence of three traits: 'soldier-like' defensive armature in a micropteran non-dispersing generation, gall defence by these micropterans, and reproductive skew between the micropterans and their foundress mother. Recently, we have examined reproductive skew in a previously unstudied gall-inducing species, Oncothrips morrisi, with a micropteran generation. Micropterans in this species do not have smaller ovaries than their foundress mother and appear to be responsible for producing all, or virtually all, of the dispersing macropteran generation. This finding has two broad kinds of implications for studies of insect sociality: (i) it raises questions about how definitions of eusociality can be applied to the spectrum of social forms existing in insects; and (ii) it indicates that defensive adult morphology in group living species need not be linked to reproductive skew. O. morrisi exhibits larger gall volumes, and larger brood sizes, than occur in other described gall forming thrips with micropteran 'soldier-like' morphology. The lack of skew in O. morrisi may be linked to the inability of foundress mothers to fully exploit the resources of large galls. If this is the case, it may be that 'soldier-like' morphology of micropterans is more an adaptation of parental care (defence of offspring) and a lack of need for dispersal, than altruistic defence of collateral relatives. However, we have also studied reproductive skew in an undescribed species which is a sister species to O. morrisi. This has much smaller galls than O. morrisi, but also exhibits little or no reproductive skew, suggesting that gall size is not sufficient to explain the fully reproductive micropterans in O. morrisi. It is possible that O. morrisi and its undescribed sister species represent a plesiomorphic state in the evolution of thrips soldiers, rather than a proximate response to gall size.

Index terms: Oncothrips, thrips, eusociality, sociality, galls.

[1043] SPATIAL INTERACTION OF *PIRATA SUBPIRATICUS* (LYCOSIDAE) AND *PACHYGNATHA CLERKI* (TETRAGNATHIDAE) IN THE RICE FIELDS

<u>J.-H. Lee</u> & J.-A. Park, Entomology Program, School of Agricultural Biotechnology, Seoul National University, Suwon 441-744, Korea, E-mail jh7lee@plaza.snu.ac.kr.

This study was conducted to investigate the patterns of colonization and the spatial distribution of Pirata subpiraticus and Pachygnatha clerki in the rice ecosystem. investigate the interactions between P. subpiraticus and Pa. clerki, 10 rice hills were covered individually with transparent acryl plastic pipes and these spiders were introduced into each arena. In July, 1 individual : 1 individual and 3 individuals : 3 individuals ratios were tested. In October, 6 P. subpiraticus without Pa. clerki, and 6 Pa. clerki without P. subpiraticus were tested. The heights of vertical distribution and changes of densities of P. subpiraticus and Pa. clerki were investigated. Intraspecific competition was stronger than interspecific competition between two species. P. subpiraticus shared their shelter in the bottom of rice hill. Pa. clerki were far off each other and removed other individuals. The heights of location (mean ±SD) of P. subpiraticus and Pa. clerki were 1.9 ±2.65 and 9.4 ±5.72, respectively, at the 1:1 ratio. The heights of location of P. subpiraticus and Pa. clerki were 3.0 ±3.70□ and 19.6 ±11.34□ respectively, at the 3:3 ratio. The height of location of *P. subpiraticus* on the rice plant at an initial density of 6 individuals/plant was location of *P. subprattices* of the rice plane at all initial density of 6 individuals/plot was $22.7\pm12.97\Box$. The densities and distributions of rice spiders were examined in 100 (10×10) hills at three sites. Dominant families were Lycosidae, Erigoninae, Thridiidae, and the dominant specie was P. subpiraticus. Densities of spiders peaked on July and September. P. subpiraticus and Pa. clerki did not occur together in the same rice hill when densities were low in early season. However, after August when spider densities became higher, their coexistence in the same hill was common. The several individuals of the same spider species were also found during this period. The spatial distribution patterns of these spiders in the rice fields were analyzed.

[1042] DEFORESTATION, DROUGHT AND EXCEPTIONAL OUTBREAKS OF THE ORIENTAL MIGRATORY LOCUST, LOCUSTA MIGRATORIA MANILENSIS (MEYEN 1835) IN INDONESIA

M. Lecoq¹, Sukirno², M.H. Luong-Skovmand¹ & T. Rachadi¹, ¹CIRAD, Centre de coopération internationale en recherche agronomique pour le développement, B.P. 5035, 34032 Montpellier Cedex 1, France, E-mail : michel.lecoq@cirad.fr; ²Directorate General for Food Crops and Horticulture, Directorate of Crop Protection, JL Aup Pasar Minggu, Jakarta Selatan, Indonesia.

Serious outbreaks of oriental migratory locusts, Locusta migratoria manilensis, have been reported on different islands of the Indonesian archipelago during the rainy seasons 1997-98 and 1998-99. Sumatra, Java, Kalimantan, Sumba, Timor, Sulawesi and Flores were particularly affected. By far the most serious outbreaks were recorded in southern Sumatra, in Lampung province, in 1998. Such large outbreaks seems a new phenomenon. They were much larger than the small local upsurges recorded in the past. On the long term prospect these outbreaks are certainly caused by drastic environmental changes. The intensive deforestation that has been under way over the last 20 years is certainly partially responsible for these outbreaks. In many places, the natural forest has been replaced by large plantations: sugarcane, oil palm, natural rubber, cassava, etc. New biotopes were created, some of which seem to be very suitable for migratory locusts, especially in sugarcane plantations on light soils. These areas are certainly source areas (at least part of them) of the recent outbreaks, specially in Sumatra. On the short term, the drought that prevailed in Indonesia in 1997 also seems to be a major recent factor that prompted these outbreaks. Meteorological data analysis indicate that these outbreaks are likely to be linked to the frequency of droughts which prevailed more often in these areas during the last ten years, as the famous 1997 El Niño drought. We have indications that the problem might become recurrent in Indonesia and grow even worse in the future. Index terms : Orthoptera, Acrididae, El Niño

[1044] DAMAGE OF CUCUMBER, CUCUMIS SATIVUS CAUSED BY FEEDING OF THE COTTON APHID, APHIS GOSSYPII

S.-W. Lee & <u>J.-H. Lee</u>, Entomology Program, School of Agricultural Biotechnology, Seoul National University, Suwon 441-744, Korea, E-mail jh7lee@plaza.snu.ac.kr.

To assess the damage of cucumber, Cucumis sativus L. caused by feeding of the cotton aphid, Aphis gossypii Glover, its direct damage and indirect damage were assessed. Plant growth analysis and crop growth analysis was conducted. A. gossypii punctured in leaf cells and significantly reduced net photosynthetic rate and total chlorophyll content of the leaf. Ultimately, their damage caused loss of productivities of leaves, stems, and fruits and resulted in hindrance of plant growth. Aphid feeding caused significant collapse of epidermis cell and parenchyma cell of the leaf during reaching phloem sap. Results of quantification of aphid feeding for leaf damage showed that net photosynthetic rates were reduced by 70% by adult aphid feeding at 300 Aphid-days and total chlorophyll contents were reduced by 75% by adult aphid feeding at 600 Aphid-days. The relationship between the cotton aphid initial density levels (control, 5, 10, 20, 40 aphids per plant) and the cotton aprild finitial density revers (control, 5, 10, 40, 40 apriles per plan) and cucumber growth stages (vegetative stage, vegetative-reproductive stage \Box) and yield were determined to develop injury levels for the establishment of control times. In the vegetative stage, leaf area, total fresh and dry weights of cucumbers decreased significantly with increasing Aphid density. In vegetative-reproductive stage , low initial aphid density levels caused non significant damage compared with control plot, but significant damage occurred in initial density levels. In vegetative-reproductive stage [], these was no significant damage by any initial density levels. Plant growth analyses such as relative growth rate (RGR), unit leaf rate (ULR), leaf area ratio (LAR) showed the most damage occurred in the vegetative stage. Results of crop growth analyses with leaf area index (LAI) and crop growth rate (CGR) also showed heavier damage occurred in the vegetative stage than in any other stages.

[1045] EFFECTS OF TRICHOMES AND CRISTALIFEROUS IDIOBLASTS DENSITIES, CONCENTRATIONS OF MINERALS AND WEATHER ON THE BEMISIA ARGENTIFOLII IN TOMATO

<u>G. L. D. Leite¹, M. Picanço², M. D. Moreira², M. R. Gusmão² & G. N. Jhan³, ¹ Dept. de Fitotecnia, Univ. Fed. de Minas Gerais, CEP 39040-006, Montes Claros, MG, Brazil, E-mail gldleite@ig.com.br; ² Dept. de Biologia Animal, Univ. Fed. de Viçosa, ³. Dept. de Química, Univ. Fed. de Viçosa, CEP 36571-000, Viçosa, MG, Brazil.</u>

The objective of this study was to evaluate the factors that affect B. argentifolii in the tomato. Thus, the weather data, the natural enemies, the leaf minerals concentrations (N and K), as well as densities of trichomes and cristaliferous idioblasts in leaves of Lycopersicon esculentum cv. "Santa Clara" were determined and these parameters were correlated with B. argentifolii infestation. The largest trichomes density/mm² observed in the face abaxial (21.29 \pm 1.52) than in the adaxial (8.19 \pm 0.57), and these trichomes were mainly non-glandular (99.65%). Trichomes and cristaliferous idioblasts densities increased from the bottom to the apex of the plants ($R^2 = 0.91$ and 0.95, P <0.01; respectively) and decreased with age ($R^2 = 0.16$ and 0.26, P <0.01; respectively). The levels of N and of K decreased with plant age $(R^2 = 0.53 \text{ and } 0.12, P < 0.01;$ respectively), and an increase in leaf levels of N increased the trichomes $(R^2 = 0.14, P < 0.01;$ <0.01) and cristaliferous idioblasts densities ($R^2 = 0.17$, P <0.01). The number of nymphs $(R^2 = 0.85, P < 0.01)$ and adults $(R^2 = 0.94, P < 0.01)$ of *B. argentifolii* increased from the bottom to the apex of the plants. There was also an increased in the number of eggs ($R^2 = 0.53$, P<0.01), nymphs ($R^2 = 0.66$, P<0.01) and adults ($R^2 = 0.22$, P<0.01) with plant age. There was a decrease in number of nymphs and adults of this insect with increasing levels of N ($R^2 = 0.67$ and 0.12, P <0.01; respectively), and trichomes ($R^2 = 0.56$ and 0.32, P <0.01; respectively), and cristaliferous idioblasts densities ($R^2 = 0.36$ and 0.14, P <0.01; respectively) in the leaves. The increase in air temperature favored the adults of this insect $(R^2 = 0.17, P < 0.01)$. The density of trichomes and cristaliferous idioblasts were negatively correlated with eggs of B. argentifolii (R² = 0.80 and 0.36, P < 0.01; respectively). The natural enemies did not correlate with any of the studied factors. There was no nymph parasitism of B. argentifolii.

Index terms: Insecta, whitefly, Lycopersicon esculentum, population dynamic, fertilization levels

[1047] THE LYFE TABLE PARAMETERS FOR ZAGLOBA BEAUMONTI (COLEOPTERA: COCCINELLIDAE) AS A PREDATOR OF DIASPIS ECHINOCACTI (HEMIPTERA: DIASPIDIDAE)

I. M. de M. Lima¹, L. M. de Almeida² & G. V. de S. Barbosa³, ¹Dept. of Zoology, Univ. Fed. de Alagoas, Praça Afrânio Jorge s/n Centro, 57010-020, Maceió – Alagoas, Brasill. E-mail iralima@dialnet.com.br; ²Dept. of Zoology, Univ. Fed. do Paraná; Dept. Univ. Fed. De Alagoas.

This study shows the longevity and reproductive performance of Zagloba beaumonti Casey, 1899 (Scymninae: Scymnillini) a potential biological control agent for Diaspis echinocacti (Bouché, 1833) the unique pest of prickly-pear [Nopalea cochenillifera and Opuntia ficus-indica (Cactaceae)] - the main food sources for the survival of cattle and even people in semi-arid areas of Northeastern Region of Brazil. The bioessays were carried out under mean room conditions of 67,44% of relative humidity and 26.70 °C. The larvae were isolated in petri-dishes and the adults were reared in plastic glasses (one couple per recipient of 250 mL, covered with organdy fixed with rubber band). The prev were produced on "rackets" of the cactaceae. The base of each recipient was lined with filter paper. A sample of adults and larvae was deposited at the Coleção Entomológica Pe. Jesus Santiago Moure, Departamento de Zoologia da Unversidade Federal do Paraná. The pre-imaginal period was 22.55 days. The viability of eggs was 11.00% and the survival from neonate larvae to adult was 57.40%, wich represents a final survival of 51,00% from eggs. The sex ratio was 0.52 (1.082 females for each male) and the mean longevity, in days was 55.53 for adults, 56.63 for males and 54.42 for females. The female reproductive features were: 12.63, 36.11 and 5.68 respectively for the preovipositional ovipositional and post-ovipositional periods; 105.32 eggs (mean fecundity which represents an oviposition rate of 2.92 eggs/day distributed on 56.21 egg batches (1.55 batches/day and 1.88 eggs/batch). The mean level of ovipositon was 44,46 eggs on the 44th day of longevity. The populational statistics based on life table parameters were: 73.48 eggs/female (the gross reproductive rate, R), 25.21 net reproductive rate (R), 13.16 days (time to double the population, DT), 0.0666 (innate capacity for increase, r_c , by iteration), 0.059 (approximated value for the capacity of increase, r_m), 1.16 females per day (the finite rate of increase, λ), 5.81 generations per year, 22.00 as the mean length of a generation that means an addiction of with an annual reproduction potential of 252,157,643 females. The value of λ confirms the Ro value, showing an increase from a generation to another. The mean length of a generation (T), 21.23 days, means that the population of Z beaumonti will grow 25,21 (Ro) times in this period. The life expectancy table shows that the key-period for field releases is the 10^{th} day after emergence when the survival and egg production are in better levels.

Index terms: Scymninae, Scymnillini, biological control, prickly-pear, Cactaceae

[1046] *EPICHLOË* GRASS ENDOPHYTES AND THEIR INTERACTION WITH A SYMBIOTIC FLY

<u>A. Leuchtmann</u>¹, ¹Geobotanisches Institut, ETH Zürich, Zollikerstrasse 107, CH-8008 Zürich, Switzerland, E-mail leuchtmann@geobot.umnw.ethz.ch

Epichloë grass endophytes (Ascomycota) and related, asexual species form systemic associations with many poold grasses in temperate regions of the Northern hemisphere. During sexual reproduction the fungus produces spore forming structures (stromata) around aborted host inflorescence referred to as choke disease. Host specific fungal species are self incompatible (heterothallic) and need to be fertilized by spermatia of opposite mating type. The vectors for transferring spermatia are specialized flies of genus Botanophila which ingest spermatia and pass them through their gut. Female flies lay eggs on young fungal stromata and, by depositing faeces, fertilize them in the process. Hatching larvae feed on developing perithecia as their exclusive food source and thus maintain a symbiotic relationship with Epichloë fungi. As a consequence of sexual incompatibility of different Epichloë taxa, dependence on fertilized stromata as food source should promote specialization of flies to one compatible taxon. Investigations were made to examine whether flies are specialized on host grasses and their Epichloë fungi, and how flies could recognize different hosts. Distribution of fly genotypes collected from different hosts did not indicate host preference of flies. However, field observations and the absence of mating among different host strains in experimental field plots clearly suggested a high degree of specificity of flies. Volatile odours collected and analyzed from infected host plants revealed different patterns for each host association. Moreover, patterns of volatiles varied between day and night and during ageing of stromata. We hypothesize that volatiles could serve as specific attractants for Botanophila flies and may provide guidance for purposeful visits among compatible fungal stromata of the same species. Index terms: Botanophila, fungi, mutualism, volatile compounds.

[1048] ARTHROPOD DIVERSITY IN AN AGROFORESTRY SYSTEM OF BLACK WALNUT AND FORAGE CROPS

M.J. Linit, W.T. Stamps & T.L. Woods, Dept. of Entomology, Univ. of Missouri, 1-87 Agriculture Bldg., Columbia, MO 65211, USA, E-mail: linit@missouri.edu.

Alley cropping holds promise for increasing insect diversity and reducing pest problems by improving natural enemy complexes and adding competition to pest species. Arthropod diversity in an agroforestry system of walnut and forage crops was examined to determine the effects of the forage crops on walnut arthropod communities and the effects of walnut on forage crop insect communities. Eighteen blocks (12m x 36m) of 4 x 5 trees on 3m x 12m spacing were identified and three treatments were applied to six blocks each (randomized block design). The treatments were alfalfa (Medicago sativa), smooth brome (Bromis inermis), and chemical herbicide. Five 12m x 36m non-tree plots were selected to the immediate east of one area and incorporated two alfalfa plots, two brome plots and one herbicide plot. We sampled the plots with pitfall traps, sweep nets, and vacuuming prior to each cutting date for the forages. Comparisons were made between treatments and sampling dates. Approximately 2500 insect samples were examined over the two-year sampling period. The data analysis was consistent across both years of sampling. Alfalfa supported a greater number of taxa and individuals than did brome, and brome likewise supported more arthropods than bare earth plots. In alfalfa, significant differences in functional taxa groups (predators, herbivores and parasitic hymenoptera) were found between agroforestry plots and monocropped plots. Alfalfa intercropped with walnut supported twice as many predators and parasitic hymenoptera and half as many herbivores than did alfalfa alone. Apparently, the walnut trees provide a real benefit for the large numbers of predators and parasitic hymenoptera found in intercropped alfalfa. The results presented here bode well for pest management in an agroforestry setting and support the associational resistance" theory that multi-species plant associations have reduced insect damage compared to single species plant systems.

Index terms: Medicago sativa, Bromis inermis, alley cropping, natural enemies, associational resistance

[1049] DETERMINATION OF THE INFLUENCE OF THE MATURITY OF THE LEAVES OF CLITORIA FAIRCHILDIANA IN THE DEVELOPMENT OF URBANUS ACAWOIOS (LEPIDOPTERA: HESPERIIDAE)

A. M. Lunz¹, J. G. N. Wendt¹, J. of M. Pinto², F. A. A. Ferrara² & A. G. Carvalho¹, 1Depto. de Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: amehl@zipmail.com.br; 2Depto. de Fitotecnia, Univ. Fed. Rural do Rio de Janeiro.

Urbanus acawoios has been causing big defoliate to the essence forest Clitoria fairchildiana (Leguminosae: Faboidae), the popular "sombreiro", used for arborization of parks, gardens and highways, since 1979, mainly in the southeast area of Brasil. Outbreaks of U. acawoios were verified in this essence in almost the whole country. This work had as main objective to determine the influence of the degree of maturity of the leaves of C. fairchildiana in the development of U. acawoios to the temperature it sets. The study was driven in the Laboratory of Forest Entomology of the Institute of Forests of the Universidade Federal Rural do Rio de Janeiro, in the period of March to April of 1999. The medium temperature during the conduction of the experiment was of $26,25 \text{ °C} \pm 1,59 \text{ °C}$, while the relative humidity of the air was of $69,49\% \pm 10,38\%$. The medium weight of the 1° and 5° instars were not verified. The leaves were classified as new, middlemen and old, being used thirteen caterpillars by treatment. The medium duration of the 1°, 2°, 3°, 4° and 5° larval instars, prepupa, pupa, the adult's longevity and cycle of total life of U. accavoios, in days, were of 2,1; 2,3; 3,1; 2,6; 2,6; 1,2; 2,0; 9,3 and 25,2 for new leaves; 2,3; 2,6: 2,5: 3,0: 3,1; 1,6; 1,8; 10,2 and 27,1 for the middlemen; and 2,1; 2,1; 2,3; 3,3; 3,1; 1,0; 2,0; 11,0; 26,9 for the old ones. The medium weight, in grams, of the 2°, 3° and 4° larval instars, prepupa and pupa of U. acawoios was of 0,0048; 0,0271; 0,1411; 0,3297 and 0,3227 in the new leaves; 0,0034; 0,0154; 0,1048; 0,3454 and 0,3311 in the middlemen; and 0,0062; 0,0187; 0,0975; 0,3197 and 0,3138 in the old ones. When compared by the Test of Tuckey to the level of 5% of probability, the medium duration of the life cycle and its phases, in days, they didn't differ significantly among the three degrees of maturity of the leaves of C. fairchildiana offered as food for U. acawoios. The comparison of the medium weight, in grams, for the three treatments, in the analyzed phases, they only showed statistical difference in two situations: in the second larval instar fed with smaller intermediary leaves than the treated ones with new and old leaves of the same instar; and in the third instar of treated caterpillars with new leaves obtained larger weight than the other types of leaves.

Index terms: Defoliate, Arborization, Outbreak.

[1051] TRITROPHIC EFFECTS OF A LEAFTYING LEPIDOPTERAN AS A KEYSTONE ECOSYSTEM ENGINEER

<u>R. J. Marquis</u>¹ & J. T. Lill¹, ¹Dept. of Biology, Univ. Missouri-St. Louis, 8001 Natural Bridge Rd., St. Louis, MO 63121-4499 EUA, E-mail robert_marquis@umsl.edu.

In addition to their trophic and competitive effects, shelter-building caterpillars can act as physical ecosystem engineers on their host plants by creating habitats that are subsequently colonized by an array of other organisms. We hypothesize that these engineering effects will influence the abundance and diversity of other herbivores (second trophic level), abundance and diversity of predators and parasitoids (third trophic level), and damage to the plant (first trophic level). In a temperate deciduous forest in the central United States (Missouri), approximately fifteen species of leaftying caterpillars are found on white oak (*Quercus alba*). We hypothesize that one species in the genus *Pseudotelphusa* acts as a "keystone" engineer, in that it creates the first wave of leafties in the early summer that are then preferentially colonized by a the remaining species. In order to examine the engineering effect of Pseudotelphusa sp., over and above its effect as a biotic interactant, we conducted a field experiment in the summer of 1999 in which we manipulated the density of leafties on individual white oak saplings and observed the effects on (1) the abundance and composition of the arthropod community, and (2) the amount of leaf damage accrued throughout the season. In order to separate the caterpillar's engineering effects from its trophic/competitive effects, we created artificial leafties both with and without caterpillars initially present. Compared to control trees, the treatments in which we clipped 10% of the leaves into leafties had twice the number of total arthropods and significantly greater species richness one month post-treatment. This difference persisted until the end of the growing season 3 months later. This pattern was largely due to recruitment of other leaftying caterpillars to trees containing artificial ties. The third trophic level, however, was also affected, as spiders and insect predators increased in the presence of artificial ties during the second half of the growing season. Finally, damage by leaftying caterpillars to artificial ties initially containing a single *Pseudotclphusa* caterpillar was twice that of initially empty ties, indicating a strong biotic effect in addition to the engineering effect (i.e., a colonization cue, such as damage, frass or feeding-related volatiles). These results suggest that in order to understand the impacts of shelter-building insect herbivores on associated arthropods and their host plant, we need to consider their role not only as herbivores, prey, and competitors, but also as engineers that create new habitats.

Index terms: Pseudotelphusa, insect herbivore, interspecific interactions, Quercus, biodiversity.

[1050] BIOECOLOGY OF URBANUS ACAWOIOS (LEPIDOPTERA, HESPERIIDAE) IN CLITORIA FAIRCHILDIANA IN CONTROLLED TEMPERATURE

M. C. Machado¹, S. R. S. Ventura¹ & <u>A. G. Carvalho¹</u>, ¹Depto, Produtos Florestais, Univ. Fed. Rural do Rio de Janeiro, Seropédica, RJ 23851-970, Brasil. E-mail: acacio@ufrrj.br.

The species forest Clitoria fairchildiana, the "sombreiro", is very used for to shade highways and for arborization of parks and gardens for the quality of its large crown. Native of the Amazon area, it was introduced in several Brazilian states for these purposes. Starting from the end of the seventies, population outbreaks of the defoliate Urbanus acawoios have been verified in this tree with more and more frequency, causing scrious damages. In this work, were obtained the parameters bioecologicals of U. acawoios in leaves of C. fairchildiana to the temperature of $29 \pm 2,1$ °C in stove. The experiment was accomplished in the Laboratory of Forest Entomology of the Universidade Federal Rural do Rio de Janeiro in the period of July 11 to September 5, 1999, with twenty repetitions. The medium duration, in days, of the five larval instars it was 3,1; 2,1; 2,1; 2,5 and 5,1, respectively. The medium duration so much for the prepupa stage as for the one of pupa it was of one day and the medium longevity for the adult it was of 15 days. The verified medium life cycle was of 35,8 days. The medium weight, in grams, of the third to the fifth instar was 0,0281; 0,1210 and 0,3217, respectively. For prepupa, the medium weight was of 0,3203 g, while for pupa it was of 0,3116 g.

Index terms: Defoliate, Arborization.

[1052] SEX RATIO IN THE ADULTS OF THE BUTTERFLY EUPHYDRYAS DESFONTAINH IN CENTRAL SPAIN

<u>J. Martín</u>¹ & J. M. Ferrín^{1, 1}Dept. de Biología, Univ. Autónoma de Madrid, Cantoblanco, 28049 Madrid, Spain.

The genus Euphydryas has some of the best known and studied butterfly species. In Europe it has two species: E. aurinia, a widespread and well known species and E. desfontainii, with a more restricted distribution and less studied. E. desfontainii can be considered the vicariant species of E. aurinia in areas with Mediterranean climate. It can be found in the Western Mediterranean: Spain, Portugal, Southern France and the North of Morocco and Argelia. As the other species of the genus it is univoltine and overwinters as larva. Adults fly in the Spring from the middle of May to mid June. Larvae are gregarious during their first instars and feed on Cephalaria leucantha. The habitat of both the butterfly and the plant consists on disturbed and marginal areas. During three years a population of the species was studied in Central Spain using mark-release-recapture (MRR) techniques. The study area was visited two or three times per week along the flight period. The captured specimens were given an individual mark, and the hour, sex, location of the capture, activity and relative wingwear were recorded for each butterfly. In the three years the total of captured and marked specimens was larger for the males in a proportion 2.5:1. The estimated number of individuals using the Poisson and the Jolly-Seber methods was also larger for the males than for the females. However, the sex-ratio obtained from laboratory cultures was not different from 1:1. There can be two possible explanations for the differences obtained between the results obtained in the laboratory and in the field. One is the different longevity of the sexes and the other differences in adult mobility. If the males live longer a larger number can be found flying in the site at a given moment. As far as differences in mobility is concerned, the males move longer distances than females. This produces more males from adjacent areas than females and results in an apparent larger number of males.

Index terms: lepidoptera, mark-release-recapture, longevity, mobility

[1053] THE SAND-FLEA HISTORY (TUNGA: SIPHONAPTERA)

<u>R. Mascarenhas</u>, Pós-Graduação Zoologia IB-UNESP-Botucatu, FAPESP Nº 98/02420-5 e-mail rita.mascarenhas@mailcity.com

The first record of sand-flea dates from 1526, when the Europeans arrived at American continent (Oviedo, 1526), but this animal was known much before by the Amerindians living from Brazil up to Mexico. The sand flea have many different common names in different languages as Maya, Aztec, Tupi and their derived languages. Brazil presents the greatest number of species of the genus *Tunga* all around the world, and an amount of folk records about the parasite-host interaction. Due to the long term relationship between this insect and humans, it is common to found many traces of it in the popular at as music and dance and even some therapies in the popular medicine to deal with the problems caused by this insect. Many of the former visitors which arrived in America as Hans Staden, De Lery, Wallace, MarcGrave and Saint Hilaire, reported their suffering with the infections and other illnesses caused by the sand flea. This insect was considered of African origin but nowadays its is known to be really Neotropical.

[1055] *DROSOPHILA* FAUNA (DIPTERA, DROSOPHILIDAE) IN THREE XEROPHYTIC AREAS OF SÃO PAULO STATE (BRAZIL)

R. P. Mateus & F. M. Sene, Dept. of Genetics, FMRP, Univ. São Paulo, Ave. Bandeirantes 3900, CEP 14049-900, Ribeirão Preto, SP, Brazil. Email: pincela@rgm.fmrp.usp.br. Financial Support: FAPESP, CNPq, FINEP, CAPES and USP.

The genus Drosophila (Diptera, Drosophilidae) includes more than 1700 described species. Some are endemic of certain regions, others are cosmopolitan due to their association with man. The majority of the Drosophila feed on microorganisms, mainly yeast, found in decaying fruits, vegetables, and cacti. We made a survey of Drosophila fauna in three cactus areas (Cereus hildemaniannus) in the state of São Paulo, comparing the frequencies of the species collected in these areas. In Serrana (SRN) we examined the temporal variation of the frequencies of the cactophilic species of the repleta group. Collections were made bimonthly in SRN from sept/98 to may/99 and in Itatiba (ITA) in april/99 and Sertãozinho (SRT) in oct/99. A total of 17894 flies were identified as belonging to 25 different species of Drosophila, 23 in Serrana, 17 in Sertāozinho and 16 in Itatiba. The species found were: D. annulimana, D. polymorpha, D. pallidipennis, D. coroica, D. mercatorum, Drosophila sp. D (formely D. serido "Type D"), D. simulans, D. sturtevanti and D. latifasciaeformis (SRN, SRT, ITA); D. immigrans, D. buzzatii, D. nigricruria, D. paranaensis, D. bandeirantorum and D. busckii (SRN, SRT); D. cardini, D. ornatifrons, D. mediostriata, D. malerkotliana, D. prosaltans and D. willistoni (SRN, ITA); D. meridionalis (SRT, ITA); D. nebulosa and D. fumipennis (SRN); and D. aldrichi (SRT). In Serrana, D. simulans was most frequent in september/98 (0.336), D. mercatorum in november/98 (0.302), D. sturtevanti in january/99 (0.754), D. willistoni in march/99 (0.413) and D. buzzatii in may/99. All Drosophila species of the repleta group were found at low frequencies in the dry season, increasing in the wet season, except D. paranaensis and D. mercatorum which showed an inverse pattern. In all areas some species simultaneously appeared at a greater frequency. D. simulans was most frequent in Sertãozinho (0.465) at the same time that it was in Serrana. In Itatiba, D. willistoni was most frequent (0.373) at the same time that it was in Serrana. D. aldrichi was collected in Sertãozinho for the first time. The high diversity found in Serrana could have been influenced by the numerous collections and because this area is of difficult access, diminishing anthropogenic action. The temporal variation found seems to be under a climatic influence.

[1054] SPECIATION AND DISPERSAL OF MARINE SHORE DOLICHOPODID FLIES IN EAST ASIA (DIPTERA: DOLICHOPODIDAE, HYDROPHORINAE)

<u>K. Masunaga</u>¹ & T. Saigusa², ¹Biosystematics Laboratory, Graduate School of Social and Cultural Studies, Kyushu Univ., Ropponmatsu, Fukuoka City 810-8560, Japan, E-mail: moaircb@mbox.nc.kyushu-u.ac.jp; ²Baikoen 2-7-1-402, Fukuoka City 810-0035, Japan.

In East Asia there are four hydrophorine dolichopodid genera, Acymatopus Takagi, Conchopus Takagi, Thambemyia Oldroyd and Cymatopus Kertész which exclusively inhabit rocky seashores. The former three are more closely related to each other than to the fourth, and appear to constitute a monophyletic group together with the Nearctic genus, Paraphrysylus Becker. In this paper, we compare the geographical distributions of species in the three genera with their ND5 gene tree, and discuss the mode and pattern of speciation and process of dispersal in this group. Most species of Continental China are either conspecific with or the sister species of a Japanese species. This suggests that speciation of the Continental species occurred relatively recently in the evolution of each genus. It is also considered that extant or ancestral species were widely distributed over the region when the Asian Continent was connected with the Japanese Archipelago during Quaternary glacial epochs. Ancestral species speciated after their ranges were isolated by higher sea levels during interglacial epochs. It has been frequently demonstrated that the Japanese fauna originated from the Asian Continent. But the present study also suggests that there are some cases in which species originated in Japan, and subsequently spread to the Continent. In other words, dispersal routes between the Asian Continent and Japan following speciation was in two directions. The present study also suggests that no long distance dispersal via ocean currents occurred in this group, at least between Japan and the Asian Continent.

[1056] SAMPLING AND POPULATION DISTRIBUTION OF MITES FROM STIGMAEIDAE FAMILY IN CITRUS ORCHARDS IN SÃO PAULO STATE

<u>A. L. Matioli</u>¹ & C. A. L. Oliveira¹, ¹Dept. Fitossanidade, Univ. Est. Paulista/Câmpus Jaboticabal, Jaboticabal, SP, Brazil, 14.870-000, E-mail amatioli@fcav.unesp.br

This work was carried out in six municipalities of São Paulo State (Limeira, Araraquara, Itápolis, Jaboticabal, Bebedouro and Olímpia), during June 1998 until January 2000. It was sampled leaves, branches and fruits of citrus, variety "Péra-rio" (*Citrus sinensis*), over there more five frequently weed of each one sampled field. The sampling was realised monthly. The weather data (temperature, humidity and rain) was compared with population fluctuation curves of stigmeids species. We have found two species of stigmeids mites *Agistemus* aff. *bakeri* and *Zetzelia* aff. *yusti* or *mapuchina*, where *A*. aff. *bakeri* was the most abundant specie (97.5%). The stigmeids mites was found in Olímpia, Itápolis, Araraquara and Limeira municipalities, and in Limeira, SP, was the municipality that was found more number of stigmeids mites. The population distribution into the plant was studied and have verified that there are preference to fruits and leaves of citrus. The relationship between weather data and population distribution of stigmeids mites, the population had peaks during July until November, the same period of large occurrence of "leprosy mite" *Brevipalpus phoenicis* (Tenuipalpidae), the transmitter of virus plant disease. In the weeds sampled was found none stigmeids wates.

Index terms: Stigmeids, Citrus sinensis, biological control, Agistemus aff. bakeri, weeds.

[1057] FOOD PREFERENCE OF AGISTEMUS AFF. BAKERI (ACARI: STIGMAEIDAE)

<u>A. L. Matioli</u>¹ & C. A. L. Oliveira¹, ¹Dept. Fitossanidade, Univ. Est. Paulista/Câmpus Jaboticabal, Jaboticabal, SP, Brazil, 14.870-000, E-mail amatioli@fcav.unesp.br. Backing: FAPESP (Fundação de Âmparo à Pesquisa do Estado de São Paulo)

The biotest aimed to establish what the best food source to the stigmeids mites Agistemus aff. bakeri, towards was tested three food source, Brevipalpus phoenicis, Panonychus citri e Tetranychus urticae. It was used 10 stigmeids females of same age, to each one treatment, isolated into 10 cages, where was valued the daily posture per stigmeid female, during a week. The treatment that was tested P. citri, as food source, the stigmeid female was isolated in leaf citrus cage, with adaxial surface to up side and into each one cage were released 20 females of tetranychid, 48 hours before to release the stigmeid female. To the treatment that was tested B. phoenicis as food source, it was selected citrus fruits that have contained more than 100 mites per fruit, to release the stigmeid female into the cages. To test T. urticae as food source, it was utilized leaf citrus cages, supplying eggs and young stages of tetranychids to stigemeids females each 48 hours. The biotest was carried out into the climate room with temperature, relative humidity and light period from 25°C, 80% and 12 hours, respectively. The assessments were realized daily during seven days. The results have showed that the best food source was B. phoenicis, that produced 2.6 eggs per day, while the stigmeids females were fed with P. citri and T. urticae laid 2.1 and 0.44 eggs per day, respectively. The daily eggs laid per stigmeid female in function of the time, when the females were fed with P. citri, the curve showed unstable, perhaps did not have a large number of eggs laid per female but it was extended the period of lay eggs. The stigmeids female fed with B. phoenicis laid the most number of eggs four days after the initial of assessments. The T. urticae as food promoted a shorter daily lay of eggs and the lay of eggs period. In reason this results, we advice to rear A. bakery feeding with B. phoenicis and P.citri in labor because those specimens have showed the most efficient supply. Index terms: Stigmeids, tetranychids, B. phoenicis, biology, biological control, rearing labor.

[1059] UTILISATION OF UNIQUE ATTRIBUTES OF LARVAL WHITEFRINGED WEEVIL FOR BIOASSAYING TOXICITY OF PURE AND PLANT-DERIVED FUMIGANT COMPOUNDS

<u>J. N. Matthiessen</u>, CSIRO Entomology, Private Bag PO, Wembley, WA 6014, Australia. E-mail: johnm@ccmar.csiro.au.

The soil fumigant metham sodium, a methyl isothiocyanate precursor, has assumed a unique application as product-of-choice for control of whitefringed weevil, Naupactus leucoloma, the 'key' soil pest in potato production in parts of Australia. Its high cost is justified by the potentially devastating threat that this insect presents, together with spinoff benefits of enhanced tuber quality from suppression of noxious soil-borne microorganisms. Arising from concerns about the long-term sustainability of this pest management practice and its high cost, considerable interest in the potential of 'biofumigation' by isothiocyanate-releasing brassicas for suppression of soil-borne pests and diseases has developed. First instars of whitefringed weevil are a particularly good bioassay model for assessing and comparing the efficacy of volatile soil fumigants and biofumigants against an entomological target. Eggs are readily obtained in the thousands and, after providing appropriate conditions for embryogenesis, can be stored for long periods. The larvae remain in the egg and only hatch when stimulated by contact with water. Thus large numbers can be stockpiled and produced at will for experimental studies. Furthermore, the first instar is a non-feeding stage capable of many days' survival with neither food nor shelter. Longevity varies with temperature, but comfortably accommodates periods required to bioassay volatile compounds at a wide range of environmentally-realistic temperatures without appreciable mortality of untreated controls. Because of their unique attributes, first instar whitefringed weevil are proving highly valuable as an entomological bioassay tool for determining the toxicity of both pure isothiocyanates, and the wide variety of these compounds emitted by hydrolysis of various Brassica tissues. It also has high relevance because it is a soil pest organism. Tests, both in vitro and in vivo, sensitively reveal widely varying toxicity of tissues from different species and cultivars, and the influence of environmental factors such as temperature and contrasting soil types. This system is being used in conjunction with chemical analysis to indicate the potential of different biotoxic plants for biofumigation of soil-borne pest organisms, and to reveal the most potent isothiocyanates and combinations of those toxins. Index terms: Naupactus leucoloma, biofumigant, bioassay

[1058] ASYMMETRIC INTERSPECIFIC INTERACTION ON WING DIMORPHISM BETWEEN RICE PLANTHOPPERS, SOGATELLA FURCIFERA AND NILAPARVATA LUGENS

M. Matsumura & Y. Suzuki, Laboratory of Pest Management Systems, Kyushu National Agricultural Experiment Station, Nishigoshi, Kumamoto 861-1192, Japan, E-mail mmasa@knaes.affrc.go.jp

The whitebacked planthopper (WBPH) Sogatella furcifera and the brown planthopper (BPH) Nilaparvata lugens are two major pests of rice throughout Asia. Females of WBPH and both sexes of BPH exhibit density-dependent wing dimorphism and occur in two forms, macropters and brachypters. We found asymmetric interspecific interaction on wing dimorphism between the two sympatric species by a series of laboratory experiments. If the total number of planthopper nymphs per rearing tube was the same, the proportion of BPH macropterous adults was higher in a mixed population of BPH and WBPH than in a pure population of BPH. This suggests that interspecific effects on wing dimorphism are more than intraspecific ones for BPH. In contrast, for WBPH, interspecific effects were less than intraspecific ones. The proportion of macropterous adults of both species was higher on rice seedlings previously infested with WBPH nymphs than those infested with BPH nymphs or uninfested (control). This phenomenon was also observed on rice plants at tillering stage. Thus, interspecific interaction on wing dimorphism between the two planthoppers occurs not directly but indirectly through the feeding of rice plants. These results suggest that planthopper-induced changes in plant physiology in WBPH are greater than those in BPH, although the quantity of rice phloem sap consumed per insect is much less in WBPH than in BPH. Further evidence for the effect of interspecific interaction on population dynamics comes from a significantly negative correlation between the density of immigrant WBPH and the population growth rate of BPH.

Index terms: density, wing-form, BPH, WBPH, population dynamics

[1060] A REVIEW OF THE SOUTH AMERICAN NOTONECTA (PARANECTA), INCLUDING N. INCA NEW SPECIES FROM PERU (HETEROPTERA: NOTONECTIDAE)

<u>S. A. Mazzucconi</u>, Laboratorio de Entomología, Departamento de Ciencias Biológicas, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria, (1428) Buenos Aires, Argentina. E-mail: mazzucco@bg.fcen.uba.ar

The South American Notonecta (Paranecta) are revised on the basis of morphological characters. Types of most of the species and large series of specimens were examined. At present 11 species are recognized: N. bifasciata from Argentina, Uruguay and Brasil; N. disturbata (= N. hungerfordi new synonymy) from Argentina, Brasil, Paraguay and Bolivia; N. fazi from Argentina, Chile and Perú; N. inca new species from Perú; N. indica from Colombia, Venezuela, Central and North America; N. peruviana from Argentina, Bolivia (herein first recorded) and Perú; N. polystolisma from Argentina and Brasil; N. pulchra from Argentina, Brasil and Paraguay; N. sellata from Argentina, Uruguay, Brasil, Paraguay and Bolivia; N. vereerbruggheni from Argentina, Uruguay, Brasil, Paraguay and Bolivia; N. vereerbruggheni from Argentina, Uruguay, Brasil, Paraguay and Bolivia; N. vereerbruggheni from Argentina, Chile and Perú, N. polystolisma from Argentina, Uruguay, Brasil, Paraguay and Bolivia; N. vereerbruggheni from Argentina, Chile and Perú, Previous descriptions are incomplete and most of the characters used to define the species are superfluous. In this regard, the genital capsule, the paramera, the aedeagus and the female urosternites are proposed to distinguish the South American species of Paranecta. In addition, three species groups are defined: (1) N. indica, (2) N. fazi and N. vereertbruggheni, and (3) the remaining eight South American species.

Index terms: Nepomorpha, backswimmers, new record, new synonymies, Neotropical Region.

Symposium and Poster Session

[1061] VELIIDAE FROM ARGENTINA (HETEROPTERA); A PRELIMINAR LIST

<u>S. A. Mazzucconi</u>, Laboratorio de Entomología, Departamento de Ciencias Biológicas, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Ciudad Universitaria, (1428) Buenos Aires, Argentina. E-mail: mazzucco@bg.fcen.uba.ar

Up to now 19 species of Veliidae were known from Argentina. The present work adds one new species and 14 new records, and establishes a new synonymy. Therefore, the following 33 species of Veliidae are known from Argentina: *Oiovelia cunucunumana* (= *Paravelia correntina* new synonymy), *O*. inedit species, *Paravelia anta* new species, *P. paxilla*, *P. platensis*, *Platyvelia brachialis* (first record), *Steinovelia virgata*, *Stridulivelia astralis*, *Rhagovelia boliviana*, *R. imatatrix* (first record), *R. janeira* (first record), *R. lucida* (first record), *R. ornata*, *R. paulana* (first record), *R. relicta* (first record), *R. versuta*, *R. zela* (first record), *M. thaumana* (first record), *R. trista* (first record), *M. hambletoni* (first record), *M. hinei*, *M. hungefordi*, *M. inannana*, *M. limaiana* (first record), *M. longipes*, *M. lujanana*, *M. minula*, *M. pulchella* and *M. venustatis* (first record). The purpose of the present work is to provide a key, distributional data, ecological preferences and comparative notes on the Veliidae from Argentina.

Index terms: Gerromorpha, new species, new records, new synonymy, Neotropical Region.

[1063] INFLUENCE OF WATER BALANCE ON THE POPULATION DYNAMICS OF THE BURROWING BUG ATARSOCORIS BRACHIARIAE (HEMIPTERA: CYDNIDAE)

M. O. Medeiros¹ & <u>O. Sales Jr.¹</u>, ¹Centro de Controle Biológico, Univ. Federal de Mato Grosso, Av. Fernando Corrêa, s/n, Cuiabá, MT 78060-900, BR, ceb@cpd.ufmt.br.

This research presents data on the population dynamics of Atarsocoris brachiariae. Comparisons are made against the water balance for the region of Rondonópolis, MT, Brazil. Population surveys were performed at Fazenda Guarita, in a 4-hectare, 8-year old Brachiaria decumbens rangeland highly infested with A. brachiariae, formerly an experimentation field owned by Empresa Mato-grossense de Pesquisa, Assistência e Extensão Rural S/A (EMPAER/MT). Weekly soil samples were taken at random from January, 1995 through December, 1997; sample size was 10 × 20 × 40 cm (width, length, depth). The number of eggs, nymphs and adults present in each sample was recorded. The highest population density for nymphs (7022/12915 - 54.37%) and for adults (1412/2318 -60.91%) was verified at the depth between 20 and 40 cm; for eggs, the highest population density (1159/1431 - 80.99%) was verified between 0 and 20 cm. The period from egg to death of the adult lasts about 11 to 12 months, with two generations per year, the first beginning in the water excess period and the second occurring during the water deficit in the soil. Eggs laid by A. brachiariae females from January through May have their population peak in February, producing first generation adults from May through October, with the population peak in June. Eggs laid between June and November have their population peak in August and produce the second adult generation between November and April, with their peak in January. Individuals from the first generation become adults during the water deficit period in the soil (drought) and do not swarm at that time, burrowing deep in the soil profile in search of more favorable humidity conditions. Conversely, second generation individuals become adults during the water excess period, in which dispersal swarms take place, beginning with the first rainfalls in October and ending with the last precipitation in May. For both generations mating occurs inside the soil; hence, swarms are for dispersal only and normally take place during the rainy season. During the soil water deficit season (drought), which happened between June through November/1995, April through October/1996, and March through May and July through October/1997, water deficit in the soil reached -1124 mm, with a monthly average of 59.15 mm for the three-year period. A total of 1012/1431 (70.72%) eggs, 7104/12915 (55.00%) nymphs and 855/2318 (36.88%) adults were observed in the period. Index terms: swarm, Brachiaria, dispersal, bioecology

[1062] IMPLICATIONS OF *DEPRESSARIA* (LEPIDOPTERA: OECOPIIORIDAE) AND HOST-PLANT PHYLOGENIES FOR *DEPRESSARIA* SPP. DISTRIBUTION, HOST-USAGE, ECOLOGY, AND SPECIATION

<u>D. D. McKenna</u>, University of Illinois Dept. of Entomology, 505 S. Goodwin Ave. Urbana, IL 61801 E-mail: mckenna@uiuc.edu

I have used methods of comparative phylogenetics to ask the question, "Have host-plant speciation events directed speciation in the 23 North American members of the genus *Depressaria* (Lepidoptera: Depressarinae) as evidenced by congruent cladogenesis?" Fifteen of the 80 species in the plant genus *Lomatium*, 6 other apiaccous taxa, and two Asteraceae are reported as hosts for these *Depressaria*. To assess patterns of cladogenesis in the genus, I compared and contrasted a morphological phylogeny I constructed for *Depressaria* and their host plants show similar patterns of cladogenesis. The resulting phylogenies for *Depressaria* and their host plants show similar patterns of cladogenesis. The results suggest that there is little temporal synchrony of speciation events in *Depressaria* compared with *Lomatium*; however, similarities between the groups with respect to distribution, ecological speciation in *Depressaria*, *Lomatium*, and allied taxa. Geographic isolation and host-use limitations based on chemistry, phenology, and morphology may account for many speciation events in North American *Depressaria*; thus future ecological study, as well as molecular study of *Depressaria* phylogeny, should be considered in future work. Comparative phylogenetics, *Lomatium*, Apiaceae

[1064] INFLUENCE OF PRECIPITATION VOLUME AND SOIL TEMPERATURE ON THE POPULATION DYNAMICS OF THE BURROWING BUG ATARSOCORIS BRACHIARIAE (HEMIPTERA: CYDNIDAE)

M. O. Medeiros¹ & <u>O. Sales Jr.</u>¹, ¹Centro de Controle Biológico, Univ. Federal de Mato Grosso, Av. Fernando Corrêa, s/n, Cuiabá, MT 78060-900, BR, ceb@epd.ufmt.br.

This research presents data on the population dynamics of Atarsocoris brachiariae. Comparisons are made against the precipitation volume and soil temperature for the region of Rondonópolis, MT, Brazil. Population surveys were performed at Fazenda Guarita, in a 4-hectare, 8-year old Brachiaria decumbens rangeland highly infested with A. brachiariae, formerly an experimentation field owned by Empresa Mato-grossense de Pesquisa, Assistência e Extensão Rural S/A (EMPAER/MT). Weekly soil samples were taken at random from January, 1995 through December, 1997; sample size was $10 \times 20 \times 40$ cm (width, length, depth). The number of eggs, nymphs and adults present in each sample was recorded. Nymphs and adults were also found within small chambers excavated in the soil in a sub-cylindrical or oval shape, showing a darker layer internally. It is suggested that these chambers are constructed as a protection during ecdysis and/or to withstand weather changes. Precipitation volumes indicated a positive correlation with number of nymphs (P > 0.05) and adults (P < 0.01), and were negatively correlated with number of eggs (P < 0.01). The greatest number of eggs (63.8%) was collected in the dry season; egg population density was highest in 1996, when the smallest rainfall amounts were verified. On the other hand, nymphs (57.17%) and adults (72.6%) were collected mainly in the rainy season. Soil temperature was negatively and not significantly (P > 0.05) correlated with number of nymphs and adults collected, whereas it was positively and significantly (P < 0.05) correlated with number of eggs. An increase in the population level of A. brachiariae in the order of 266.5% was observed from 1995 to 1997. This should serve as a warning for technicians and farmers to plan control measures for the pest, which is already expanding to other regions in the state of Mato Grosso.

Index terms: rainfall, ground, Brachiaria, pest

[1065] LIFE CYCLE OF MARTAREGA URUGUAYENSIS (HETEROPTERA: NOTONECTIDAE) UNDER LABORATORY CONDITIONS

<u>A. L. Melo</u> & M. R. V. Sant'Anna, Dept. of Parasitology, Federal University of Minas Gerais, P.O. Box 486, Belo Horizonte, 30161-970, MG, Brazil, E-mail: aldemelo@icb.ufmg.br. Support by CNPq.

Predation studies of invertebrates by aquatic Heteroptera, adults or nymphs, have been used mainly with species belonging to the family NOTONECTIDAE, which contains insects that are efficient predators of mosquito larvae implicated on the transmition of parasitic diseases. Martarega, a relatively small gender, is endemic in America, and M. uruguayensis is a common species in Belo Horizonte, Brazil. Aiming to determine the post-embryonic period and duration of the instars of M. uruguayensis individual were reared in laboratory and fed exclusively of C. quinquefasciatus, M. uruguayensis individual were reared in laboratory and fed exclusively of C. quinquefasciatus larvae. The photoperiod was of 12 D/E and temperature of 25,5 ± 0.8 °C. It was verified that the mean duration of the each instar was of $8,57 \pm 0.98$ days for the first instar, $8,75 \pm 1,55$ for the 2^{n4} , $12,45 \pm 1,23$ for the 3^{r4} , $12,79 \pm 1,47$ for the 4^{th} and $15,00 \pm 0,74$ for the fifty. During the nymphal period the predation average was $3,52 \pm 1,39$ for the 3^{r4} , 412, 46 ro the 3^{r4} , $3,28 \pm 1,31$ for the 4^{th} and $3,48 \pm 1,44$ for the fifty. The daily consumption of mosquito larvae by adults was $2,16 \pm 1,27$ larvae The mortality rate was restricted to the 2^{9} and 3^{9} instar, with rates of 8,69% and 4,35%, respectively, and adults of M. uruguayensis survived over six months in laboratory conditions. Those notonectids can be reared in large scale in laboratory for control of mosquito larvae population. Index terms: Aquatic insects, predation, biology.

[1067] AGONISTIC BEHAVIOR BETWEEN COLONIES OF THE FORMOSAN SUBTERRANEAN TERMITE, *COPTOTERMES FORMOSANUS* (ISOPTERA: RHINOTERMITIDAE), FROM LOUIS ARMSTRONG PARK, NEW ORLEANS, LOUISIANA

M. T. Messenger¹ & N-Y. Su², ¹City of New Orleans Mosquito and Termite Control Board, 6601 S. Shore Harbor Blvd., New Orleans, LA 70126-8012, USA; ²Ft. Lauderdale Research and Education Center, Univ. of Florida, 3205 College Ave., Ft. Lauderdale, FL 33314-7799, USA.

Intra- and intercolony interactions between Formosan subterranean termite (FST), Coptotermes formosanus Shiraki, colonies from New Orleans, Louisiana, were studied in the laboratory. In 1998, a field study was initiated in Louis Armstrong Park to identify and characterize each FST colony present in this 31-acre fenced-in park. By following a triple-mark recapture procedure, the foraging territory for each colony was defined and other characteristics such as wood consumption rate and mean body weight were calculated. Agonistic responses between each colony were studied after each colony had been characterized and their foraging territories defined in the field. Half of the termites collected from each colony were dyed with 0.1% Nile Blue A and the other half were undyed. Groups of dyed and undyed termites from each colony were then paired with termites from different colonies in a dish, in addition to being paired with termites from the same colony. Each pairing was videotaped and any form of agonistic behavior was recorded. Agonistic responses included mandible flares, mandible insertion, biting, fleeing, and chasing or no aggression. Agonistic behavior was observed from most colonies; however, a few intercolony pairings resulted in no aggression. The nonaggressive, intercolony pairings were further studied by placing groups of termites from each colony into two-dimensional foraging arenas to determine whether or not each colony would display any agonistic behavior. The data revealed that each colony displayed at least one type of agonistic behavior towards another colony. Some colonies tended to be more aggressive than others but some tended to be more submissive and flee from the aggressive colony. Intracolony pairings resulted in no aggression. The relationship between foraging territory sizes in the field and agonistic behavior in the laboratory will be discussed.

Index terms: intra- and intercolony aggression, territoriality, foraging territory

[1066] A NEW HYPOTHESIS FOR INSECT GALL-MAKER SPECIES RICHNESS: RESOURCE SYNCHRONISATION AND THE EFFECTS OF FIRE

<u>M. S. Mendonca Júnior.</u>¹, ¹Centre for Population Biology & Dept. of Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, UK, E-mail: m.mendoncajr@ic.ac.uk.

I propose a new hypothesis to explain the insect gall-maker species richness pattern found by Price et al. (1998, Journal of Biogeography, 25:581-591). A hump-shaped latitudinal pattern was found, peaking at the warm temperate region (25°-45° in altitudinal-latitudinal equivalents). Xeric sites had higher gall-maker richness than more mesic sites, but xeric vegetation growing in mesic sites also had high gall-maker richness. This indicates that the correlation is to be found in the vegetation characteristics, and not in the climatic conditions per se. Host-shifts are believed to be the most likely way by which gall-makers can speciate. Since most galls are induced on young plant tissue, and mainly on leaves, the dynamics of leaf flushing in different vegetation types (i.e. how many plant species flush synchronously) can be of capital importance determining host-shifts for dispersing insect females. I suggest that vegetation types with synchronous leaf flushing facilitate gallmaker host-shifts and are therefore more likely to harbour higher insect gall-maker species richness. This is why the pattern found by Price et al. (1998) showed a low species richness of gallers for tropical rain forests and higher richness for other vegetation types in high latitudes. Additionally, perhaps more importantly, Mediterranean-like vegetation suffer seasonal influence of fires, and plants resprouting in response to this can provide further synchronous leaf flushes during which more host-shifts can occur. Plant species richness also underlies the host-shifting process in different biomes. Fire-prone areas of high plant richness like the South-African fynbos are expected to have even higher richness of insect gallers. Plant phylogeny is another important aspect of host-shifting, since barriers for host shifts between unrelated host plants (e.g. different families or genera) are probably stronger than for more closely related ones. Once an unrelated host type is colonised, host shifts can increase gall-maker species richness within this new plant group. This could be the reason why certain species-rich host plant taxa like Quercus or Eucalyptus have species-rich gall-maker communities: many members of these groups occur in fire-prone Mediterranean-like vegetation, and therefore could be more frequently subject to host shifting events. More information is needed to disentangle the ecological aspects promoting host-shifts, especially in relation to the relatively neglected question of the dynamics of the resources for gall induction, reactive plant tissues. Resprouting in response to fire is one of these ecological aspects, perhaps the most important. Index terms: host shift, host plant phylogeny, speciation.

[1068] ON SOME BEHAVIOURAL DECISIONS FOR POSTEMBRYONIC DEVELOPMENT AND FOR RESOURCE COMPETITION OBSERVED IN EULOPHID ECTOPARASITES (HYMENOPTERA: CHALCIDOIDEA)

<u>G. Minto</u>¹ & M.C. Rizzo², ^{1,2}Inst. of Agricultural Entomology, Univ. of Palermo, Viale delle Scienze 13, 90128 Palermo, Italy. E-mail: mineog@unipa.it.

Over the time in which the role of antagonists in the natural control of Phyllocnistis citrella has been studied, some little known and unknown behaviours looking at either the postembryonic development or the competition for resource were recorded in the following Eulophidae: Cirrospilus diallus, C. pictus, Ratzeburgiola incompleta and Semielacher petiolatus. Two of such behaviours realize the instruments permitting to the adult pharate stage an easier emergence from the pupal skin. The first one is made from the eonymph and its decision is related to danger of collapse of the mine onto the naked pupa. In order to prevent that, it voids the meconial pellets in a sort of pillars located between the roof and the floor of the mine and just at the points where the risk of collapse could eventually occur. The second one, observed in about all the individuals of the cited species, either in laboratory rearing or in the field, is realized from the young pupa when it slips off the integument of last instar larva from its body. Such a skin, by appropriate sequence of shakes of the body, is converted in a sort of ligament connecting the last abdominal sternite to the floor of the mine or to the meconium, with both ends welded by substances probably secreted from ileac tubes. The other behavioural decision refers to eventual competition for resource and involves the using of ovipositor as an instrument to prevent superparasitism and multiparasitism. In a series of observations made in laboratory submitting hosts previously parasitized from C. pictus or R. incompleta, the conspecific female, before a new deposition took place, proceeded to kill about all the eggs previously laid and in some cases also the new hatched larvae, stinging them with ovipositor. Such a behaviour has also been recorded in nature, where however the event is rather rare, perhaps due to the large amount of available unparasitized hosts.

Index terms: Cirrospilus spp., Ratzeburgiola incompleta, Semielacher petiolatus, emerging behaviour, ovipositor use

Symposium and Poster Session

[1069] LENGTH-MASS RELATIONSHIPS FOR AQUATIC INSECTS IN FRESHWATER ENVIRONMENTS OF PATAGONIA (ARGENTINA)

<u>M.L. Miserendino¹,</u> ¹Laboratorio de Ecología Acuática. Universidad Nacional de la Patagonia, Sede Esquel, Sarmiento 849, 9200 Esquel, Chubut, Argentina, E-mail lauram@teletel.com.ar

Ecological studies of aquatic insects often lack information on benthic biomass, although many ecological questions at the organism, population, community and ecosystem levels of organization can be understood using biomass data. Body mass relationships can be described by the general power equation DM=a. L^b, or after logarithmic transformation la $DM = \ln a + \ln b$ (where: a, b = regression constants, DM = dry mass and L = lengthparameters). The purpose of this work is to present length-mass relationships for insects of running waters from Patagonia. Aquatic insects were collected from 1991 to 1996 in different rivers found from 41° 53' S to 50° 25' W. Rivers were located in the mountains and in the Andean Patagonian plateau. Animals used were formalin-preserved (4 %). Body size of the animals was measured to the nearest 0.1 mm; body length included the distance between the anterior part of the head and the posterior part of the last abdominal segment. For dry mass determinations, the specimens were transferred into aluminum foils. Drying was performed at 105° C for up to 4 h. Animals were weighed on an electronic balance with 0.5 mg accuracy. In the procedure, 673 specimens were analyzed. Predictive equations for the conversion of length parameters into dry mass were obtained for 30 taxa. Regressions included the orders Plecoptera (10 species), Ephemeroptera (3 species, 3 genera), Trichoptera (4 species, 1 genus), Diptera (6 genera), Coleoptera (1 species, 1 genus) and Anisoptera (1 genus). Correlations were highly significant and explained a high proportion of variation of the dependent variable as expressed by the coefficient of determination (r^2 = 0.58-0.98). The predictive equations obtained may be used for biomass determinations of Patagonian running water insects, facilitating calculations of benthic standing cron and secondary production.

Index terms: length-mass regression, biomass, rivers, Patagonia.

[1070] RADE AND DISAPPEARING INSECT SPECIES (COLEOPTERA) IN THE NORTH-EAST OF UKRAINE

A.A. Mishchenko¹, V.L. Meshkova², l. Institute of Experimental and Clinical Veterinary Medicine under Ukrainian Academy of Agricultural Sciences. Pushkinskaja Str., 83. Kharkov, 310023, Ukraine, e-mail: admin@vet.kharkov.ua. 2. Ukrainian Research Institute of Forestry & Forest Melioration. Pushkinskaja Str., 86. Kharkov, 310024, Ukraine, e-mail: zahist@u-fri.kharkov.com.

In the East of Ukraine practically all natural biocenoses are under anthropogenic pressure which brought to insect fauna changes. There are the data not only on some species number but also on frequency of their occurrence. These are Staphylinidae: Emus hirtus L.; Scarabaeidae: Odontaeus armiger Soop., Ceratophyus policeros Scop., Geotrupes spiniger Marsh., Scarabaeus sacer L., S.affinis Brule., Amhicoma vulpes F., Chioneosoma pulvereum Knoch.; Tenebrionidae: Anatolica abbreviata Gebl., Pimelia sublobosa Pall., Prosodes obtusa F., Opatrum riparius Gerh. Recently the number of forest insects connected with dead wood or fungi decreased. These are Lucanudae: Lucanus servus L., Dorcus parallelopipedus L.; Scarabaeidae: Orictes nasicornis L., Trichius fasciatus L., Potosia aeruginosa Drury., P. lugubris Hbst.; Cerambicidae: Strangalia septempunctata F., Cerambyx cerdo L., Dorcadion carinatum Pall., D.fulvum Scop., D. holocericeum Kryn.; Carabidae: Calosoma sycophantha L., C. inquisitor L., Carabus violaceus L., C. corinatus L, Chaeres F.-W, Laemostenus terricola Hbst.; Staphylinidae: Oxyporus maxillosus F. Our observations in 1979-1995 showed that insect species composition changes with industrial cattle-breeding development, artificial pastures creation. The number of coprophages which utilize manure and predators of zoophilous and synanthropic flies has decreased. Ph. spinipes which was known from Japan and Manjury recently spread in Ukraine in the pastures in manure pellets of cattle, rarely under the decaying plants. It may be found more often in the cattle-breeding complexes in the fresh manure and in the stalls. It is one of the main regulators of synantropic and zoophilous flies number. Inspected area is located in the limits of two natural zones - Forest Steppe and Steppe. Here is the north limit of steppe species (Pentodon idiota Hbst., Monotropus nordmanni Blanch.), Mediterranean and Pontium (Aphodius conjugatus Pz., Psammobius laevipennis Costa., Anoxia villosa F.h.) and south limit of transpalearctic species (Cicindela maritima Latr., C. silvatica L.) and south holarct Tachyta nana Gyll. These species are rare, many of them are almost disappeared. To increase the protection of rare species, the more detail study of their ecology and anthropogenic factors influence is necessary. The sites of their preference must be protected too. Any species is a part of biocenosis, its destruction brings to important component loss.

[1071] DIVERSITY AND - FUNCTIONAL STRUCTURE OF INSECT COMMUNITIES UNDER GRAZING AND EXCLUSION REGIMES IN A MONTANE ARGENTINE GRASSLAND

S.I. Molina¹, L. Cagnolo¹ & <u>G.R. Valladares</u>¹, ¹Centro de Investigaciones Entomológicas, F.C.E.F.y N., U.N.C., Av. Vélez Sársfield 299, 5000-Córdoba, Argentina. E-mail: smolina@com.uncor.edu.

In the mountain grasslands of Central Argentina, a long history of cattle grazing has altered plant communities by increasing their diversity, while reducing their structural complexity and the frequency of tall grasses. The effects of grazing disturbance on the associated insect communities was examined in a grassland with two types of grazed habitats (intense and moderate grazing) and two cattle exclusions differing in age (7 and 20 years). Taxonomic and functional aspects of insect diversity and two levels of taxonomic resolution (family and species) were considered. Insects associated to the vegetation were sampled with a vacuum sucking device, and pit-fall traps were used for ground dwelling insects. Collected specimens were counted, identified to family (all insects) or species (Coleoptera) level, and allocated to trophic guilds. Intense grazing changed insect families and Coleoptera species composition both in vegetation associated and ground dwelling communities. Most groups were underrepresented or absent in the intensely grazed habitat but a few families and species seemed to be favoured by grazing. Abundance, richness, diversity and evenness of the insect communities had minimum values in the most intensely grazed habitat. Results of community functional analyses varied depending on taxonomic level. At species level no significant change was observed. At family level the functional structure of both ground and plant associated communities was modified under intense grazing. The former showed a relative increase of scavengers (which could be linked to alterations in the nutrient cycling in such habitats). In the latter community, the phytophagous guild was dominated by chewers at the intensely grazed habitat while suckers dominated the habitats with scarce or no grazing. According to these observations, intense grazing in montane grasslands in central Argentina would result in important taxonomic and functional changes in the associated insect communities, but such effects would not be noticeable with less intensive use. Conservation of a patch mosaic might allow conservation of a greater fraction of biodiversity, though the appropriate spatial arrangement and size should be studied. Moreover, the results suggest that higher (family) taxonomic level could be used in order to characterise insect communities in these habitats under varying disturbance regimes, thus allowing to evaluate biodiversity and human impact on them with less effort.

Index terms: Biodiversity, Colcoptera, feeding guilds

[1072] GEOGRAPHIC DISTRIBUTION OF CUPUAÇU FRUIT BORER CONOTRACHELUS HUMEROPICTUS ON CUPUAÇU IN THE STATE OF AMAZONAS, BRAZIL

C.M.D'A. Lopes¹ & N.M. Silva², IDAM, rua Paraíba, Conj. Celetrazon, rua 4, casa 5, Adrianópolis, CEP 69057-000, Manaus, AM, Brazil, E-mail consuelo@inpa.gov.br.² Fac. de Ciências Agrárias, Univ. do Amazonas, Campus Univ., CEP 69077-000, Manaus, AM, Brazil, E-mail neliton@argo.com.br.

The Cupuaçu fruit borer (Conotrachelus humeropictus) is the most important pest on cupuaçu plants in the state of Amazon. The insect is found in the states of Acre, Amazonas, Mato Grosso, Pará, and Rondônia. This study was conducted to evaluate the geographic distribution of *C. humeropictus* in the State of Amazonas during April and June of 1997 and 1998 in 15 counties: Apuf, Autazes, Careiro-Castanho, Fonte Boa, Humaitá, Iranduba, Itacoatiara, Manacapuru, Manaquiri, Manicoré, Maués, Manaus, Presidente Figueiredo, Rio Preto da Eva, and Urucará. Cupuaçu is predominately grown as a monoculture, though polycultures occur. The polyculture system includes several fruit and forest species. Ten fruit were collected per sampled site: five from the border and five from the middle, per hectare of cupuaçu cropping. The fruit were characterized as healthy or damaged. The number of larvae in each fruit were counted. The infestation level ranged from 100% at Manicoré, 80% at Manaquiri, 66% at Iranduba, 64% at Manacapuru, 60% at Castanho-Careiro, and 56% at Itacoatiara. We also found the borer damaging fruit from Autazes, Fonte Boa, Humaitá, and Rio Preto da Eva.

Index terms: Theobroma grandiflorum, Sterculiaceae, Curculionidae, Coleoptera

[1073] OCURRENCE AND FLUCTUATION IN POPULATION SIZE OF A RECENTLY INTRODUCED DROSOPHILIDAE SPECIES IN BRAZIL

E. M. Moraes; <u>R. P. Mnteus</u> & F. M. Sene, Dept. de Genetica, FMRP, Univ. São Paulo, Av. Bandeirantes 3900, CEP 14049-900, Ribeirão Preto, SP, Brasil. Email: emarsola@rgm.fmrp.usp.br. Financial Support: FAPESP, CNPq, FINEP, CAPES and USP.

Zaprionus indianus (Diptera, Drosophilidae), recently introduced in Brazil, is supposedly of African origin. Its discovery in Brazil in Santa Izabel, SP was first published by C. R. Vilela (Instituto de Biologia of Universidade de São Paulo, Brazil) in March 1999. This species is reaching major pest status in the main fig producing region in São Paulo State. We examined Z indianus occurrence in some areas of São Paulo state and studied shortterm fluctuations in population size. This species was collected in wild xerophytic vegetation areas in traps with orange and banana baits, along with other Drosophilidae species. It represented 25% of total collected flies in Itatiba, 22% in Serrana, 20% in Altinópolis, 19% in Itirapina, 14% in Santa Maria da Serra and 4% in Sertãozinho, being the main species in some sites. Three collections were made bimonthly in both Serrana and Altinópolis localities from January 1999 to June 1999. In Serrana Z. indianus represented only 0.07% of 4166 flies in January. In March there was a dramatic rise in population size, since it composed 20% among 8027 flies. This rate declined to 0.7% in May. In Altinópolis site the same kind of fluctuation was found, Z. indianus was collected at a rate of 2% in February, 20% in April and 3% in June. Several collections were made in these two sites beforehand and no specimens were collected. These preliminary data suggest that after the invasion of Z indianus in a wild area, there is an increase in population size, followed by a substantial fall. However, more extensive surveys are need to determine the impact on wild environments, of this introduced species.

Index terms: Zaprionus indianus; ecology; environmental impact

[1075] EFFECTS OF A PREDATORY ANT ON FLORAL VISITORS

H. C. Morais¹,³ & W. W. Benson², 1. Programa de Pós Graduação em Ecologia, Univ. Estadual de Campinas; 2. Depto. Zoologia, Univ. Estadual de Campinas, CP 6109, 13081 970 Campinas, SP; 3. endereço atual: Depto. Ecologia, Univ. de Brasília, Brasília, DF, email morais@unb.br.

Ants rarely pollinate plants and may interfere in the pollination process by reducing the pollen grain viability and nectar availability of flowers or even by impeding other insects from visiting flowers. Observations were made over the frequency of floral visitors to branches of a plant with and without Azteca cf. lanuginosa (Formicidae: Dolichoderinae) workers. This ant species builds carton nests in high trees of the cerrado, the savanna-like vegetation of central Brazil, and is predatory, with the workers capturing, in a cooperative manner, insects that land on the vegetation. The ants actively patrol the plant and some may remain in an alert position with their mandibles open, on the tips of branches and on Inflorescences, forming sit-and-wait groups. The study was conducted on the Fazenda Água Limpa experimental ranch (15° 30 ' S - 47° 25 ' W) of the University of Brasflia (DF, Brazil). Observations were made over two isolated branches of a legume (Stryphnodendron adstringens - Mimosoidae), one patrolled by the ants and the other not. The inflorescences are cylindrical (= 2 x 10 cm) with the flowers side by side, forming a cover of stamens. About 20 or more workers remained still among the stamens and attacked floral visitors. Observations were made on each branch for one hour, always in the morning, on eight different days from the 11th to 28th of September. During a total of 16 hours, 302 floral visitors were recorded, the majority being bees from the genus Apis. Azteca workers organized themselves into sit and wait groups and were present on 28 open These inflorescences received 21 visitors, during eight hours of inflorescences. observation, being that 15 (71%) were predated and 11 of them were Apis bees. The number of visitors per open inflorescence, on each date, was always greater on the branch not occupied by Azleca, despite having a lesser number of inflorescences present on that branch. During the observation period, there was a trend for reduction in the frequency of visits by bees to the branch with ants and an increase on the branch without ants. These results suggest that the bees learned to recognize the presence of the predators and began to avoid those inflorescences. In this case, a reduction in fruit production could be expected on plants having the presence of this species of Azteca. The area was accidentally burned on October 4th, impeding further observations.

Index terms: Azteca, Formicidae, cerrado, pollinization

[1074] CATERPILLARS ASSOCIATED WITH THE REPRODUCTIVE STRUCTURES OF PLANTS IN THE CERRADO

H. C. Morais¹ & L R. Diniz², ¹ Departamento de Ecologia; ² Departamento de Zoologia, Universidade de Brasília, 70910 900 Brasília, DF, Brazil. E- mail: morais@unb.br. * Partial funding from CNPq Proc. n° 5010225/92.

Flowers and fruits are more ephemeral and less predictable resources than leaves, but tend to be more nutritious and less protected against herbivores. Insects that attack the reproductive structures of plants tend to specialize on these resources, synchronizing their life cycles or utilizing these resources in a sequential fashion. This study presents the results of a preliminary inventory of Lepidoptera larvae associated with the buds, flowers and fruits of plant species of the cerrado, a savanna vegetation of central Brazil. The reproductive structures were collected and kept in plastic pots, in the laboratory, so as to obtain the adults. Forty-four species from 11 families of Lepidoptera were obtained from 28 species of 18 plant families. Three families included 77% of the total number of Lepidoptera species: Gelechtidae (18 spp.), Tortricidae (10 spp.) and Pyralidae (6 spp.). The results indicate three groups of lepidopterans: (1) specialists or oligophagus species, on one resource in the same genera of plants, representing 66% of the species; (2) polyphagus in relation to plant families and structures, representing 11% of the species; (3) oligophagus but opportunists on resources of the same plant, representing 23% of the The majority of species were found on only one species or genus of host plant. Only two of them have cryptic larvae on the petals of open flowers: Michaelus thordesa (Lycaenidae) on Jacaranda ulei (Bignoniaceae) and Fundella sp. (Pyralidae) on Senna rugosa (Leguminosae). Two species of Cydia (Tortricidae) were found attacking flowers and fruits of more than one family of plant and three species are highly generalist, attacking flowers and leaves on three or more plant families: Fregela semiluna (Arctiidae), Pleuroprucha asthenaria (Geometridae) and Phidotricha erigens (Pyralidae). Tem species were known as herbivores of leaves, restricted to host plants of one genus or one family in the study area, and were found to be feeding on flowers of the same plant. For example, Heliothis planaltina (Noctuidae) on Chamaecrista spp. (Leguminosae) and Cerconota achatina (Elachistidae) on Byrsoninna spp. (Malpighiaceae). This species group is not dependent on flowers as a food item, but use them in an opportunistic manner, enriching their diet.

Index terms: Gelechiidae, Lycaenidae, Pyralidae, Tortricidae

[1076] OCCURRENCE OF WEED PLANTS AS ALTERNATIVE HOSTS OF SILVERLEAF WHITEFLY (*BEMISIA ARGENTIFOLII*) (HEMIPTERA: ALEYRODIDAE), IN THE STATE OF RIO GRANDE DO NORTE, BRAZIL

M. A. B. Moreira¹, ¹Embrapa Roraima, Br 174, km 08, Distrito Industrial, Boa Vista -RR. Caixa Postal, 133. CEP 69.301.970. E-mail marcos@cpafrr.embrapa.br.

A study was carried out in field condition at Baixo-Açû region (state of Rio Grande do Norte, Northeastern Brazil) with the purpose of collecting native plants, that are alternative host of silverleaf whitefly, *Bemisia argenifolii*, and establish pest management strategies. The plants were collected on irrigated crops in thirty aleatory sample points, measuring 6 m² of effective area each and in twenty neighbouring sample points without irrigation, with the same dimension, between august and november of 1998. Plant leaves were analysed on the abaxial portion, to observe imatures forms of silverleaf whitefly. Twenty-three plants that are alternative host of the pest were identified, including weed plants, semi-shrubs and shrubs. The plants identified were *Amaranthus, Sida* and *Ipomea*, each with two species, and *Eufhorbia, Physalis, Acanthospermum, Caesalpinia, Phaseolus, Heliotropium, Waltheria, Croton, Sidastrum, Cassia, Cucumis, Cobretum, Bauhuinia, Terminalis, Minosa, Bearhavia and Phylanthus, each with one specie.*

[1077] POPULATIONS OF NECROPHAGOUS COLEOPTERA AS BIOLOGICAL INDICATORS OF PHYSIOGRAPHIC SUB-REGIONS IN THE TACHIRA'S MOUNTAIN PASS

O.I. Moros¹ & O. Tapias², ¹⁻²Parque Natural Paramillo. Univ. del Tachira. Av. Universidad. Paramillo. San Cristobal, Tachira. 5012-A. Venezuela.

The mountain pass of Tachira is a very particular physiographic region, which separates the Tovar-Uribante mountain range from the rest of the great Andes mountain range and communicates the flora and fauna from the Caribbean regions with the ones from the Amazon region. This area has the influence of a double wind front, conformed by the Alisian winds, coming from the northeast and the intertropical winds, which come from the southeast. This creates a big ecological hallway that has served as a bridge for human society, flora and fauna. Along the extension of the mountain pass, different physiographic sub-regions have been conformed, having a reasonable amount of animal and plant species, proportioned to the extension and climate of the sub-region. Plus each one of this sub-regions has a reasonable proportion of carnivorous and herbivorous. In this paper, the authors intend to determine the presence of necrophagous coleoptera in each sub-region of the mountain pass, as well as the influence of the Caribbean and Amazon regions in these populations. To achieve this objective, a set of traps was placed in twelve different locations along the 150 Km. of the mountain pass. As bait, these traps were provided with chicken skin. The samples were taken every 21 days, during the months of January, February and March. A total of 15 different species was obtained, represented by 370 specimens. Five species where present in just one determined subregion. These species where, Coprophaneus jasyus (in the passage woods); Dichotomius protector and Oxystenun conspicillatum (Pre-mountain woods); Dichotomius agenor and Ontherus sulcatur (Transition woods); and Canthon cyanellus (dry woods). Eleven species where present only in the area close to the Amazonian basin and only one species was found only in the area close to the Caribbean basin. This species was Canthon cyanellus. Three specific species, which are Canthidium sp., Canthon triangularis and Coprophanaeus telamon show that the mountain pass can be considered an ecological hallway, because they move free trough it, between the Caribbean and the Amazon.

[1078] BATFLIES OF THE FISHBAT NOCTILIO LEPORINUS (MAMMALIA: CHIROPTERA): EFFECTS OF HOST SEX, SIZE, DEVELOPMENTAL STAGE AND SEASON

M. O. Moura¹, <u>G. Graciolli¹</u> & M. O. Bordignon², ¹Curso de Pós-graduação em Entomologia, Depto. de Zoologia, Universidade Federal do Paraná. C. P. 19020, CEP: 81531-990. Curitiba, Paraná, Brasil. Laboratório de Sistemática, Ecologia e Evolução. ²Curso de Pós-graduação em Zoologia, Depto. de Zoologia, Universidade Federal do Paraná.

Among Diptera there are several families that have species with haematophagous feeding habits, but only three of them are exclusively ectoparasites; Streblidae, Nycteribiidae and Hippoboscidae. Bats are one of the most diverses mammals of neotropics, becaming a very interesting system to study population and community ecology of ectoparasites. Our sytem study comprises the fishbat Noctilio leporinus, a large (50-90g) psicivore species that is common in the Neotropics. Our aim is to describe the component batfly community of Noctilio leporinus rufipes, specifically trying to describe the temporal patterns of prevalence and intensity as well as to identify possible causal relationship between host sex, size, and developmental stage on prevalence and intensity. Field workes were done at Balneário Caiobá (PR) during january 1998 and february 1999. During the study, four ectoparasites species were recorded for the 56 (n) Noctilio leporinus. Two of them were streblids, Paradyschiria fusca and Noctiliostrebla aitkeni; one was a bedbug Latrocimex spectrans and one was an undescribed Acari. The prevalence showed to be independent between seasons and sex for *P. fusca* and *N. aitkeni* but not between reproductive, (*P.* fusca $\chi^2 = 8.50$, p=0.036 and N. aitkeni, $\chi^2 = 7.43$, p=0.059) and size classes (P. fusca $\chi^2 =$ 9.86, p= 0.019 and N. aitkeni, $\chi^2 = 14.21$, p=0.002). ANCOVA revealed that weight classes and sex of the host was not a source of variation to intensities of N. aitkeni ($F_{1.52}$ =2.264, p=0.138) as well as to *P. fusca* ($F_{1.52}$ =3.64, p=0.068). There were an effect of season on intensities of both batflies (*P. fusca* $F_{3.52}$ =2.85, p=0.046 and *N. aitkeni* $F_{3.52}$ = 4.97, p=0.004). For P. fusca, the effect was more pronounced on females ($F_{3.52}$ = 3.29, p=0.02) than on males ($F_{3.52} = 2.57$, p = 0.06). N. aitkeni intensity analysis showed that season influencied significatively both males ($F_{3.52} = 3.95$, p = 0.01) and females ($F_{3.52} =$ 5.5, p = 0.002). The reproductive stage did not show to be a source of variation for both species. Based on it, the population of these batflies should be regulated by other factor than host features, and probably by hyperparasitism and maybe grooming could be the main factors.

Index terms: Paradyschiria fusca, Noctiliostrebla aitkeni, ectoparasites, community ecology, parastism ecology

[1079] EFFECTS OF NATURAL ENEMIES AND RESOURCE QUALITY ON HERBIVORE ESABLISHMENT IN TWO HABITATS

C.B. Miiller & II.C.J. Godfray, Imperial College at Silwood Park, Dept. of Biology & NERC Centre for Population Biology, Ascot, Berkshire SL5 7PY, UK

In a field experiment, population development of Aphis jacobacae on Senecio jacobaca was followed. In a $2x^2$ factorial design, we manipulated simultaneously the density of natural enemies and the quality of the plant resource in two different habitats. The first habitat was diverse in other species of plants, herbivores and natural enemies, while the second habitat was species-poor in plants due to heavy rabbit grazing. Increased plant quality was achieved by adding fertiliser to the plants every week. Predator pressure was reduced by placing interception traps around the plants to protect the aphid colonies from flying and crawling predators. A. jacobaeae can be tended by mutualistic ants, and the occurrence of ant-attendance was treated as a site factor and left unmanipulated. The number of tended colonies was not different between sites and treatments, but in the species-poor site Lasius niger was predominantly tending the aphids while in the speciesrich site Myrmica ruginodis was the dominant ant species tending the colonies. During the initial phase of the experiments, all possible effects on colony development of the aphids were blurred by extremely unfavourable weather conditions in which aphid colonies did not grow much. Later on we show that the two opposing factors, effects of natural enemies and resource quality, act with differential strength on the probability of establishment and growth of the aphid populations. In both habitats the interactions with predators were stronger than effects of plant quality. In the species-rich habitat, the persistence of the aphid colonies was significantly shorter than in the species-poor habitat. This could either be caused by 'diffuse apparent competition' via predator populations that were maintained at high densities on other species of aphids or by the presence of the 'wrong' species of ants in this site. In the species-poor site, most colonies that were protected form natural enemies or consistently tended by ants persisted up to two months. This explains why A. jacobaeae is occurring at very low natural densities in the species-rich site. At the end of the experiments we measured various plant fitness traits, such as plant fresh weight, the weight of reproductive versus vegetative biomass and the number of flowers produced. The fertiliser treatment did not have a significant effect on these plant fitness traits in the species-rich site, presumably due to interspecific plant competition for nutrients, which would explain why the plant quality did not translate into colony performance in this kind of habitat. In the species-poor environment, we found a significant increase in total fresh weight and the number of flowers produced for the fertilised plants.

[1080] FEEDING RESPONSES AND GROWTH OF *HELICOVERPA ARMIGERA* (LEPIDOPTERA: NOCTUIDAE) LARVAE MAINTAINED ON CHICKPEA, COWPEA, BLACKGRAM AND PIGEONPEA DIETS

S. Mullick & A. K. Singh, Dept. of Zoology, Univ. of Delhi, Delhi-110007, India,

Studies on the feeding preferences and growth of last instar Helicoverpa armigera larvae on legume seed based synthetic diets were carried out in controlled laboratory conditions. The basic ingredients and their proportions were similar in all the test diets, save these differed in powdered seed materials, i.e. chickpea, cowpea, blackgram, and pigconpea-The larvae were tested in early last instar after rearing them on a particular diet upto the penultimate larval instar. Food intake of larvae in 24 hrs was minimum on pigeonpea diet (p<0.05). However, the consumption of chickpea diet by chickpea diet- reared last instar larvae, cowpea diet by cowpea diet- reared larvae, and blackgram diet by blackgram dietreared larvae, was statistically identical. Growth of the larvae was also observed significantly lower on pigeonpea diet in comparison with other test diets (p<0.05). The results indicated equal food value of chickpea, cowpea, and blackgram diets for the gram podborer larvae. Consumption of chickpea, cowpea and blackgram diets by chickpea dietreared larvae was statistically similar. However, consumption of chickpea diet by chickpea diet-reared larvae was significantly higher compared to consumption of pigeonpea diet. Growth of chickpea diet-reared larvae on chickpea diet was also significantly higher (p<0.05) as compared to growth of chickpea diet-reared larvae on pigeonpea diet, but this was statistically identical to growth of chickpea diet-reared larvae on cowpea and blackgram diet. Food consumption of cowpea diet- reared larvae on cowpea diet was statistically equal to consumption of chickpea and blackgram diets, but significatly lower as comapred to pigeonpea diet (p<0.05). However, growth of cowpea diet-reared larvae on cowpea, chickpea, pigeonpea, and blackgram diets was identical. Consumption of blackgram diet by blackgram diet-reared larvae was significantly higher than the consumption of chickpea and cowpea diets, but identical to consumption of pigeonpea diet. Growth of larvae reared on blackgram was significantly lower on pigeonpea diet compared to blackgram diet. Food consumption and growth of pigeonpea reared larvae on chickpea, cowpea, blackgram and pigeonpea diets was identical. The results indicated that pigeonpea seed kernels contain both antixenotic and antibiotic factors, which is reflected by lower food intake and lower growth rate of larvae. Also, induction of feeding preferences in terms of quantitative consumption were observed for blackgram diet reared last instar larvae for the blackgram diet. However, such preferences were not evident for the larvae reared on other diets.

Index terms: Food consumption, antixenosis, antibiosis, induction.

[1081] NUTRITIONAL AND BIOLOGICAL ASPECTS OF VELVETBEAN CATERPILLAR ON SOYBEAN GENOTYPES WITH AND WITHOUT INJURY

A.T. Murata¹, S. A. De Bortoli², O. A. Fernandes² & L.M.X. Lopes³, ¹Dept. de Biologia, Fac. Filosofia, Ciências e Letras de Ribeirão Preto, Univ. de São Paulo, Av. dos Bandeirantes, 3900, 14040-901, Ribeirão Preto, SP, Brasil (Bolsista Fapesp), E-mail: murataat@asbyte.com.br; ²Dept. de Fitossanidade, , Unv. Estadual Paulista, 14884-900, Jaboticabal, SP, Brasil; ³Dept. Química Orgânica, Instituto de Química, Unesp, Araraquara, SP, Brasil; FAPESP (96/10486-0)

The Anticarsia gemmatalis Hueb., 1818, is the major pest defoliator pest in Brazilian soybean crops. The relationship between defoliation and plant response is essential to understanding better the pest management. This work was carried out to analyze the consumption, food utilization and performance of velvetbeen caterpillar reared on soybean leaves (genotypes BR37 and Embrapa 4) with and without previous injury. This work was conducted in the Insects Biology Lab, under controlled conditions $(27 \pm 2^{\circ}C, 70 \pm 10\%$ RH and 10 hours photophase). Were used 4th instar caterpillars, being placed 15 larvae in Petri dishes with 15 cm of diameter. The larvae were fed twice a day (7:00 AM and 18:30 PM). The trial loads 6 repetitions by treatment, performing 30 dishes with 15 caterpillars each. It was found difference between plants (injuried and non-injuried) being uninjuries plants better to the larvae development. The same results were found to caterpillar performance. The leaves from injuried plants increase the time of development and decrease the insect weight. The damage plants led to the larvae. Showing lowest approximate digestibility, Efficiency of conversion of Ingested food, and Efficiency of Digested food than undamaged plants.

Index terms: Anticarsia gemmatalis, consumption, and correct performance.

[1083] OCCURRENCE PATTERNS OF *SPODOPTERA LITURA* (LEPIDOPTERA: NOCTUIDAE) IN SOUTHERN JAPAN AND SOUTH-EASTERN ASIA

<u>M. Murata</u>¹, A. Mishima², K.S. Chaug³, N. P. Oka⁴ & S. Tojo¹, Fac. of Agricul., Saga Univ., Saga, 840-8502, Japan, E-mail kd8333@edu.cc.saga-u.ac.jp; ²Fac. of Agric., Univ. of the Ryukyus, Okinawa, 903-0213, Japan, ³Dept. of Plant Protect., Natn. Chiayi Inst. of Agricul., Chiay, 60083, Taiwan, ⁴Fac. of Agricul., Hasanuddin Univ., Ujung Pandaug, Indonesia.

The moths of Spodptera litura have been regarded to be involved in long-distance migration, because they were captured together with long-distance migratory insects on the ships in the Pacific Ocean and East China Sea located at few hundred km distance from mainland Japan. But no evidence has been obtained for their immigration to western mainland Japan. In this research, we compared fluctuation patterns of S. litura males caught in sex pheromone traps in Japan, China, Taiwan, Philippines and Indonesia, especially in relation of weather factors associated with rain falls. The fluctuation patterns of the male adults were considerably similar between Kyushu (31-34°N), the most southern mainland of Japan and Chekiang (30°N, China), where prominently increased from late summer. On the other hand, in Okinawa (26°N), which is one of the most southern islands of Japan, the males abruptly increased during early summer, and further in autumn at the time of typhoon approach. The yearly numbers of males caught in Fukien (26°N, China) and Okinawa were less than halves of those recorded in above-mentioned two places. Numbers of males caught per year further declined as the observation places located to more south to the equator. In Kyushu, males were caught abruptly in the traps, when typhoons approached there, or when western air current from Chinese continent passed Kyushu and caused heavy rain falls at cold or stationary fronts. These facts support the possibility that the moths of this species are conveyed by typhoons or other weather factors from mid-southern China to Japan.

Index terms : the common cutworm, migration, typhoon, sex pheromone trap.

[1082] VELVETBEAN CATERPILLARS PREFERENCE TO SOYBEAN GENOTYPES WITH AND WITHOUT INJURY

A.T. Murata¹, S. A. De Bortoli², O. A. Fernandes² & L.M.X. Lopes³, ¹Dept. de Biologia, Fac. Filosofia, Ciências e Letras de Ribeirão Preto, Univ. de São Paulo, Av. dos Bandeirantes, 3900, 14040-901, Ribeirão Preto, SP, Brasil (Bolsista Fapesp), E-mail: nurataat@asbyte.com.br; ²Dept. de Fitossanidade, , Unv. Estadual Paulista, 14884-900, Jaboticabal, SP, Brasil; ³Dept. Química Orgânica, Instituto de Química, Unesp, Araraquara, SP, Brasil.

Soybean presents as several medicinal and defenses compounds. The productions of these compounds can came from the secondary metabolism and it occurs in response to injury, stress, and climatic factor, among others. The answer to these compounds is denominated Induce defense. These changes can increase the plant resistance to the herbivore attack, reducing the preference or the herbivore injury. It have being reported that soybean plant injuried produce or change the amount of certain compounds as flavonoids, isoflavonoids, proteins, acids and enzymes. The present work had the objective to study the velvetbean caterpillar behavior on two soybean genotypes (Embrapa 4 and BR37) with different amounts of isoflavonoids. The tests (choice and non-choice) were made in Petri dishes arenas 30 cm of diameter using leaf disks with 2.5 cm of diameter. The evaluations were accomplished 6 hours after to be released the caterpillars, being evaluated the damage in each disk by a scale of notes and through the foliar area reduce by Liquer-Lead-300. By the results could be observed that genotypes without injury was more damaged. The leaves from injuried plants went less attractive to the caterpillars.

Index terms: Anticarsia gemmatalis, Glycine max, secondary compounds, isoflavonoids. FAPESP (96/10486-0)

[1084] SYNOPSIS OF THE ARGENTINEAN DIABROTICINI (COLEOPTERA, CHRYSOMELIDAE, GALERUCINAE)

<u>N. C. Cabrera</u>, Depto. Entomología. Facultad de Ciencias naturales y Museo. Paseo del Bosque s/n. 1900 La Plata. E-mail ncabrera@museo.fcnym.unlp.edu.ar

The subfamily Galerucinae (Alticines excluded) constitute one of the most diverse groups of neotropical chysomelid with 58 described species for Argentinean fauna. The classification of Galerucinae is still now controversial, the nomenclature used in this paper follows Bechyné & Bechyné (1969). These authors recognize three tribes: Galerucini, Luperini and Diabroticini. Diabroticini is the most diverse and of economic importance group as several species are pests of crops. Diabroticini can be distinguished from those other tribes by having antennae very close to each other, placed above the anterior edge of the eyes, six segments in male's abdomen and five in female's, posteriorly rounded, without central incision. This contribution provide a synopsis of Argentinean Diabroticini with a key to identify them, diagnoses, habits and a detail of their geographical distribution. Specimens examined are from personal collections and specimens housed at different national and international museums. As a result of this study, Argentinean Diabroticini include now 40 species belong to seven genera. Diabrotica (17 species), Synbrotica (10 species) and Acalymma (7 species) constitute the best represented genera; the remainders, Paranapiacaba, Anisobrotica, Deuterobrotica and Cochabamba have one to three species each one. However, while the species of *Diabrotica* recorded here represent only 4.92% of all neotropical species, those of *Acalymma* 10,29% and those of Synbrotica 5,58%; Anisobrotica and Deuterobrotica with a single species each one, represent 25% of all species cited for the Neotropical Region. Only eight of these 40 species are exclusive from Argentina, the others are also distributed in bordering countries. Argentinean Diabroticini are distributed in the Amazonian and Chacoan Domains (Cabrera y Willink, 1980) and extends to Neuquén, the southernmost limit. Misiones province presents the greatest biodiversity (72% of all species cited for Argentina). Following Misiones, the provinces of Buenos Aires, Corrientes and Salta are those with the highest number of species. The lowest number is found in Patagonia. Index terms: biodiversity, Argentina, Diabrotica, Acalymma.
[1085] COST OF FLIGHT DISPERSAL IN *OREINA CACALIAE* (COLEOPTERA: CHRYSOMELIDAE)

<u>N. M. Kalberer</u> & M. Rowell-Rahier, Zool. Inst., Univ. of Neuchâtel, Rue Emile Argand 11, 2007 Neuchâtel, Switzerland. nicole.kalberer@zool.unine.ch

Movement patterns in Oreina cacaliae were compared all over the season. Mark-recapture experiments showed that in spring, the beetles flew from overwintering sites to the flowering spring host, where they started feeding. As soon as their main host plant Adenostyles alliariae emerged, they changed to that host by flight. The decision to fly is taken in autumn, when a part of the population leaves the host plant patch to fly to overwintering places. The non-flyers stay in the host plant patch and overwinter in the soil beneath the plants. In spring and summer of the following year they stay in the host plant patch and never fly. Flight and reproduction make demands on the insect's energy resources. The existence of the described dispersal polymorphism suggests that the possession of wings and ability to fly adversely affect demographic components like reproduction and survivorship. This hypothesis was tested by an analysis of the differences in life history parameters of the two dispersal morphs of O. cacaliae. We hypothesised that (a) there is a trade-off between dispersal and reproduction and (b) that size and survivorship differ in the two groups. Flyers laid fewer larvae than non-flyers but only when the beetles did not have access to food for some days after their flight, representing the situation in the field. Flyers were smaller in size than non-flyers, measured as elytra length. Small females larviposit significantly less than large females in the non-flyer group and survivorship was always reduced in the flyer group compared to the non-flyer group. Insect dispersal by flight may be an investment, of a portion of a population, in colonising and exploiting resources in a new habitat. Since there is a high degree of patchiness in plant communities, herbivores are continually faced with the problem of how to respond to the distribution and quality of their host-plant resources, and investing high costs may be justified.

mark-recapture, reproduction, survivorship

[1086] THE FAUNA HYMENOPTERA-BRACONIDAE MEDICAGO SATIVA IN SOUTH OF REPUBLIC TAJIKISTAN

N. SH. Saidov, Lab. of Experimental Ecology & Biomethod, Inst. of Zoology & Parasitology, 734025, P. Box 70, Tajikistan, E-mail: nurali@ac.tajik.net

The Medicago sativa, as fodder culture in agriculture of Tajikistan, is widely used in crop rotation as by the predecessor of a cotton plant. Restoring fertility of soil, serves the simultaneously important food supply of cattlebreeding. As a result of our researches on Medicago sativa fields of the South of Tajikistan 82 species Braconidae, relating to 13 subfamilies and 25 genus are established. Most abundantly in alfalfa biocenoses the species of a subfamily Microgastrinae (26) - endoparasites of Lepidoptera, from them 21 species belong to a genus Apanteles. From customary species relating to genus Apanteles, it is necessary to mark A. glomeratus L. - a parasite of the larva's Pieridae, A. metacarpalis Thoms. - is known as a parasite Coleophora tadzhikilla Danilev, A. telengai Tobias and A. vanessae Reinch. - parasites of the larva Chloridea viriplaca Hufn. Subfamilies Braconinae is represented by genus of Bracon with 12 species - ectoparasite, mainly - Lepidoptera. Among them it is necessary to mark a role of species B. hebetor Say and B. quadrimaculatus Tel. in depressing of number of the most dangerous pest technical and vegetable of cultures the Heliothis armigera Hbn. and parasites of many Coleoptera and Lepidoptera B. intercessor Nees and B. variator Nees. The subfamilies Euphorinae parasites of the Coleoptera, larvas Lepidoptera, larvas Hemiptera are includ 11 species. Here too of more often other species there are species from genus Aleiodes (7), Opius (7) and Chorebus (5). Other subfamilies of Braconidae by quantity of species considerably succumb described above: Cheloninae (4), Doryctinae (2), Brachistinae (2) and Exothecinae, Macrocentrinae, Homolobinae, Orgilinae on 1 species. The presence of considerable number Braconidae, marked on alfalfa biocenoses, is explained, firstly, that the alfalfa is a place of concentration of the pests and attracts Braconidae, basically as a forage plant of the hosts. The second factor attracting Braconidae are climatic conditions. The number Braconidae notably increases in the hot season of year, when temperature of air in apron plains mounts till 40-46 °C and microclimate alfalfa fields more suitable for Braconidae, than microclimate of other biotopes. Such conditions also promoted because on alfalfa except watering and harvesting, other measure are not carried out, in particular chemical control measure.

Index terms: Braconidae, endoparasite, ectoparasite, pest.

[1087] SEASONAL OCCURRENCES AND THE COMMUNITY STRUCTURE OF DUNG BEETLES IN NORTHERN JAPAN

N. Yamashita, Dept. of Animal Husbandry, Tohoku National Agricultural Experiment Station, Morioka, Iwate Pref. 020-0198, Japan, E-mail yama@tnaes.affrc.go.jp

The disposal of dung in cowshed has become a big problem in Japan in recent years. So, keeping livestock in pastures has drawn attention as the solution measure. Although some people claim that dung beetles consume and decompose dung in the pastures for the purpose of feeding and breeding, there are few quantitative and long-term surveys of dung beetle occurrence in northern Japan and the actual behavior of dung beetles is unclear. The intention of this study is to clarify the occurrence and dynamics of dung beetle community structure in the pastures of northern Japan. Surveys had been taken at three sites of the author's station from 1990 to 1992. Site A was a grazing pasture with about 40 head of cattle; B, pasture with about 18 head; and C, a hay pasture. Dung beetles were collected with traps using dung as bait during the pasturage period. A total of 148,980 individuals were collected. The collection included 13 species of tunneler-type beetles that dig tunnels below the dung pats and transport dung into it for feeding or breeding, such as Onthophagus lenzii and Aphodius haroldianus, and 14 species of dweller-type beetles that deposit eggs in dung pats on the ground and the imago feed in pats, such as A. rugosostriatus and A. urostigma. The numbers of tunnelers comprised 27.38%, and dweller's did 72.62% of a total individuals captured. From pasturage starting time (early in May), some species of dweller-type beetles were active and the tunnelers increased in June. The number of species and individuals, along with the diversity index (H'), peaked in June and July. After they temporarily declined in August, their numbers increased again in September and October as new beetles emerged. The largest number of beetles was collected from site A, followed by B and C, respectively. The number of species collected was about 20 from each site for three years. The population constructions were different at each site. The most dominant species from site B was the A. rugosostriatus, which made up $30\square 40\%$ of the individuals collected, and *O. lenzii* made up less than 15% of the population for three years from site A. But from site C, *O. lenzii* made up $30\square 45\%$ of the population, and A. rugosostriatus accounted for less than 20% over the three years. The community structures changed mainly with the relative abundance of the species. Most of the dung beetle activity occurred during one or two months, primarily before midsummer in northern Japan; however, O. lenzii contributed to the decomposition of dung in the pastures during the pasturage period.

Index terms: Aphodius rugosostriatus, Onthophagus lenzii, A. rugosostriatus, A. urostigma, diversity

[1088] COPPER INFLUENCE ON CHIRONOMID LARVAE IN NATURAL AND LABORATORY POPULATIONS

L. Nazarova, Kazan State University, Russia

Theratogenic effect of heavy metals on chironomid larvae mouth parts structure were investigated in natural populations of cooling pond of Zainsk power station. Methods of multiply regression were applied. There were found that association of few heavy metals (Pb, Cu, Cd, Zn, Co) have influenced on incedence of Chironomid larvae morphological deformities with the high level of probability. Most significant influence was revealed for Cu. In laboratory tests were investigated influence of different Cu concentration (5 mg/l, 1 mg/l, 0,1 mg/l, 0,02 mg/l) on incedence of morphological abnormalities and some biological features (mortality, behaviour, development) in Chironomus riparius larvae. In concentration 5 mg Cu/I all larvae have died in 2 hours from the beginning of experiment. Ratio of "larvae-pupae-imagos" amount at the end of the experiment in different Cu concentration has allowed us to make a supposition that Cu in concentration not exceed 1 mg Cu/l accelerate onthogenetic processes in Chironomids. With the increasing of Cu concentration an amount of morphological abnormalities increased from 10% in control to 75% in concentration 1 mg Cu/l. Mentum splits, gaps, lack of some teeth in mentum, mandibles or epipharingeal plate, hypo- and hiperpigmentation of head capsule were found. Linear dose-responsibility was observed only for the sum of all abnormalities including hypo - and hiperpigmentation and abrasion.

[1098] CHARACTERIZATION OF THE WAXY PARTICLES, AND THE PENETRATION AND FEEDING PROCESS OF WHITEFLIES

D. R. Nelson¹, **T. P. Freeman²**, **J. S. Buckner¹**, **& D GERLING**³, ¹Biosciences Research Laboratory, Agricultural Research Service, U.S. Dept. of Agriculture, 1605 Albrecht Boulevard., Fargo, ND 58105-5674, USA, E-mail denelson@prairie.nodak.edu; ²Electron Microscope Facility, Dept. of Plant Pathology, North Dakota State University, Fargo, ND 58105, USA, ³Dept. of Zoology, Tel Aviv University, Ramat Aviv, Israel 69978.

Whiteflies are a problem in greenhouses and on many economically important plants worldwide. The silverleaf whitefly, Bemisia argentifolii, is particularly devastating. Our recent findings of silverleaf whitefly feeding on cotton leaves showed that both the adults and nymphs can reach the phloem bundles from any position on the leaf, contrary to previous theory. This is believed to be true for any host plant and true for the greenhouse whitefly, Trialeurodes vaporariorum, the giant whitefly, Aleurodicus dugesii, the spiraling whitefly, Aleurodicus dispersus, and a recently discovered New World whitefly on the Canary Islands, Lecanoideus floccissimus. The labium of the adult whitefly feeding apparatus consists of four segments. The first segment is attached to the thorax and the three distal segments include a deep longitudinal groove that contains the stylet used to penetrate the leaf and feed on the phloem sap. The length of the labial groove, contained within the three distal segments, is equivalent to the length of the stylet. This length represents the maximum distance that the whitefly can penetrate the leaf in search of a phloem bundle. The average length of the stylets for the different species was: B. argentifolii 210 Im, T. vaporariorum 272 Im, A. dugesii 391 Im, A. dispersus 302 Im, and L. floccissimus 357 Im. The whitefly adult produces copious amounts of waxy particles, which they use to cover themselves. Many particles are shed over their surroundings. The waxy particles are formed from filaments extruded from wax plates present on the adult abdomens of these whitefly species. All of these adults had similar abdominal wax plates. Particles from *Bemisia* and *Trialeurodes* have a semi-circular shape. The particles from Aleurodicus are linear fragments. Also, female Aleurodicus have other abdominal wax plates that produce waxy filaments used to form oviposition trails. The whitefly species produced and shed waxy particles consisting of a mixture of long-chain aldehydes and long-chain alcohols of which the major components, depending on species, are 30, 32 or 34 carbons in length. The waxy filaments from female Aleurodicus are largely wax esters.

Index terms: Bemisia argentifolii, Trialeurodes vaporariorum, Aleurodicus dugesii, Aleurodicus dispersus, Lecanoideus floccissimus, waxes, aldehyde, alcohol, labium, stylet, feeding, phloem

[1090] GALLING HERBIVORY MEDIATED BY MUTUALISTIC INTERACTIONS BETWEEN ANTS AND APHIDS IN *BACCHARIS DRACUNCULIFOLIA* (ASTERACEAE)

<u>F.S. Neves¹</u>, M. Fagundes^{1,2}, B.G. Madeira & G.W. Fernandes¹, ¹Ecologia Evolutiva de Herbívoros Tropicais, DBG/ICB, Univ. Federal de Minas Gerais, CP 486, 30161-970 Belo Horizonte MG Brazil, e-mail: fneves@icb.ufmg.br, ²Dep. Biologia Geral, UNIMONTES, Montes Claros-MG Brazil.

A diverse fauna of insect herbivores, basically composed of free-feeding insects, ants, aphids, insect gallers, and their parasitoids occurs associated to Baccharis dracunculifolia (Asteraceae). In this system, Uroleucon erigeronensis (Homoptera: Aphididae) plays an analogous role to that of extrafloral nectaries, attracting several ants that feed on their Secretions, thus promoting a plant-aphid-ant association. Neopelma baccharidis (Homoptera: Psyllidae) is the most common galling herbivore found on B. dracunculifolia, and it is, in turn, attacked by three different parasitoid species. We tested the hypothesis that the ant-aphid interaction reduces the herbivory caused by N. baccharidis on B. dracunculifolia. 27 plants located in the Estação Ecológica at the Universidade Federal de Minas Gerais, Belo Horizonte, Brazil, were marked and used in an exclusion experiment to assess the effects of the ant-aphid interaction on the attack rates of N. baccharidis and its parasitoids. 4 shoots in each plant were selected and randomly rearranged in 4 treatments: T1 = shoots infested by aphids, without ants; T2 = shoots without ants and aphids; T3 = shots infested by aphids, with free access to ants; T4 = shots without aphids, with free access to ants. The exclusion of ants from treatments T1 and T2 was attained by applying a non-toxic resin (Tanglefoot[™]) on the base of the shoots and by cutting off the shoots which would allow access to ants. The treatments T1 and T3 were manually infested by U. erigeronensis. All plants were monitored twice a week. The number of galls was used as a measure of herbivory, and all N. baccharidis galls found were taken to the laboratory, where gall weight, number of larvae per gall, and parasitism rates were measured. The number of galls per shoot, number of larvae per gall, and parasitism rates did not vary among the treatments (p > 0.05, all). However, gall weight varied among the treatments (ANOVA: F = 7.949, p < 0.001, n = 1112), being significantly smaller on treatments T1 and T3. Therefore, the interaction between ants and aphids extended its effects to the first trophic level, limiting the injuries caused by N. baccharidis.

Index terms: three-trophic interactions, mutualism, Neopelma baccharidis

Symposium and Poster Session

[1091] A FAUNAL INVESTIGATION ON THE LONG-HORNED GRASSHOPPERS (ORTHOPTERA-TETTIGONIIDAE) OF GAZVIN TO DAMAVAND DISTINCT

M. M. Neyestanak & <u>P. A. Fard</u>⁴, Plant Pests and Diseases Institute, Evin Street, Tabnak Ave., Tehran, Iran, Entomology Dept. College of Agriculture Univ. of Tehran, Karaj Iran 31584 E-mail:pafard@chamran.ut.ac.ir.

During 1994 to 1996, the long-horned grasshoppers of different localities of southern slopes of Alborz mountains (Gazvin to Damavand distinct) were collected weekly in various methods, from April to November. The specimens were identified by means of the important morphological features, i.e. shape and denticles of the male genitalia (litillator), cerci, ovipositor, stridulatory and hearing organs, subgenital and supra anal plates in both sexes, etc. The determined specimens consist of five subfamilies, fifteen genera and nineteen species. The first records of the species not yet mentioned from this distinct are shown by an asterisk (*): 1) Bradyporus latipes; 2) Polysarcus elbursianus; 3) Leptophyes iranica; *4) Leptophyes trivitata; *5) Isophya caspica caspica; 6) Phaneroptera falcata; 7) Tettigonia viridissima; 8) Tettigonia caudata; 9) Platycleis escalerai iranica; 10) Platycleis intermedia mesopotamica; *11) Decticus annalisae; 12) Decticus albifrons; 13) Medecticus assimilis; 14) Paradrmadusa siazovi; 15) Uvarovistia incertus; 19) Homorocoryphus nitidulus.

Index terms: Grasshoppers-Titillator-Stridulatory

[1092] SPATIAL PATTERNS IN OVERWINTERING SURVIVAL OF *MELITAEA* CINXIA ON TWO HOST PLANT SPECIES

M. Nieminen, Dept. of Ecology and Systematics, Div. of Population Biology, P. O. Box 17 (Arkadiankatu 7), FIN-00014 Univ. of Helsinki, Finland, E-mail: marko.nieminen@helsinki.fi.

In Åland Islands, Melitaea cinxia feeds on two host plant species: Plantago lanceolata and Veronica spicata. These species have dissimilar distribution patterns, such that P. *lanceolata* occurs in practically all meadows, whereas V. spicata is most abundant in northwest and absent from the extreme east of Åland Islands. Recent studies have shown that in many regions within Åland egg-laying females prefer one host species to the other, but no constant spatial variation exists in the suitability of host species or in larval performance. Here I present results of one of the most important factors of larval performance in this highly dynamic system: the spatial variation in overwintering survival of larval groups between host species, subregions, and years in 1993-1999. The overall survival has been statistically significantly different from the average level in every winter. The survival has been higher on V. spicata (overall survival 69%) than on P. lanceolata (66%) in five out of six winters, but the survival has been statistically significantly higher in only one winter. There are no subregions (out of eleven where both hosts are present) where survival has been better on one host species in every winter. The survival has often been very variable both within and between subregions in a certain year, e.g. in 1995-96 40% on *P. lanceolata* and 82% on *V. spicata* in the westernmost subregion (Eckerö), but 85% on P. lanceolata and 64% on V. spicata in another subregion (Stalsby). Within subregions, the survival on one host has also varied enormously, e.g. in the east (in Kumlinge, where only P. lanceolata is present) the minimum has been 39% and maximum 82%. The spatial patterns of overwintering survival and extinctions of local populations caused by overwintering mortality will be compared with metapopulation dynamics of M. cinxia.

Index terms: Åland Islands, metapopulation, population extinction

[1093] AN ENTOMOFAUNA STUDY RELATED TO THE GROWING OF THE JAPANESE PEAR, VARIETIES (HOUSUI, KOUSUI AND NIJISEIKI), IN SANTA CATARINA STATE, BRAZIL

<u>I. Nora</u>¹ & T. Sugiura², ¹EPAGRI. Empresa de Pesquisa Agropecuária e Difusão de Tecnologia de Santa Catarina and ² JICA Japan International Cooperation Agency. Caixa Postal, 591 – 89500.000-Caçador, S. C., Brasil- Fone/Fax 55 (014) 49 563 3332 - E-mail: nora@unc-cdr.rct-sc.br

Studies were made during 1997/99 season to identify the main pests on Japanese pear. Several problems were discovered: nutritional, alternate bearing, damages caused by fungi and pests. Among the Arthropods, the South American fruit fly (Anastrepha fraterculus) caused serious injuries and was considered the key pest. In years when its incidence was too high it damaged 100% of the fruits. The second most important pest was the oriental fruit moth (Grapholita molesta) which caused deep galleries in the fruit turning them improper for commercialization, besides injuring the shoots and impairing the development of the whole plant. The two spotted spider mite (Tetranychus urticae), the European red mite (Panonychus ulmi), the pear-bud mite (Eriophyes pyri) and the desert spider mite (Tetranychus desertorum) also occurred in the region. However the dominant species was the P. ulmi followed by, T. urlicae. The E. pyri mite damaged young branches of the pear tree, mainly in the Nijiseiki cultivar and injuried with less intensity the other pear cultivars. The red mite (T. desertorum) was noticed, for the first time, in the cycle of the years 96/97 and produced leaf damages, in the pear trees, similar to those caused by T. urticae, however it occurred only in this cycle. Common cutworm litura (Spodoptera litura), weevils (Naupactus spp) and (Panthomorus spp), caused occasional damages in leaves. The leaf beetles (Diabrotica speciosa) injured flowers, leaves and young fruit of the pear tree and occurred during the whole cycle of the culture. The San Jose scale (Comstockaspis perniciosa) and oystershell scale (Lepidosaphes ulmi), caused damage in young branches and in the tree-trunk. The Aphis spp, damaged shoots, buds and normally occurred at the beginning of the vegetative cycle of the pear tree. The ants Atta spp and Acromyrmes spp, are important pear tree pests, they damaged the plant during its whole cycle but they injured the plant most during blooming and at the beginning of burgeoning. Predators and parasites also recorded were: Phytoseiulus persimilis, Amblyseius fallacis, Neoseiullus chilenensis, Cycloneda sanguinea, Stethorus punctum, Scymnus spp Doryctobracon areolatus, Doryctobracon brasiliensis, Opius bellus and Utetes anastrephae.

Index terms: The Japanese pear (Housui, Kousui, Nijiseiki), Tetranychidae, Eriophyidae, Tephritidae, Olethreutidae, Curculionidae, Chrysomelidae, Diaspididae and Phitosciidae.

[1094] DYNAMIC STATE VARIABLE MODEL OF OPTIMAL CLUTCH SIZE IN UROPHORA AFFINIS (DIPTERA: TEPHRITIDAE) ON SPOTTED KNAPWEED, CENTAUREA MACULOSA

R. M. Nowierski¹, Z. Zeng² & B. C. Fitzgerald¹, ¹Dept. OF Entomology, MONTANA State Univ., Bozeman, MT 59717, ²National Crop Insurance Services, 7201 W. 129th Street Ste. 200, Overland Park, KS 66213

A dynamic state variable model was developed for Urophora affinis (Frauenfeld)(Diptera: Tephritidae), an introduced biological control agent of spotted knapweed, Centaurea maculosa. The model predicts optimal clutch size (i.e., egg allocation) in U. affinis for the maximization of fitness given the frequency distribution of flower bud sizes and density of available buds for oviposition. Model predictions are then compared to field data obtained from six spotted knapweed sites in Montana. In general, the model predicted gall densites per capitulum well across a range of seed head sizes. Index terms: egg allocation, fitness, resource exploitation, behavioral ecology.

[1095] DIURNAL AND NOCTURNAL DRIFT OF AQUATIC INSECTS

<u>A. M. Oberto</u>, G. B. Raffaini & M. del C. Corigliano, Departamento de Ciencias Naturales, Universidad Nacional de Río Cuarto, 5800 Río Cuarto, Argentina. E-mail: aoberto@exa.unrc.edu.ar

The behaviour of the aquatic insects that composed diurnal and nocturnal drift was analysed in a second order stream of the Comechingones mountains, Cordoba, Argentina. Samples were collected with drift nets of 300 microns of mesh, placed every hour in the stream, during 57 serial hours. Benthos and marginal community samples were also taken from the studied stretch. Population densities were calculated for each community and the drift fraction. Descriptive statistics were carried out. Taxa were categorised according to their distribution and behaviour. The categories resulted from a combination between their presence in benthos, marginal communities, diurnal drift and nocturnal drift. From a total of 15 categories, 9 of them described organism behaviour and the others were empty sets. For the organisms that exhibited diurnal and nocturnal drift the ratio between densities was calculated. Among 42 studied population, 34 % were in benthos, marginal communities and diurnal and nocturnal drift. To develope time series statistics a group of species was selected by their frequency and abundance. These selected species were Baetis sp.1, Camelobaetidius penai, Caenis sp., Leptohyphes sp., Tricorythodes popayanicus, Chimarra argentinica, Smicridea sp. and of Simulium wolffhuegeli larvae. These species presented a clear circadian rhythm with significant higher densities during darkness. For the other species the variance and range between minimum and maximal drift density and other statistical parameters indicated specific behavioural drifting patterns. The majority of populations increased their abundance during the dark phase at a ratio of 1:10. It was observed that benthos organisms presented diurnal and nocturnal drift, while riverside taxa, like some Coleoptera and Heteroptera species, presented heterogeneous behaviour patterns.

Key-Words: Camelobaetidius penai, Tricorythodes popayanicus, Chimarra argentinica, Simulium wolffluegeli.

[1096] TRI-TROPHIC INTERACTIONS AMONG SPECIES ON MIKANIA GLOMERATA (ASTERACEAE) GALLS ON SOUTHEASTERN BRAZIL: A SPECIES RICH SYSTEM

R. A. M. Oda & <u>R. F. Monteiro</u>, Lab. Ecologia de Insetos: Depto Ecologia/IB/UFRJ -CP68020 - CEP21941-590 Rio de Janeiro, Brazil / E-mail: oda@biologia.ufrj.br; monteiro@biologia.ufrj.br

To understand the structure and dynamics of communities is of fundamental interest in ecology. Since one quarter of all insect species are parasitoids, analyses of such hostparasitoid assemblages are a major step in understanding the interaction types governing terrestrial communities, mainly in the Tropics, where the knowledge in this field is very scarce. The present research analyses the community associated to entomogenous galls of Mikania glomerata within six different locations, five of which placed within Tropical Rain forest conservation units (Atlantic Forest) in southeastern Brazil. Between february 1998 and march 1999, all galls found within a three-hour-time-lapse were collected every three months in each locality. A total of 12.441 galls induced by eight species have been collected, seven of these being regarded as new species or new genera (2) of gall midges (Diptera, Cecidomyiidae). A great number of inquiline species (17spp.) as well as hymenopterous parasitoids (87spp.) were also reared. The locality presenting the larger richness shown 57spp, among gall midges, inquilines and parasitoids, while the locality that presented the least species richness had 19spp, although most species were different with regard to the composition. The high parasitoid species wealth (maximun:47spp.) and the high parasitism rates found (84% at the most) have been common characteristics among the galls midges. Variation in gall maker composition was of 5.8 ± 1.17 , less than among the parasitoids (27.8 ± 9.78). Therefore wider distribution studies may shown an increase in parasitoid species rather than in gall maker species. Considering each locality as a unique system, there was no correlation between the number of galls and the richness of parasitoid species reared (r=0.68; p>0.05). If by one side the galls of M. glomerata sustain a great wealth of parasitoids, on the other hand the richness of species and the high parasitoid rates over the gall midges seem to be important for the diversity and the coexistence of these phytophagous. The work shows that M. glomerata galls are rich in species, but it is suggested that this may not be an exception and other plant species may present species rich systems. Taxonomic and ecological data of such still unknown species is essential for the understanding ecological patterns and processes as well as an alert for tropical biodiversity threatened of extermination.

Index terms: Insect galls, community structure, parasitoids.

[1097] MODELLING THE POPULATION DYNAMICS OF ATHERIGONA ORIENTALIS (DIPTERA, MUSCIDAE)

<u>S. G. Oliveira</u>¹, C. Bustamante² & J. R. Almeida^{1, 2}, ¹ Univ. do Est. Rio de Janeiro, Departamento de Biologia Animal e Vegetal, Setor de Ecologia, Rua São Francisco Xavier, 524, Maracanã – 20559-900, E-mail: sigomes@uerj.br; ² Univ. Fed. do Rio de Janeiro, Escola de Engenharia, Departamento de Hidráulica e Saneamento, CT – COPPE, bloco C, sala 211 Ilha do Fundão, 21941-590, E-mails: claudio@pec.coppe.ufrj.br e josimar@ppe.ufrj.br

Mathematical models are fundamental tools when dealing with populations from both scientific and management perspectives. In fact, the very idea of population dynamics is intertwined with mathematical descriptions and models. Custom-tailored models, developed to represent the most important factors that influence biological populations within specific contexts, can be extremely useful. They organize and integrate the knowledge about the organisms and their environment in a way that: 1) reveals issues that are poorly investigated or understood, helping to stabilish research directions and priorities, 2) show current trends in demographic behavior and potential consequences of changing conditions, allowing to assess different courses of action and 3) help in gaining deeper understanding, by testing hypothesis and analyzing relationships and causality chains. The complexity of interactions and the multiplicity of factors that influence their behavior undoubtedly place biological populations among the so-called high-order, complex systems, a class that includes most social and economic entities. The approach for analyzing and modelling such systems differ from the traditional one, developed for physical systems. It is based on an iterative multi-step procedure, in which the system is delimited, its main elements are recognized and their most important relationships with each other and with external factors are represented by mathematical formulations. We employed that approach to model the population dynamics of Aterigona orientalis in four different environments: tropical rain forest, mangroves and urban. A. orientalis is a cosmopolitan, hemisynanthropic fly in temperate and subtropical regions. The overall form of the model, as well as the most important processes, were based on the general ecology and natural history of Muscidae, but specific aspects, pertaining to A. orientalis were embedded in the mathematical formulations. This was mainly accomplished by estimating equations' parameters based on a significant body of data which includes the results of many laboratorial experiments as well as field surveys and experiments. Currently, the model is ready for first simulations and we will be going through calibration and validation to complete the model-building process.

[1098] THE POTENTIAL USE OF WOLBACHIA INFECTIONS AS TOOLS FOR MODIFYING INSECT POPULATIONS

<u>S. L. O'Neill</u>, Dept. of Epidemiology and Public Health, Yale University School of Medicine, 60 College St, New Haven CT 06520 USA. scott.oneill@yale.edu

Wolbachia are intracellular bacteria that naturally infect up to 20% of all arthropod species. These transovarially transmitted agents are well known for distorting the reproduction of their arthropod hosts so as to enhance their own transmission into populations. Their widespread occurrence, ability to be transferred between species in the laboratory and their ability to rapidly spread into host populations make them ideal candidates to be developed into tools for the genetic modification of insect pest species. I will present data on ongoing work in our group which is seeking to develop two different approaches to the use of *Wolbachia* in an applied context. The first will be the development of *Wolbachia* as a platform to express foreign genes in insect populations and the second will be the use of *Wolbachia* to distort population age structure of insects. Both of these approaches will be presented in the context of reducing the ability of insects to transmit pathogens to humans, plants or livestock. [1099] BIOLOGY OF *THYRINTEINA ARNOBIA* (LEPIDOPTERA: GEOMETRIDAE) ON THREE SPECIES OF *EUCALYPTUS*

A.L.T. Ottati¹ & <u>C.F. Wilcken¹</u>, ¹Dept. Plant Production, FCA/UNESP, Campus of Botucatu, P.O. Box 237, Botucatu, SP, 18603-970, Brazil, E-mail: aottati@fca.unesp.br

Among defoliator Lepidoptera, *Thyrinteina arnobia* (Geometridae) is considered the most important species than can inflict economic damage to eucalyptus forests in Brazil. Based on its importance, it is fundamental to gather basic informations that would lead to alternative methods of control of this pest. The objectives of this experiment were to compare the biology of *T. arnobia* fed with three species of *Eucalyptus* (*E. camaldulensis, E. dunnii* and *E. urophylla*), in oder to evaluate the effects caused by those hosts in two consecutive generations of the insect. Leaves used in the experiment were collected at the ErAUNESP (Botucatu, São Paulo sate) campus, and the studies were carried out at the Entomology Laboratory of the Plant Production Department (FCA/UNESP), under a

temperature of $25 \pm 1^{\circ}$ C, relative humidity of $70 \pm 5\%$ and photophase of 13 hours. The experimental design was a completeley randomized design, with 3 treatments and 100 replications. Data were submitted to analysis of variance and means separated by Tukey test. The results of biology, food consumption and food utilization showed distinct patterns for both generations. *E. urophylla* did not affect the general biology of *T. arnobia*; *E. camaldulensis* affected it moderately while feeding on *E. dunnii* resulted in deleterious effects in the biology of this species. We verified that the performance of *T. arnobia* in the second generation in *E. canaldulensis* and *E. dunnii* was worse than on the first generation, while insects reared on *E. urophylla* presented similar performance. Index terms: Forest pest, eucalypt.

[1100] FIRST RECORD OF SETINA IRRORELLA IN SOUTHERN ITALY AND OF SETINA ROSCIDA IN ABRUZZO (CENTRAL ITALY) WITH SOME CONSIDERATIONS ON EUROPEAN SPECIES OF GENUS SETINA (LEPIDOPTERA ARCTIIDAE LITHOSIINAE)

P. Parenzan¹ & S. Scalercio², 1- Ist. di Entomologia, Univ. di Palermo, Viale delle Scienze, 13, 90128 Palermo, Italia; 2 - Dip. di Ecologia – Sez. Zoologia e Zoocenosi, Univ. della Calabria, 87036 Cosenza, Italia.

Setina species are typically glacial relicts confined to the mountain of Southern Europe. In this work, we reporto on the first capture of Setina roscida on Gran Sasso (Passo delle Capannelle and Mt. S. Francesco, Abruzzo, Central Italy) as well as on the first observation of Setina irrorella in South Italy (Basilicata, Mt. Pollino: Serra Dolcedorme,). A survey of the six European species of Setina (i.e. Setina roscida ([Denis & Schiffermueller], 1775), S. flavicans (Hubner & Geyer, [1834-1836]), S. cantabrica de Freina & Witt, 1985, S. irrorella (Linnaeus, 1758), S. alpestris Zeller, 1865 and S. aurita (Esper, 1787)), is also provided. A new taxonomic grouping of European Setina species is suggested on the basis of morphological evidence drawn from the male genitalia. The S. irrorella group (S. irrorella, S. alpestris, S. aurita) has a spiny clasper, whereas the S. roscida group (S. roscida, S. cantabrica, S. flavicans) has a concave clasper. This new arrangement also is supported by ecological features.

[1101] BIOLOGY AND ONTOGENY OF ZELUS LEUCOGRAMMUS, (HEMIPTERA: REDUVIDAE) IN CERRADO-SAVANNA, BRAZIL: THE IMPORTANCE OF CLIMATIC VARIATIONS.

C. M. Paro, K. Del-Claro & F. R. Oliveira, Univ. Fed. Uberlândia, Inst. Biology, PG-Ecology, CP 593, Zip: 38400-902, Uberlândia, MG, Brazil. e-mail: cmparo@yahoo.com

The Heteroptera are one of the most diverse insect group in Brazil and they are importants for many economic, ecological and medical reasons. The Reduviidae family has been studied mainly by its medical and agricultural importance. Although insect biology and ecology are basic to the complete use of these animals in biological control, there are few studies in this field with Brazilian Reduviidae. *Zelus leucogrammus* is pointed out as a potential predator to be used in biologic control in Brazil. In our study we investigated the biology (ontogeny) of *Z. leucogramus* in laboratory conditions and directly in the field (cerrado-savanna like vegetation) between July, 1997 and March 1999. This Reduviidae presents 5 nymph instars and are bivoltine. Egg eclosion delayes (30.47 ± 4.31 days, n= 1033) in dry season (February-September), it presents an egg diapause (196.51 ± 4.95 days, n= 105) on the rainy season (October-January). Eggs with diapause arise individuals that have faster ontogenetic development (47 ± 3.02 days, n=34) than individuals borned during the dry season (80.18 ± 7.55 days, n=73). Our results showed that in cerrado climatic variations and food availability are critical factors on the ontogeny of Reduviidae. Index terms: *Zelus leucogrammus*, Reduviidae, biology, ontogeny, cerrado-savanna.

[1103] DIPTERA COMMUNITY COMPOSITION AND SUCCESSION FOLLOWING HABITAT DISTURBANCE BY WILDFIRE

M. A. Patten^{1,2}, J. C. Burger², T. R. Prentice², <u>J. T. Rotenberry</u>^{1,3} & R. A. Redak^{2,3}, ¹Dept. Biology, ²Dept. of Entomology, ³Center for Conservation Biology, Univ. California, Riverside, CA 92521 USA; E-mail rote@citrus.ucr.edu.

Both biogeographic and local processes determine composition and succession of biotic To infer processes involved, we compared patterns of richness and communities. community composition of families of Diptera at 12 burned and 12 unburned sites of coastal sage scrub vegetation type in southern California. Sites were sampled at 3-month intervals in 1996 and 1997. Fluctuations in richness over time were parallel in burned and unburned sites, permitting us to pool data over all sampling periods. Whereas burned and unburned sites clearly separated when ordinated by vegetative characteristics, they were not discernable as such on the basis of relative abundance of Diptera families. Thus, the overall Diptera community recovered more quickly than did vegetation. However, there remained a strong association between abundance within families of Diptera and vegetation on the plots, indicating the burn had effects on at least some components within the community. Recolonization of burned plots followed a predictable pattern, with generalized scavengers recolonizing fiirst, followed by animal feeders (predators, parasitoids, and hematavores), then by plant feeders (herbivores and pollinators), and with detritivores recolonizing most slowly. These results support the hypothesis that climate, seasonal fluctuations, and geography of a region determine overall community composition (i.e., communities on plots were more similar than different), but disturbance alters local distributions within the community (e.g., by altering microhabitat, which affects certain taxa more than others).

Index terms: Diptera, community succession, wildfire, recovery from disturbance

[1102] TRANS-OCEANIC DISPERSAL OF INSECTS OVER BAY OF BENGAL

S.C. Pathak, Department of Post - graduate studies and Research in Biological Sciences, Rani Durgavati University, Saraswati Vihar, JABALPUR 482001. India. E-mail pathaksc@hotmail.com

Trans-oceanic dispersal of insects (TODI) has been studied over and in Bay of Bengal. Air borne insects of terrestrial origin in the acolian environment were trapped using multinet trapping systems mounted at vantage points aboard the Ocean going Research Vessel (ORV) Sagar Kanya. Terrestrial insects that had fallen in the flotsam and the endemic ones (Halobatinae) were collected using regular neuston nets towed for 20 min at a time. Air borne insects trapped belonged to eleven orders of which four viz. Hemiptera, Diptera, Hymenoptera and Coleoptera accounted for almost 99 % of the total haul. A 45 day cruise of the area yielded as many as 16,429 air borne insects. Of these over 94% were hemipterans while dipterans (4%), hymenopterans (1%) and coleopterans (0.5%) constituted the rest. Trichoptera, Neuroptera, Thysanoptera, Odonata and Dictyoptera were represented by single digit numbers. Although order-wise diversity appeared to be low in this catch, diversity with families and species in focus was quite high, the proportions being 40 - 45% for Diptera, 16 - 25% each for Hemiptera and Hymenoptera and 10 - 12% for Coleoptera. Aerial density of these insects was not uniform and the sampling stations were grouped in clusters on the basis of the relative density of insects. Indices of species diversity, richness, and evenness highlight interesting aspects of this population. Homoptera dominated most of the clusters (Aphididae in clusters I & II, Psyllidae in clusters IV to VII, Delphacidae in clusters VIII & IX) except in cluster III which had Agromyzidae (Diptera) as the dominant group. A total of 82 insects including 23 live specimens of Halobates were recovered from the flotsam. These belonged to Hemiptera (82%), Diptera (4%), Coleoptera (4%) Hymenoptera (1%) and Neuroptera (1%). The rest (8%) were in such stages of disintegration that they could not be identified. Of the endemic insects, 21 specimens of Halobates germanus and 2 specimens of Halobates micans were trapped, both being reported for the first time from this region. Contribution of insects to the oceanic biomass in the study area was found to be 40 g/km² including 30 g/km² contributed by *Halobates*. The study area was toulous to be 700 km² minute study and 100 km² minute s Index terms : TODI, Halobates germanus, Halobates micans, oceanic biomass, insects of terrestrial origin

[1104] COLEOPTERA LIVING IN SUBTERRANEAN NESTS OF AVES ALCIDAE AND SPHENISCIDAE IN THE SUBTARCTIC AND SUBANTARCTIC REGIONS

M. Perreau, Université Paris 7, case 7020, 2 place Jussieu, 75251 Paris cedex 05 France

The burrows of mammals are a well known biotope for Coleoptera and many works have been made on their Coleopterous fauna. Less studied are the burrows of the few species of birds which are living in a subterranean nest. Among them are several species of the families Alcidae and Spheniscidae which are living respectively in subarctic and subantarctic regions. The coleopterous fauna of the nests of five species of Alcidae: Lunda cirrhata (Pallas, 1769) (tufted puffin), Fratercula corniculata (Naumann, 1821) (horned puffin), Aethia cristatella (Pallas, 1769), (crested auklet), Cyclorrhynchus psittacula (Pallas, 1769), (parakeet auklet), Synthliboramphus antiquus (Gmelin, 1789) (ancient murrelet) have been invetigated in north-eastern Siberia (Talan, oblast of Magadan). The nests of Spheniscus demersus (Linné, 1758) (Spheniscidae) (African Penguin) have been also investigated on Dassen island near Cape town, South-Africa. In Alcidae nests, several species of Staphylinidae, Silphidae, Agyrtidae, and Leiodidae Cholevidae have been collected. The main result is the rediscovery of Catops carinatus Jeannel, 1936, known up to now by only 5 specimen from Central Asia and Siberia, which appears to be quite common in nests. Calops alpinus Gyllenhal, closely related to C. carinatus, and very common in all eastern Europa and in Siberia, outside nests appears to be absent in nests. The auks carrions appear to be an intermediate biotope where both species can be found. Statistics have been done for each birds species, but no correlation has been found between the number of Catops collected and the species of bird.In the nests of Spheniscus demersus, species of the following families have been recorded (Carabidae, Trogidae, Scarabaeidae Aphodiinae, Staphylinidae, Histeridae, Tenebrionidae). Among them, one new species of Histeridae of the genus Atribalus has been discovered.

[1105] THE SUCCESSION OF A FRESHWATER POND AFFECTING THE FAUNA OF WATER BEETLES (COLEOPTERA: HYDRADEPHAGA) IN WESTERN SIBERIA

<u>P. Petrov</u>, Dept. of Entomology, Fac. of Biology, Moscow State Univ., 199 899, Moscow, Russia, E-mail pp@3.entomol.bio.msu.ru.

The succession of a freshwater pond in Boreal regions is the process of the pond's eutrophication and its becoming a bog. Knowledge of this succession's affecting a pond's insect fauna gives a tool for bioindication of succession stages and provides data on ecological preferences of species. In Western Siberia water beetles of the suborder Adephaga are represented by the families Haliplidae, Noteridae, Dytiscidae and Gyrinidae. Studying four freshwater ponds at different stages of succession (three ponds, a mesotrophic, a eutrophic and a distrohpic, and a bog) near the city of Tyumen in Western Siberia, 48 species were found. Most of them occur in the mesotrophic pond only, e.g. Hydroporus neglectus), yet there are several species occurring in the bog only (e.g. Hydroporus tristis). It has been shown that water-beetle fauna is changing gradually as pond succession goes on.

Index terms: *Hydroporus neglectus, Hydroporus obscurus, Hydroporus tristis,* eutrophication, bioindication.

[1107] THE ROLE OF PREDATORS IN THE POPULATION AND BEHAVIOURAL ECOLOGY OF THE SOLDIER-PRODUCING APHID SPECIES, PEMPHIGUS SPYROTHECAE

N. Pike & W. A. Foster, Dept. of Zoology, Univ. of Cambridge, CB2 3EJ, U.K. Email: np223@cam.ac.uk.

Only approximately 40 of the more than 4400 species of aphid described are social. This is notable because aphid colonies are often clonal; genomic conflict among individuals should not interfere with the evolution of altruistic behaviour. Ecological factors must determine the extent of altruism. The habit of gall formation is almost ubiquitous in the social aphid species, and is likely to have been prerequisite to their sociality. Pemphigus spyrothecae (Hemiptera: Pemphigidae) forms galls on the black poplar, Populus nigra, and has 1st instar morphs which are behaviourally and morphologically adapted for defence. Predation is likely to have heavily influenced the evolution and maintenance of such aphid 'soldiers'. Drawing from ecological surveys and behavioural experiments, we discuss the influences of a variety of specialist and generalist predators of P. spyrothecae. We demonstrate that Anthocoris minki (Hemiptera: Anthocoridae) and Heringia heringi (Diptera: Syrphidae) exhibit behavioural adaptations for predation upon P. spyrothecae and are responsible for significant mortality at different times during the galling season. Generalist predators occur only rarely with P. spyrothecae and may be foiled by the structural protection provided by the spiral galls as well as by the soldiers' behaviour. We discuss how predators are likely to have influenced the evolution of soldiers in P. spyrothecae.

Index terms: Anthocoris minki, Heringia heringi, sociality, altruism, gall

[1106] FIELD BIOLOGY OF THE GLASSY-WINGED SHARPSHOOTER IN SOUTHERN CALIFORNIA

P. A. Phillips, Cooperative Extension, Univ. of California, 669 County Square Dr. #100, Ventura, CA 93003, USA, E-mail paphillips@ucdavis.edu.

The glassy-winged sharpshooter (GWSS), Homalodisca coagulata, was introduced into Southern California from the southeastern US around 1990. Increasing populations of this bacterial plant pathogen vector pose a significant threat to several of California's valuable agricultural industries, including citrus, grapes, stone fruits, and almonds. In 1999 surveys for GWSS life stages and for associated parasitoids were conducted in five study sites: commercial lemon, orange, and avocado orchards: door-yard macadamia trees; and wild, native laurel sumac (Rhus ovata) shrubs. Two generations of GWSS occur each year in southern California. After a peak in adult activity during the winter months of January and February, oviposition begins in late February or early March, peaking in May. Adults live for several months. They lay their small, sausage-shaped eggs side-by-side in masses averaging 10 to 11 eggs each and ranging in size from single eggs to masses containing as many as 27 eggs. These eggs are laid just under the lower leaf epidermis of host plants. Oviposition damage to lemon fruit rinds was documented for the first time in late summer, 1998. An early September harvest in one orchard had a documented 8% of the fruit with GWSS egg masses noted on the packing line during fruit grading. No damage reports were received for 1999. Nymphs hatch in about two weeks and proceed to feed into leaf petioles or small stems while they progress through four molts before becoming winged adults. A second peak in adult activity occurs in the summer during the months of July and August. Peak oviposition from these first generation adults occurs in August. After the eggs have hatched, the old egg mass blister leaves a tan to brown scar. The last nymphs of this second generation can be observed during October. By November, only the adult stage is found, these being the adults that will over-winter to produce the first generation the following spring. Oviposition into laurel sumac and macadamia is about 2 to 3 times that of oviposition into citrus. Avocado also supports low levels of GWSS, although egg masses don't appear to be as readily laid into avocado leaf tissue as citrus leaf tissue. Only one biological control agent of any significance has been noted to date. A small egg parasite, Gonatocerus ashmeudi, (Hymenoptera: Mymaridae), attacks the GWSS egg masses starting in the spring. Its activity peaks in May and again in late summer, with this latter peak being the greatest when as much as 80-85% of the eggs can be parasitized. A short and successful foreign exploration trip into northern Mexico during April, 1999, produced another potential egg parasite on GWSS, G. triguttatust.

Index terms: Homoladisca coagulata, oviposition, citrus, avocado, Rhus ovata

[1108] NITROGEN AND POTASSIUM FERTILIZATION WERE INFLUENCING THE WHITEFLIES POPULATIONS IN CITRIC PLANTS

J. M. Pinto¹, W. C. Rodrigues¹ & P. C. R. Cassino², ¹Dept. de Fitotecnia, CPGF, UFRRJ, Seropédica, RJ 23.890-000, Brasil, E-mail: jmiranda@ufrtj.br; ²Dept. de Entomologia e Fitopatologia, CIMP, UFRRJ, Seropédica, RJ 23.890-000, Brasil.

This study was performed in a orchard of *Citrus reticulata*, cv. Ponkan, at the Universidade Federal Rural do Rio de Janeiro in Seropédica city, state of Rio de Janeiro, Brazil, during the period from October 1997 to July 1998 with the aim of assessing the influence of nitrogen and potassium mineral fertilizers on the populations of whiteflies: *Aleurothrachelus cruzi, Aleurothrixus floccosus, Dialeurodes citrifolii* and *Paraleyrodes bondari*. A two-factor experiment in a randomized complet-block design with four treatments and six replicates was used. The treatments consisted of two nitrogen (N) levels (0 and 110g/plant) and two potassium (K) levels (0 and 150g/plant), that were divided in two applications (2/3 on the first one, and 1/3 on the second one). Seven days after the start of fertilization treatments, the insect population densities were weekly sampled for each replicate. Only the populations of the whitefly *Dialeurodes citrifolii* significantly differed between treatments. The treatments exerted different effects on the population of this specie, showing an effect reduced on its population when N and K were applied concomitantly.

Index terms: Dialeurodes citrifolii, Aleurothrachelus cruzi, Aleurothrixus floccosus, Paraleyrodes bondari, Citrus

[1109] INFLUENCE OF DIFFERENT LEVELS OF NITROGEN AND POTASSIUM FERTILIZATION ON THE SCALES POPULATIONS ASSOCIATED WITH CITRIC PLANTS

J. M. Pinto¹, W. C. Rodrigues¹ & P. C. R. Cassino², ¹Dept. de Fitotecnia, CPGF, UFRRJ, Seropédica, RJ 23.890-000, Brasil, E-mail: jmiranda@ufrrj.br; ²Dept. de Entomologia e Fitopatologia, CIMP, UFRRJ, Seropédica, RJ 23.890-000, Brasil.

This study was performed in a orchard of Citrus reticulata, cv. Ponkan, at the Universidade Federal Rural do Rio de Janeiro in Seropédica city, state of Rio de Janeiro, Brazil, during the period from October 1997 to July 1998 with the aim of assessing the influence of nitrogen and potassium mineral fertilizers on the populations of scales: Coccus viridis, Orthezia praelonga, Pinnaspis aspidistrae and Selenaspidus articulatus. A two-factor experiment in a randomized complete-block design with four treatments and six replicates was used. The treatments consisted of two nitrogen levels (0 and 110g/plant) and two potassium levels (0 and 150g/plant), that were divided in two applications (2/3 on the first one, and 1/3 on the second one). Seven days after the start of fertilization treatments, the insect population densities were weekly sampled for each replicate. Only the populations of the ensign coccid Orthezia praelonga significantly differed between treatments. The treatments exerted different effects on the population of these species. The study of trophic relationship and bioecology showed that the accumulation of free amino acids on the leaves of *C. reticulata*, cv. Ponkan, caused a significant increase of the population density of O. praelonga. The populations of the armored scales Selenaspidus articulatus and Pinnaspis aspidistrae were correlated negatively with the concentration of potassium in the leaves. It indicated the potassium was a mineral element necessary for insect nutrition, and controlled the population increase of those scales. The diversity of predators in each treatments was also observed. The lacewing Chrysoperla spp. was the most effective predator of O. praelonga.

Index terms: Coccus viridis, Orthezia praelonga, Pinnaspis aspidistrae, Selenaspidus articulatus, Citrus

[1110] DRY-SEASON EMBRIONIC DORMANCY IN DEOIS FLAVOPICTA (HOMOPTERA: CERCOPIDAE): ROLES OF TEMPERATURE AND MOISTURE IN NATURE

C.S.S. Pires¹, E.R. Sujii¹, E.M.G. Fontes¹, C.A. Tauber², & M.J. Tauber², ¹ Embrapa Cenargen, Cx. Postal 02372, Brasília – DF, 70849-970, Brazil, E-mail cpires @cenargen.embrapa.br; ² Dept. of Entomology, Comstock Hall, Cornell University, Ithaca, NY 14853-0901. USA.

A field-based experimental study examined the roles of temperature and moisture in the dry-season embryonic dormancy and post-dormancy hatching of the spittlebug *Deois flavopicta* Stal from Brazil's dry interior region. The results show that dormancy consists of two discrete parts: an initial period of diapause that persists from April to the beginning of July, followed by a period of postdiapause quiescence that prevails until the rainy season begins (usually Oct.). Low temperature during the early part of the diapause period of postdiapause development whereas contact with liquid water determines the timing of postdiapause hatching. Soil temperatures during June and July and the relative humidity of the soil during August and September strongly affect overwintering survival and thus are important in determining the size of the nymphal population after dormancy. The findings indicate that, like hibernation and aestivation in temperate-zone insects, dry-season dormancy in tropical insects is a dynamic state that is influenced by seasonal changes in key environmental factors.

Index terms: Deois flavopicta, dry-season dormancy, moisture, temperature, egg diapause

[1112] PATTERNS OF HOST PLANT GROWTH AND ATTACK AND ESTABLISHMENT OF GALL-INDUCING WASP, ANDRICUS SP.

C.S.S. Pires¹ & P.W. Price², ¹ Embrapa/ Cenargen, Cx. Postal 02372, Brasília - DF, 70849-970, Brazil, E-mail cpires@cenargen.embrapa.br; Dept. of Biological Sciences, Northern Arizona University, Flagstaff, AZ 86001, USA.

We examined the effect of shoot size distribution within plants and different stage of host plant development on the pattern of attack of Andricus sp. on gambel oak, Quercus gambelli Nuttall. The gall-inducing wasp prefered large diameter shoots to small ones in 2 populations of host plant. Attack on larger shoots was significantly nonrandom and occurred even though these shoots were relatively scarce in the shoot population. Large shoots accounted only for 5.51% and 12.72% of the total shoots in an urban and forest site respectively. The percentage of attack on shoots in the largest shoot diameter class was 10.53 and 48.74% in the urban and forest site, respectively. Gall density decreased with maturity of the host plant and was 3 times higher on juvenile plants compared with mature plants. The distribution of attack in relation to plant age was not related to changes in shoot size with the age of the plants. Gambel oak may become resistant to gall formation with increasing age, Survival was 33.72% higher on large shoots (83.72%) compared to small shoots (50.00%). Larval survival did not change with plant age among host plants. The pattern of attack in relation to shoot size suggests that Andricus sp. prefer to oviposit on large shoots in which larval performance was highest. Andricus sp. might show a flexible oviposition preference hierarchy for shoot lengths. Females attacked the longest shoots available rather than showing a fixed preference for specific shoot lengths. Index terms: oviposition preference, population dynamics, plant vigour hypothesis.

[1111] FEEDING BEHAVIOR OF THE SPITTLEBUG DEOIS FLAVOPICTA (HOMOPTERA: CERCOPIDAE) ON WILD AND CULTIVATED HOST PLANT

C.S.S. Pires¹, P.W. Price², E.R. Sujii¹ & C. Avelar¹, ¹ Embrapa Cenargen, Cx. Postal 02372, Brasilia - DF, 70849-970, Brazil, E-mail cpires@cenagen.embrapa.br; ² Dept. of Biological Sciences, Northern Arizona University, Flagstaff, AZ, 86001-5640, USA.

We studied the movement and feeding behavior of nymphs of the grass feeding spittlebug Deois flavopicta Stal to evaluate the role of host plant species on the spatial distribution of the nymphs. The inter- and intraplant foraging patterns of the nymphs contributed to their patchy distributions. The young nymphs, despite their weak motility, moved from the hatching spot and chose feeding sites. They tend to move less when host plants were present. Plant quality near hatching sites influenced the movement pattern of newly hatched nymphs. Egg densities at the oviposition sites did not influence the movement of newly hatched nymphs. The distribution of nymphs in relation to differences in host species and shoot age of host plant was studied in the field and in multiple choice experiments. Both young and old nymphs preferred plants of the introduced host in the genus Brachiaria over the native grass Axonopus marginatus (Trinius) Chase. The nymphs fed gregariously on buds and young shoots as first and second instars and in small groups of third, fourth and fifth instar individuals on old shoots of different sizes. These patterns of atttack may be related to differences in tissue hardness and /or amino acid content between young and old shoots, and between host species. Nymphal survivorship was higher on B. ruziziensis, the preferred host plant. In addition, survivorship of newly hatched nymphs was higher on young buds and shoots compared to old shoots. The possible consequences of nymphal feeding behavior on population dynamics are discussed.

Index terms: grass-feeding, population dynamics, feeding preference.

(HYMENOPTERA: CYNIPIDAE)

[1113] MORTALITY RATE, REPRODUCTIVE OUTPUT, AND TRAP RESPONSE BIAS IN POPULATIONS OF THE BLOWFLY LUCILIA SERICATA

K. M. Pitts¹ & R. Wall¹, ¹School of Biological Sciences, Univ. of Bristol, Woodland Road, Bristol, BS8 1UG, United Kingdom. E-mail: Kieren.Pitts@bristol.ac.uk.

The sheep blowfly, Lucilia sericata, is the primary agent of sheep myiasis in Northern Europe. Current health and environmental concerns over the use of organophosphate dips have led to their phasing out as a control measure for the sheep blowfly within the UK. Novel control methods are therefore being developed. To maximise the success of these devices a clear understanding of the ecology of L. sericata and its responses to traps is required. In a field study the ages of female blowflies collected from farms in the southwest of England, between May and September 1996, 1998 and 1999, were determined using a combination of ovarian dissection and wing fray analysis. Using survivorship analysis, the mortality rates over the entire field season were estimated in day-degrees (a physiological measure of age). From this a mean life expectancy was calculated and also an estimate of lifetime reproductive output per female. The change in mortality rate throughout the season was also examined. The effect of emergence and senescence of generations will be discussed. In addition, the response of L. sericata to liver baited traps will be assessed and, in light of population age-structure information derived from the work, the effectiveness of baited traps as a control measure for the sheep blowfly will be discussed.

Index terms: Age, survivorship, day-degrees

[1115] FAT-BODY, A DECISIVE FACTOR OF SUNN PEST POPULATIONS LEVEL OF *EURYGASTER* GENUS

C. Popov, ¹Research Inst. for Cereals and Industrial Crops, 8264 Fundulea, N Titulescu Str., 1, Calarasi District, Romania, E-mail: fundulea@cons.incerc.ro

Eurygaster genus is represented in Romania by the species Eurygaster integriceps, Eurygaster maura, Eurygaster austriaca and Eurygaster testudinea, however only E. integriceps is able to develop numerous populations, which are extremely dangerous to some 1.500.000 ha. Methodology. Periodical analyses throughout diapause duration on fat body level, aimed to explain differences recorded between the size of populations of various species and the fat supply in E. integriceps. Fat extraction has been performed by Soxhlet method in petrol ether, with groups of 100 insects. For E. integriceps, due to its numerous populations, differentiate analyses of fat body by insect groups was feasible, starting from their weight. Results. On a 3-year average high difference has been detected between the fat-body of species analysed both in autumn and spring. In August, at diapause start, the level of fat-body was 36.8% in E. integriceps, 28.5% in E. maura, and 27.9% in E. austriaca. It was appreciated that physiological preparation of E. integriceps was better over the other species by more than 25%. Differences between species also maintained at the end of diapause, in April: 27.2% in E. integriceps, 22.0% in E. maura and 21.3% in E. austriaca. It resulted from these values that decrease of fat-body during diapause is similar to all species, reaching 23-25%. Differences between sexes have been revealed: cunsumption of females ranged between 19-26% from the total of accumulated supply, while in males was 26-34%. Fat-body level strongly influenced insect mortality during diapause (r=-0.94^{XX}), however without recording differences between species. Likewise, the level of physiological preparation of Eurygaster species adults, is strongly

reflected in their evolution, during the active period, after diapause, negatively influencing sterility (r=-0.838^{XX}), and positively female fecundity (r=+0.885^{XX}). There were high differences between percentage of sterile females (9.7% in *E.integriceps*, 18.5% in *E. maura*, and 27.6% in *E. austriaca*), and also average fertility (64.3 eggs/female in *E. integriceps*, 26.2 in *E. maura* and 19.8 in *E. austriaca*). Conclusions. It could be appreciated that the peculiarity of *E. integriceps* to develop numerous populations, and implicitly to be a particularly dangerous pest, is mainly due to its capcaity to accumulate a high food supply, as fat body. This fat-body provides good survival during winter, and high fecundity, fairly superior to the other species.

Key words. Eurygaster species, fat-body, diapause, fecundity, populations level.

[1114] BIOLOGICAL AND NUTRITIONAL ASPECTS OF NEZARA VIRIDULA (HEMIPTERA:PENTATOMIDAE) ON SOYBEAN GENOTYPES

<u>G.C. Piubelli</u>^{1,4}, I.C Arruda², F. M. Lara¹ & C.B. Hoffmann-Campo^{3,3}, ¹ Dept. de Fitossanidade (FCAV/Unesp), Via de Acesso Prof. Paulo Donato Castellane, Km 05, 14870-000, Jaboticabal, SP, Brasil; ² Protex (Núcleo Manejo Integrado de Pragas); ³ Embrapa Soja, C. Postal 231, CEP 86001- 970, Londrina, PR, Brasil. ⁴ Present address: Universidade Federal do Paraná, Departamento de Zoologia, Caixa Postal 19020, CEP 81531-900, Curitiba, PR, Brasil E-mail: giorla@enpso.embrapa.br

Stink bugs are important soybean pest and efforts have been made to obtain cultivars with, at lest, moderate level of resistance. Experiments were carried out to evaluate the effect of soybean genotypes ('BR-16', 'IAC-100', PI 227687, PI 229358, PI 274454) on Nezara viridula survival, initial weight, adult fresh weight, growth, weight gain and lipid accumulation. When fed on PI 227687 and 'BR 16' (control) pods, survivorship of N. viridula nymphs were 33.7 % and 72.5 %. Nymphs placed in Petri dishes containing PI 274454 and 'BR 16' pods, at the first day of second instar, weighed 1.06 mg and 1.04 mg, being heavier than those with PI 227687 (0.74 mg) and 'IAC 100' (0.66 mg). Adult fresh weights were 146.85 mg when insect fed on 'BR 16', 127.04 mg on PI 227687 and 125.50 mg on 'IAC 100'. The last two genotypes negatively affected stink bugs growth (adult fresh weight adjusted for development time, by ANCOVA) and gain of weight (adult fresh weight adjusted for nymph initial weight, by ANCOVA); they also accumulated less lipids in their bodies. Consequently, PI 227687 and 'IAC-100' are inadequate food source to N. viridula, being a promising alternative to be used in soybean breeding programs as source of resistance to stink bug.

Index terms: plant resistance, antibiosis, growth, gain of weight, lipid

[1116] BIOLOGICAL ASPECTS OF ORYZOPHAGUS ORYZAE (COLEOPTERA: CURCULIONIDAE) IN WATER-SEEDED RICE

II. F. Prando¹, D. R. Sosa-Gómez² & G. H. Rosado Neto³, ¹EEI-Epagri, Cx. Postal 277, 88301-970, Itajaí SC. E-mail: hfprando@zaz.com.br; ²Embrapa Soja E-mail: sosa@cnpso.embrapa.br; ³Zoologia/Entomologia UFPR E-mail: pgento@ufpr.br

In Santa Catarina state (SC), Brazil, around 135 thousand ha of irrigated rice are cultivated under the water-seeded system. The main insect pest in this system is Oryzophagus oryzae. Adults and larvae attack the crop. The adults cause greater damage on germinated seeds, by eliminating the epicotyl and radicle right after sowing, or on seedlings. The larvae attack the irrigated rice roots. The present research was conducted during 1997/1998 growing periods, with the purpose of investigating the biology of this pest. Adult insects were collected in Itajaí SC for identification and morphological studies. At the laboratory, the oviposition site, fertility and incubation period were observed. Larval instars were based on measurements of the head capsule. O. oryzae presents a well-defined sexual dimorphism, with females being larger than males (3.44 mm and 2.85 mm, respectively). Morphological characteristics are evident on the ventral side of the insect. The oviposition takes place on the rice plant sheath, preferably in the submersed parts. The eggs, white and slightly curved, are 0.88 mm long and 0.23 mm wide, and are located in each aerenchyma of the sheath. The average incubation period is 6.5 days, under $25 \pm 2^{\circ}$ C of temperature. After egg eclosion, the larvae remain for 1-1.5 days inside the sheath, feeding on the divisory membranes of aerenchyma. They leave the sheath through a circular orifice at 6-10 days after oviposition. The larvae are white almost transparent in the first instar, and yellowish white in the subsequent instars. They are apodal, have six pairs of spiracles on the dorsal abdomen, which bears strongly sclerotized hook-like structures. Head capsules measurements evidence five larval instars: I (0.18 mm), II (0.24 min), III (0.31 mm), IV (0.37 mm) and V (0.46 mm). The cocoons are impermeable, made of clay and plant residues. They attach firmly to young roots, from where the pupa removes its O2 supply. Inside the cocoon, the rostrum of the pupa is always turned to the fixation root.

Index Terms: rice weevil, behavior, oviposition, morphology.

[1117] COMPARATIVE STUDY OF NYMPHS AND ADULTS OF NUBITHIA GRISESCENS (HEMIPTERA, FULGOROIDEA, ISSIDAE)

P. H. Prates-Ir.¹ & G. S. Carvalho¹, ¹PUCRS, Entomology Laboratory, Ave. Ipiranga, 6681, P.O. Box 1429, RS, Brazil. E-mail: prates74@pucrs.br

Issidae includes one of the largest families among Fulgoroidea. The family is generally compost of small species. The immature and adults issids can be separate from the others planthoppers for the presence of two apical spines, one each side in the second segment of hind tarsus, as well as, for the presence of pre-apicals spines in the hind tibia. The immature issids present rostrum reaching hind trocanters and second segment of hind tarsus wider than third. They are moderately humpback. Nubithia grisescens is found predominantly in graminea. The present work has for objective the morphologic characterization of the immature stages and of the adults of Nubithia grisescens. Nymphs and adults were collected in Viamão, Rio Grande do Sul, Brazil. The insects were dissected with aid of tongs and histologic hole, include in solution of NaOH at 10% for 24 hours and colored with Fucsina. The pieces were examined and drawn with aid of estereoscope microscope and clear camera and photographed with aid of photographic machine coupled this. The pieces of genitalias were examined in eletronic microscope. Resulted of work drawings and/or pictures in the immature and adults of head; pronotum, mesonotum e metanotum; abdome; first, second and third pair of legs; first and second pair of wings; genitalia male and female in the several positions and subdivisions. Nymphs presents the same brownish coloration of the adults. Both presents three spines pre-apicals and eight apicals in the hind tibia. Immatures present front the bigger than adults. The first instar has only two tarsomeres being the hind tarsus more develop. The second to fifth instar have two tarsomeres in fore and median legs and three tarsomeres in hind leg. Rudimentary wings arise in thrid instar.

Index terms: planthoppers, Issidae, morphology, immature, adult

[1118] LINKING MULTITROPHIC INTERACTIONS ABOVE-BELOWGROUND

W.H. van der Putten, H. Duyts, J.A. Harvey, F.L. Wackers, L.E.M.Vet, E.P. Brinkman, G. de Deyn, G.T.A Doodeman, & C.D. van der Stoel. Centre for Terrestrial Ecology, Netherlands Institute of Ecology, P.O. Box 40, 6666 ZG Heteren, The Netherlands, E mail putten@cto.nioo.knaw.nl

Research on multitrophic interactions aims to identify the forces that regulate populations, and which ultimately shape community structure and function. To facilitate this objective, it is necessary to elucidate the cues and mechanisms used by plants (the first trophic level) when interacting with above- and belowground herbivores and pathogens (the second trophic level), as well as parasitoids and antagonists of the herbivores and pathogens (the third and higher trophic levels). The experimental programme we are establishing will aim to address the following questions: (i) under what conditions do above-ground multitrophic interactions dominate over belowground multitrophic interactions or vice versa?, and (ii) are common or different cues of communication between trophic interactions present in different ecosystem compartments (above- vs. belowground)? Another set of questions concerns aspects of selection. Are there hotspots of selection in these linked multitrophic interactions, or can selection be equally active at any trophic level both above- and belowground? A common theme to be addressed in all questions is to determine if there are drivers and passengers in these linked multitrophic interactions. Finally, we want to assess consequences of linkages of multitrophic interactions for maintaining biodiversity and ecosystem functions in a changing world.

Index terms: biodiversity, indirect, parasitoid, pathogen, herbivore

[1119] DISTRIBUTION WITHIN PLANT, SURVIVORSHIP AND MORTALITY SOURCES OF IMMATURE STAGES OF A TROPICAL LEAFMINER

J. M. Oueiroz, Dept. de Zoologia, C.P. 6109, Universidade Estadual de Campinas, Campinas SP 13083-970, Brasil, E-mail: jqueiroz@obelix.unicamp.br.

The ecological studies with Pachyschelus coeruleipennis, that mine leaves of Croton floribundus (Euphorbiaceae), was conducted along trails in Serra do Japi Reserve, Brasil (23°16' S, 47°00'W). The larval stadia of the leafminer are three, and the development time on leaves takes = 1 mo. To determine the distribution pattern, sources of mortality and survivorship of immature stages, 120 shrubs were sampled in February 1999. All leaves were examined for eggs and larvae, and each leaf with immatures was labelled with tape. Position of leaves on plants and eggs on leaves was noted. I observed plants biweekly until June when all leaves containing eggs and mines were cut off and brought to the laboratory to examine the fate of eggs. The density of eggs was $25 \pm 2/100$ leaves and most leaves had only one egg (71% of cases). Most of eggs recently oviposited are found on the top leaves and there was a significantly preference by females to oviposite in the upper portion of plants ($\chi^2 = 41.45$, d.f. = 4, P<0.001). Density of active mines and pupal cells were, respectively, $6 \pm 1/100$ leaves and $1 \pm 0.3/100$ leaves. Natural enemies were the main factor that regulated leafminer populations. Predation, parasitism and fungal attack account for 35.8% of mortality causes and interactions with external feeding herbivores added 9.8%. Mortality rate increased with the age of larvae, thus survivorship curve for the leafminer was slightly convex. Parasitism rate increased much more than predation at the last larval instar and was greater in late-season than in early-season population. While the absolute number of larvae that was predated increased only 1.2 times between early and late season, parasitized larvae increased 11 times. There was an increase in the leafminer mortality due to interactions with external folivores in late season population. Hence leafminer survival to pupal stage was significantly greater in early season population ($\chi^2 = 5.79$, d.f.=1, P<0.02). These factors contributed to the different shapes of survivorship curves in early and late season of Pachyschelus populations. The data presented here suggest that parasitism of larvae is the main factor that explains the survivorship pattern of this tropical leafminer.

Index terms: Pachyschelus coeruleipennis, Buprestidae, natural enemies, Croton floribundus, Euphorbiaceae

[1120] RELATIONSHIP BETWEEN BEMISIA SPP. DENSITY AND DAMAGE IN DRY BEAN (PHASEOLUS VULGARIS)

E. D. Quintela, Embrapa Arroz e Feijão, Caixa Postal 179, Santo Antônio de Goiás, GO, Brazil, 75375-000. E-mail: guintela@enpaf.embrapa.br

Whiteflies (Bemisia tabaci and B. argentifolii) injury to dry beans can result in significant yield reduction due to the transmission of the Bean golden mosaic virus (BGMV). Bean growers had sprayed weekly for whiteflies control during the winter cropping (May-July), even when the adult population and plants infected with BGMV are low. This study was conducted to determine quantitative action thresholds for whitefly control to help growers to make reliable decision when to spray. The dry bean (cultivar Perola) was planted in May 20, 1999 at Santa Helena de Goiás, GO, Brazil. The experiment was laid out in randomized block design with four replications, in plots of 64.80 m² (6x10.8 m). Treatments consisted of: 1. control (no insecticide spray); 2. seed treatment; 3. control of adults and nymphs weekly; 4. seed treatment and control of adults and nymphs weekly; 5, 6 and 7, control when adult thresholds reached 30, 50 and 70% of the plants infested, respectively; 8, 9 and 10. seed treatment and control when adult thresholds reached 30, 50 and 70% of the plants infested, respectively. The plant was considered infested when it had one or more adult per plant. Iniidacloprid 700 PM (300g/100 kg of seeds) was used for seed treatment. Insecticides were used in rotation when adult thresholds were reached. They included imidaeloprid 200 SC (500 ml/ha), methamidophos 600 SNAQ (800 ml/ha), and betacyfluthrin 50 CE (200 ml/ha). Adults, nymphs and eggs were counted weekly by sampling ten trifoliate leaves per plot. Crop phenology and environmental conditions were documented. At maturity, beans were hand-harvested and treatment yields determined. *Bemisia* populations were very low at all treatments in the first two weeks and never reached the lowest adult threshold of 30% of infested plant. After the 3rd week. the adult population and the number of eggs increased gradually in all treatments. The highest number of adults and eggs were reached at the 5th week (72.5% of plants infested and a mean of 3.7 eggs/leaf) and was similar for all treatments. Adults and number of eggs declined after the 6th week when the plants were in the flowering stage. No significant difference between treatment was observed for adults, number of eggs and nymphs sampled weekly. Preliminary analyses suggested that migratory influx was a major factor compromising the efficacy of all treatments. Yield of dry bean was similar for all treatment. The control treatment (no spray) produced 3085.2 kg/ha compared with 3096.6 kg/ha in the treatment that received the highest number of sprays (seed treatment + weekly spray). These preliminary results suggest that at this level of whitefly infestation, when the virus inoculum is low, there is no need of weekly insecticide treatment and some level of whitefly population can be tolerate.

Index terms: Aleyrodidae, action threshold, Bemisia tabaci, B. argentifolii.

[1121] BIOLOGY OF BEMISIA ARGENTIFOLII ON DRY BEAN (PHASEOLUS VULGARIS)

<u>E. D. Quintela¹</u>, E. S. Barbosa² & W. C. J. Silva³, ¹ Embrapa Arroz e Feijão, Caixa Postal 179, Santo Antônio de Goiás, GO, Brazil, 75375-000. E-mail: quintela@enpaf.embrapa.br. Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) internship ² Embrapa Arroz e Feijão, CNPq internship. ³ Embrapa Arroz e Feijão.

The silverleaf whitefly, Bemisia argentifolii, introduced in Brazil in 1991, has become the major pest of dry bean. It has replaced the sweetpotato whitefly, *Bemisia tabaci*, in several locations in Brazil. Various aspects of the insect biology, have been reported on tomato and cabbage. However, little information is available regarding the biology of this species on beans. Studies were conducted to determine some basic biological information of B. argentifolii reared on beans in greenhouse. One hundred plastic pots with three bean seedlings each (Cultivar Perola), 13 days old, were held in greenhouse with adults of whiteflies for 24 h, after which the adults were removed. The plants were then transferred to a small room in another greenhouse at fluctuating temperatures and relative air humidities between minimal and maximal means of 17.8 °C to 27.7 °C and 61.2% to 94.6%, respectively. Four bean leaves were examined daily for measurements of egg, nymph and empty pupal skins size (length and width) of 30 individuals. The time of egg hatch and adult emergence were also examined daily. An ocular micrometer attached to a dissecting microscope was used for the measurements at 50× magnification. The egg began to hatch 7 days after oviposition, but the highest hatching occurred after 8 days. A frequency distribution of nymph length and width and some exuviae identification for 1544 nymphs showed a range of 0.22 to 0.92 mm and 0.10 to 0.78 mm, respectively, and revealed 4 distinct modal peaks. The mean nymph length was 0.28 ± 0.02 , 0.36 ± 0.02 , 0.52 ± 0.05 , 0.78 ± 0.07 mm for the 1st - 4th stadia, respectively. The mean nymph width was 0.17 ± 0.02 , 0.23 ± 0.02 , 0.35 ± 0.05 , 0.54 ± 0.07 mm for the 1st -4th stadia, respectively. The mean growth ratio of nymph length and width was 1.41 and 1.47 for 1st 4th instar, respectively, and fitted the Dyar's rule for Lepidoptera. Nymph length and width increased steadily for 22 days and remained constant thereafter. The relationship between mean nymph length and time was best described by the exponential model $(r^2=0.87, n=1544)$. Similar results was observed for the relationship between mean nymph width and time. Adults of B. argentifolii began to emerge 15 days after egg hatch. After 24 days from egg hatching, most adults had emerged (91.2%). The measurements of empty nymph skins, showed nymph length and width ranging from 0.64 - 0.94 and 0.40 -0.66 mm, respectively. However, most of the adults emerged when the nymph length was $0.70-0.74\ mm$ and nymph width was $0.46-0.50\ mm.$

[1122] SURVEYS ON *BEMISIA ARGENTIFOLII* WITH STICK TRAPS IN COTTON CULTIVATIONS IN MIGUELÓPOLIS - S.P. - BRAZIL

Z. A. Ramiro¹, A. Raga¹, K. C. A. Send², C. Tamaguti² & F. A. Colmanetti², ¹Centro Experimental do Instituto Biológico, C.P. 70, 13001-970, Campinas, SP, BRAZIL. E-mail zamiro@uol.com.br;

The first reports on the occurrence of white-fly in Brazil date from 1923. Nevertheless, the register of B. tabaci species occurring in levels of economic damages was made from 1968 on, in soybean, cotton and bean cultivations. Since then, this species has been seen in various regions all over the country in different cultivations, being the responsible for direct damages, by the adults as well as the nimphs - due to their eating habits: they suck all the sap from the plants – and indirect damages owing to the production of sooty mold that does harm to the photosynthesis. They are also vectors of virotic diseases such as mosaic on cottons. In 1992, a huge raise on this plague population in olericultures and in ornamental plants, in the state of São Paulo, proved that a new white-fly biotype, B. argentifolii, had been brought to Brazil. This biotype, of almost cosmopolite distribution, is considered the most important plague from this end of century. It is featured by easily adapting itself to new hosts and to different climate conditions as well as by presenting, in a short amount of time, populations which are resistant to the insecticides traditionally used on the B. tabaci control. In the crop dated from 1997/98, in Miguelópolis region, it occurred a B. argentfolii outbreak in soybean and cotton cultures, which resulted on total losses in some areas and a huge raise on insecticides applications. In the next crop, 1998/99, surveys on B. argentifolii adults were done from December/98 till February/99 in an area planted with cotton - "Coodetec". Aiming for the accompaniment of the incidence of this species over this area, stick traps were used. Twenty-five traps were weekly set around the culture and, twenty-four hours later, they were taken out in order to have the number of captured adults/trap counted. The greatest capture of adults collected into traps (an average of 9.3 adults/trap) happened in the last week of December. From the first week of January till the second week of February, collects that varied from 37 to 291 adults/trap/day were registered. It was verified that the greatest number of adults collected in the traps occurred in the two first weeks of each of those months. In situations of high populations of this plague, there are no possibilities of control. By the obtained results, in the areas of B. argentifolii occurrence, the agriculturist must monitor his cultures since the very beginning of germination and respect the necessary control measures before this insect population increases.

Bemisia argentifolii, cotton, floating

Symposium and Poster Session

[1123] IMPACT OF AREA ON THE BEHAVIORAL INTERACTIONS OF SOLENOPSIS INVICTA AND MONOMORIUM MINIMUM COLONIES

<u>A. Rao</u>¹ & S. B. Vinson¹, ¹Dept. of Entomology, Texas A&M University, College, Station, TX 77843-2475, USA, E-mail asha@tamu.edu & bvinson@acs.tamu.edu.

We have developed methods to assess the impact of native ant species on fire ant, *Solenopsis invicta*, colonies in the laboratory and greenhouse. When established native ant colonies, such as *Monomorium minimum*, were given access to small fire ant colonies in the laboratory, the fire ant colonies with up to and including 250-300 workers were destroyed. However, these fire ant colonies had no opportunity to move or escape. Therefore, we conducted similar studies in greenhouse arenas that more closely simulated field conditions, allowing fire ants to move or escape. Our hypothesis is that the farther a fire ant colony can move away from a competitor, the longer it may take for it to be discovered, and for competitive interactions to occur. Our study included areas ranging from 1.78×0.66 m to 0.19×0.18 m. *M. minimum* was observed to take over the fire ant colony even in the largest studied area in two months. Fire ant colonies were observed to move its nests several times, however, was eventually killed. These initial experiments have showed that *M. minimum* can negatively impact *S. invicta* colonies. The impact of these areas on the interactions, and the relationship between the area and the rate at which the fire ant colonies are eliminated are discussed.

Index terms: Solenopsis invicta, Monomorium minimum, behavior, competition, fire ant, native ant.

[1124] TEMPORAL AND SPATIAL DISTRIBUTION OF DIVING BEETLES IN A HIGHLY SEASONAL ENVIRONMENT (COMOÉ NATIONAL PARK, IVORY COAST)

N. Reinties & K. E. Linsenmair, Dept. of Animal Ecology and Tropical Biology, Theodor-Boveri-Institute of Biosciences, Am Hubland, D-97074 Würzburg, Germany. Email: reintjes@biozentrum.uni-wuerzburg.de

Seasonality combined with a high degree of unpredictability challenges the biota in the respective system. The analysis of Diving Beetle communities (Coleoptera, Dytiscidae) in temporary and permanent waters of the Guinea Savanna aims at contributing to our understanding on the evolution of spatial and temporal niche differentiation. From January to May 1999 beetles were collected in Comoé National Park, northern Ivory Coast. Owing to the highly seasonal climate the majority of the waters desiccates during the dry season from November to March. The study focused on two lotic systems, a river and a creek, and two lentic temporary ponds. In the course of the study period the creek and the ponds fell entirely dry for several weeks. The water body of the river shrank to isolated pools. Heavy rains at the end of March refilled the water system. Sampling of additional waters and light-trapping yielded supplementary data. Only results on the adults of the subfamily Dytiscinae are reported on here. Up to date adults of 12 species in 4 genera were found. Rhanthaticus congestus was the most common species, followed by Hydaticus matruelis and Hydaticus dorsiger. Species composition differed between the lotic and lentic sites. The lentic sites were dominated by species of the genus Cybister, while species of Hydaticus mostly inhabited the lotic systems. Adults were found throughout the study period. Especially adults of the three species mentioned above were recorded during all but 5 or 6 weeks, respectively. Five species were collected with light-traps. The results are discussed in the light of life history adaptations to the highly dynamic environment and the temporary limited availability of water.

Index terms: Dytiscidae, Dytiscinae, temporary waters, life history, Ivory Coast, West Africa

[1125] REPRODUCTION OF *DIURAPHIS NOXIA* (HOMOPTERA: APHIDIDAE) ON DIFFERENT WINTER CEREALS

M.E. Reviriego¹, L.R. Descamps¹ & <u>A.A. Suarez</u>², ¹Univ. Nac. Del Sur, San Andrés S/N, (8000) Bahía Blanca, Argentina, e-mail Errol Indicador não definido. ²E.E.A.INTA Anguil, Ruta Nac. N°5 Km 580, C.C. 11, (6326) Anguil, La Pampa, Argentina, e-mail asuarez@anguil.inta.gov.ar.

Russian wheat aphid (RWA) is an important pest of winter cereals in Argentina. The objective of this experiment was to determine the intrinsic rate of increase of RWA on wheat, barley, rye, oats and tritordio (*Triticum x Hordeum*). Under controlled conditions, $21\pm1^{\circ}$ C temperature and 14:10 (L:D) photoperiod, plant pots were arranged in a randomized complete block design with seven replications. Newly born nymphs were place on the youngest leaf of each 20 d old plant and covered with a plastic clip-on cage. The intrinsic rate of increase (rm) for each observation was estimated using the formula developed by Wyatt and White. The data obtained were analized using PROC GLM and means were compared using Means / LSD (p=0.05) (SAS Institute, 1988). Significant differences on rm were found among winter cereals. However, no significant differences were found on RWA pre-reproductive period. Rm was higher on wheat, barley and tritordio. RWA feeding on rye and oats showed lower rm.

Index terms: Russian wheat aphid, intrinsic rate of increase, winter cereals.

[1127] TRICHOMYCETES FUNGI (ZYGOMYCOTINA) ASSOCIATED WITH THE DIGESTIVE TRACTS OF BLACK FLY LARVAE (DIPTERA: SIMULIDAE) IN CENTRAL AMAZONIA, BRAZIL

C.M. Ríos-Velásquez¹ & <u>N. Hamada</u>², Instituto Nacional de Pesquisas da Amazônia (INPA), Caixa Postal 478, 69011-970, Manaus, AM, Brazil. ^{1,2}DCEN, ²CPEN, E-mail: nhamada@inpa.gov.br.

The Trichomycetes are filamentous fungi that grow in the digestive tract of arthropod larvae or nymphs, attached at the peritrophic matrix or on the chitinous walls of the hind gut. Many species in the order Harpellales have been found in black fly larvae. The relationship with the host can vary from comensal to parasitic, depending on the environment and on developmental factors. Host specificity can be at the specific, generic or family level. In Brazil, there is no record of a relationship of these fungi with black flies. The objetive of this study was to identify the Tricomycetes (Zygomycotina) fungi associated with the digestive tracts of Simulium goeldii and Simulium "6-B1" larvae, determining if there is any preference of the fungi for host species. Simulium goeldii and 3. "6-B1" larvae were collected in streams in Presidente Figueiredo and Manaus counties, Amazonas state, Brazil. Black fly larvae were dissected individually in distilled water and its digestive tract was mounted between slide and coverslip in distilled water, a light pressure was applied on the top of coverslip to squash the fungi. Measurements of talli and spores were made under a compound microscope for identification of the fungi, after this procedure, a drop of blue lactofenol was placed on the edge of the coverslip. After complete substitution of the water by lactofenol, the coverslip was scaled with finger nail polish. Infection rate was calculated, based on the total number of examined larvae and number of larvae with fungi. We dissected 68 larvae of S. goeldii, 54 of S. "6-B1" and 79 immature (instars prior to the last larval instar). Of the total latvae dissected, 85.1% were infected with Harpellales, within this order, one genus was associated with the peritrophic intered with Harpennes, within the solution of the solution with the hind gut: Genistellospora, matrix: Harpella; and three genera were associated with the hind gut: Genistellospora, Pennella and Smittium. Harpella, Genistellospora and Smittium were found in both black. fly species; the genus Peunella was only observed in S. goeldii larvae. More studies on biological aspects and ecology of the Trichomycetes and their hosts are needed to understand the relationships among them, the specificity of Trichomycetes and black fly species and the factors that determine this specificity.

Index terms: aquatic insects, comensalism, Harpellales, infection rates, Simulium

[1126] THE POLLINATORS OF CHICKLING VETCH (LATHYRUS SATIVUS, LEGUMINOSAE) IN CENTRAL ITALY

<u>G. Ricciardelli D'Albore & N. Palmieri,</u> Dept of Arboriculture and Plant Protection, Univ. of Perugia, Borgo XX Giugno, 06121 Perugia, Italy, E-mail ENTOMOL@UNIPG.IT

In two years (1998 - 1999) some researches have been carried out on the pollinators of Chickling vetch (*Lathyrus sativus* L), grass crop still cultivated enough in Central Italy, whereas on the pollinators of this species references are lacking. In an Umbrian tableland (Colforito 800 m. a.s.l.), on two chickling vetch fields of one hectare each, during the flowering bees have been observed and counted; a lot of those wild ones, have been catched and determined. In the same time fifty plants have been disposed for a free pollination and as many have been caged. The pollinators observed were: 90.94 % honeybees, 8.30 % some species of bumblebees and 0.76 % other solitary bees (*Anthidium, Ceratina, Chalicodoma, Halictus, Lasioglossum, Osnia* and *Megachile*). The free plants produced more seed than the caged (increase 436,60 %); therefore the chickling vetch is partially selfincompatible and not self-pollinating; consequently the enthomophilous pollination, besides conserving or increasing the genotype variability, is necessary for an excellent seed production.

[1128] THE BLACK LIGHT TRAP FOR MONITORING OF CODLING MOTH CYDIA POMONELLA (LEPIDOPTERA: TORTRICIDAE) IN POME FRUIT ORCHARD UNDER MATING DISRUPTION

O.G. Rivkina, S. B. Sexton¹ & <u>A. L. Il'ichev</u>², Corboy Fresh Fruit Pty. Ltd. P.O. Box 160, Merrigum, Victoria, 3618, Australia. ¹Biocontrol Ltd. 3Acacia Crt., Mt. Crosby, Qld, 4306, Australia. ²Inst. of Sustainable Irrigated Agriculture, P.O. Box1, Tatura, Victoria 3616, Australia.

The Pome Fruit orchard of 20 hectares (ha) located in Kyabram area of Goulburn Valley, Victoria had a history of high level of Codling Moth (CM) Cydia pomonella infestation. The orchard was under conventional spray program since established in the early 1920's. The population of CM increased dramatically during the last decade as a result of management decisions. In September of 1998 the orchard management was taken over by Corboy Fresh Fruit Pty. Ltd. The chemical spray program was tailored to target CM in particular with the use of methyl-parathion based spray insecticides. During the first year of management CM population was monitored by Delta Traps (DT) (AgriSense-BCS Ltd. USA) with 1mg of CM sex pheromone lure. The level of CM population at the end of 1998-99 season was very high and well in excess of 200 moths per trap accumulated over the season. In October of 1999 the orchard was treated with "Isomate C" (Biocontrol Ltd., Australia) for mating disruption (MD) at the rate of 500 dispensers per ha to reduce the CM population. The spray program remained unchanged as in the previous season. CM population was monitored by 3 DT with 10 mg CM sex pheromone lure and 3 Black Light Traps (BLT), supplied by Biocontrol Ltd. BLT consisted of a 4 watt blue violet fluorescent tube mounted in a flat aluminium baffle above a funnel trap. The automatic controllers contained a light sensor and a microprocessor programmed to switch on at sunset and turn off two hours later. DT was placed apart from BLT at the distances of 2, 10 and 20 meters in the William Bon Cretien (Bartlett) pear blocks to estimate possible interaction between the two trap types. No interactions were observed during monitoring period regardless the distance. During the 1999-2000 season BLT monitoring showed dynamic changes in CM population with two flight peaks of 70 and 20 moth per trap per week, while DT weekly catch was 1-3 moth per trap over the season without any flight peak indication. At the end of the season the level of CM population had dropped dramatically but BLT was sensitive enough to show a presence of CM in the orchard with the weekly average catch of 3 moth per trap. DT catch was zero at that time. The results show that BLT is a sensitive and reliable source of monitoring for CM population under MD in Goulburn Valley conditions compare to DT with 10 mg lure and will be discussed.

Index terms: Black Light Trap, Codling Moth, mating disruption.

[1129] FITTING POPULATION DYNAMICS MODELS TO SPATIAL INSECT DATA: SCALING DISPERSAL TO LANDSCAPE STRUCTURE AT MULTIPLE SPATIAL SCALES

J. Roland, Department of Biological Sciences, University of Alberta, Edmonton, Alberta, Canada, T6G 2E9, and S. Lele, Department of Mathematical Sciences, University of Alberta, Edmonton, Alberta, Canada, T6G 2E9.

We use estimating functions to fit density-dependent population models which incorporate parameters for dispersal among sites. We fit these models to spatial data from 130 populations of forest tent caterpillar collected over 8 years near Edmonton, Alberta, Canada. In fitting these models, we are able to scale parameters for density-dependence and dispersal by covariates such as landscape structure around each site where population data were collected. In doing so, we are able to assess the effect of landscape on the dynamics of tent caterpillar, and by having estimated landscape variables at multiple spatial scales, we are able to determine at which scale landscape has the strongest effect. Landscape effects on the dispersal parameter implicate moth dispersal as being affected by landscape structure.

Index terms: population dynamics, density-dependence, dispersal, parameter, landscape.

[1131] POPULATION FLUCTUATION OF ANASTREPHA SPP (DIPTERA: TEPHRITIDAE) IN AMAZONAS STATE, BRAZIL

<u>B. Ronchi-Teles</u>¹ & N. M. Silva², ¹ Dept. of Entomology - Instituto Nacional de Pesquisas da Amazônia - INPA, P.O. Box 478, ZIP 69011-970, Manaus-AM, Brazil.² FCA - Universidade do Amazonas - Faculdade de Ciências Agrárias, Campus Universitário, ZIP 69077-000, Manaus-AM, Brazil

The genus Anastrepha is endemic to the American continents. It is widely distributed in tropical and subtropical regions from southern USA to northern Argentina. The North region of Brazil consists of seven states totaling 3.867,886 km², or about 50% of Brazil and is largely covered by rain forest. Approximately 180 species of native and exotic fruit trees are known in this region. In spite of the high diversity and great quantity of fruit trees in this region, records of fruit flies are from occasional collecting. About 60% of the species of Anastrepha recorded from this region have no known hosts, and eight species (20%) are known only from the holotype. Thirty-two species of Anastrepha have been recorded from five states in Amazonia. However there is no records of Anastrepha species in two North region states (Acre and Tocantins). Between 1996 and 1998, adults of several Anastrepha species were collected in two orchards on the BR 174 (Km 20 and 40) north of Manaus. These adults were obtained by using MacPhail traps. Of the total number of fruit flies collected (4,742 specimens) 53.3% were females and 46.7% males. Thirteen species were collected: A. distincta, A. obliqua, A. striata, A. leptozona, A. serpentina, A. furcata, A. coronilli, A. bahiensis, A. atrigona, A. flavipennis, A. antunesi, Anastrepha sp 1 and Anastrepha sp 2. The most abundant species observed in this study, representing 87.9% of the all fruit flies collect in MacPhail traps were A. obliqua (35.5%) A. leptozona (26.5%) and A. distincta (25.9%). The number of flies/trap/day (FTD) peaked between December and March (rainy season) witch is the period of the maturation of fruits, and was highest in February. The voucher specimens are deposited at INPA (Instituto Nacional de Pesquisas da Amazônia) - Manaus, Amazonas, Brazil. This is the first fruit fly population fluctuation study in the Amazon region.

Index terms: Ecology, fruit flics, taxonomy, MacPhail traps

[1130] POPULATION ECOLOGY OF CORECORIS DENTIVENTRIS (ILEMIPTERA: COREIDAE) IN AN EXPERIMENTAL PLOT OF NICOTIANA TABACUM (SOLANACEAE): SPATIAL DISTRIBUTION AND DISPERSAL

H. P. Romanowski¹ & C. R. Canto-Silva¹, ¹Depart. de Zoologia, Inst. de Biociências, Univ. Federal do Rio Grande do Sul, Av. Paulo Gama, s/n, Porto Alegre, RS, Brasil, Cep. 90046-900. E-mail: hpromano@vortex.ufrgs.br.

The spatial distribution of organisms within populations is of crucial importance for their ecology. Processes that may govern the population dynamics of insects, such as predation and parasitization, are directly or indirectly influenced by their spatial distribution. Also, for efficient monitoring and management of pest species, knowledge on the patterns of distribution and dispersal within and between plants are fundamental. These patterns were studied for all developmental stages of Corecoris dentiventris (Hemiptera; Coreidae) in an experimental plot of Nicotiana tabacum (Solanaceae), at Porto Alegre (30° 05'S and 51° 13'W), RS, Brazil. Twenty plants were sampled in 31 sampling occasions, from November 1996 to March 1997. In each occasion, the number of individuals in each stadium and their position in the plants were registered. Adults were marked to allow subsequent recognition. Adjustment of the data to the Poisson, Positive and Negative Binomial models was tested; indexes of dispersal were estimated. The spatial distribution pattern was aggregated for the immature stages and random for the adults. Values obtained For the "Taylor power law" index revealed a gradient of increase in aggregation from eggs (b=1.987), young (b=2.312) and old nymphs (b=3.307). Within-plant dispersal is started by young nymphs and culminates with aggragation at the upper third of the plant. Adults disperse between plants: at least an average of 1.4 ± 0.05 movement per individual and a mean distance covered of 8.8 ± 0.57 meters was recorded. Dispersal was most intense soon after the teneral period and there were not registers for flyght during the daylight. Index terms: Tobacco, within-plant distribution, between-plants distribution, population dynamics

[1132] ASSOCIATION BETWEEN ANASTREPHA SPP (DIPTERA: TEPHRITIDAE) AND THEIR PARASITOIDS IN TWO SPECIES OF FRUIT IN AMAZONAS STATE, BRAZIL

N. M. da Silva ¹ & B. Ronchi-Teles ², ¹ Universidade do Amazonas – Faculdade de Ciências Agrárias, Campus Universitário, CEP 69077-000, Manaus-AM, Brazil. ² Dept. of Entomology – Instituto Nacional de Pesquisas da Amazônia – INPA, P.O. Box 478, CEP 69011-970, Manaus-AM, Brazil.

This study deals with the occurrence of intraspecific competition between fruit fly species and their parasitoids in two species of fruit tree (Pouteria caimito and Spondias mombin) collected at two sites in Amazonas state; the highway BR 174 (Km 08) and the University of Amazonas both in Manaus. Observation were made between November and January (harvest time) in 1997-1998 and 1998-1999. These fruits were heavily infested by fruit flies. P. caimito by Anastrepha leptozona and A. serpentina, S. mombin by A. obliqua and A. antunesi. A total of 4,627 fruit fly pupae were obtained, from which emerged 3,377 adults and 375 parasitoids. The fruits were placed in individual containers to obtain the fruit flies and parasitoid adults. Intraspecific competition was detected between polyphagous species (A. leptozona and A. obliqua) and monophagous (A. serpentina and A. antunesi) in both species of fruit tree No association between the parasitoids and their hosts (fruit fly) could be established because the emergence of two species from the same fruit and the size of pupae obtained from fruits were similar. The fruit fly species collected from S. mombin were parasitized by Opius bellus, Opius near bellus and Asobara anastrephae. Doryctobracon areolatus was found parasiting only Anastrepha species that infested P. caimito fruits.

Index terms: Ecology, intraspecific competition, fruit flies..

[1133] MIGRATIONS OF LOCUSTS OUT OF THEIR NORMAL RANGE

L.J. Rosenberg & P.J.A. Burt. Environmental Sciences Dept., Natural Resources Inst. Univ. of Greenwich, Chatham Maritime, Chatham, Kent, UK ME4 4TB, E-mail peter.burt@gre.ac.uk

Desert Locusts (Schistocerca gregaria) are major pests of agriculture in Africa, the Middle East and South-West Asia. Swarms are known to make downwind flights over hundreds and thousands of kilometres between seasonal breeding areas. At the end of the summer of 1988, swarms of locusts moved north and south along the western margin of North Africa, and in October and November they crossed the Atlantic Ocean, reaching the Caribbean and neighbouring parts of South America for the first recorded time. This longdistance migration was investigated through the construction of over 100 trajectories, at heights of 950 and 850 hPa and an associated examination of the weather conditions at the time of the migration. Results suggest that the locusts are most likely to have travelled on easterly waves, although the duration of the trajectories suggests that the locusts' flight time was significant longer than previously estimated for other long-distance migrations. Potential source areas in Mauritania, Senegal, Gambia and Guinea-Bissau have been identified. During the same period as the trans-Atlantic migration, groups of locusts also reached Europe, as did dust clouds from the Sahara. This migration will be discussed in relation to more common Desert Locust migrations and possible unique weather conditions over the Atlantic Ocean. Implications for pest control are also discussed. Index terms: Schistocerca gregaria, Desert Locust, migration, Atlantic Ocean

[1135] USE OF NATURAL EXTRACTS OF BASIL, DILL AND FENNEL LIKE ALTERNATIVE MEASURE OF CONTROL OF *MACROSIPHOM EUPHORBIAE* (HEMIPTERA: APHIDIDAE)

<u>S. Russo¹</u>, S. M. Rodríguez¹, M. H. Michetti¹, S. Delfino² & A. E. Pelicano¹, ¹Cátedra de Zoología Agrícola, ² Cátedra de Estadística. Fac. de Agronomía, Univ. of Bs. As. Av. San Martín 4453 (1417). Bs. As. Argentina, E-mail Errot Indicador não definido..uba.ar

Vegetables extracts were prepared from stems, leaves and flowers of basil (Ocinum basilicum), dill (Anethemun graveolens) and fennel (Foeniculum vulgare). The solvent was benzene to 1% and 2%. Filter papers humidified with different solutions, and over them were put leaves of lettuce with 10 aphilds each one. A randomized complete design DCA were used and the sampling unit was the Petri dish. Six treatments with four repetition were evaluated: T1 to T4: control with solvent applications; E1 to E4: dill essence at 1%; A1 to A4: basil essence at 1%; H1 to H4: fennel essence at 1%; AH to AH4: basil essence at 1%; H1 to AE4: basil essence and dill at 1%; these series were repeated at 2%. The effect "knock- down" and the percentage of dead aphilds to the 30 minutes, 6, 24 and 48 hours were verified. The analysis of the data was made througt an ANVA corresponding to the DCA and Tukey comparation applying a significance level of 5%. Not significant differences was registred at low concentrations. There were differences at highest ones. The mixture of: a) basil and dill, b) basil and fennel showed sinergic effect, "know-down", lettuce.

[1134] DIPTERA OF THE PÁLAVA BIOSPHERE RESERVE OF UNESCO (CZECH REPUBLIC)

<u>R. Rozkošný</u> & J. Vaňhara, Dept. Zoology and Ecology, Faculty of Science, Masaryk Univ., Kotlářská 2, 611 37 Brno, Czech Republic. E-mail: rozk@sci.muni.cz & vanhara@ sci.muni.cz

In coordination with the interested institutions and 36 specialists, a project of commented prodromus has been prepared, comprising all literary records and recent data obtained from investigations on Diptera inhabiting the Pálava Biosphere Reserve of UNESCO in its proposed extended concept. Each family included is briefly characterized and documented by a complete list of species found in the study area, with references to published data and collection materials. The lists of references present complete bibliography of the group from the Pálava B.R. The concluding part summarizes information on the present state of knowledge, taxa described from the Pálava B.R., monitoring and biomonitoring, and conservation. Although the research of Diptera in the area under review is by far not complete, 2,862 species have been ascertained. This number represents more that 46 % of the relevant fauna of Diptera occurring in the Czech Republic (6,211 spp.). From the species described at least partly on the basis of type material originating from the study arca (37 spp.), 31 taxa are still valid. Some 209 species are known to occur exclusively in the Pálava B.R. within the framework of the Czech Republic. Analysis of some long-term observations has proved the extinction of 5 species in the area. A comparatively high number of species (149 spp.) is, regarding the authors' experience and specific natural conditions in southern Moravia, included in the categories of species conservation and treated as critically endangered (23 spp.), endangered (57 spp.) and vulnerable (69 spp.). The survey is a rich source of information that can be used for completing the natural characteristics of the study area, for launching programmes monitoring the dipteran families included, for objective assessing the risks connected with the human activities in this area and, at the same time, for improving the protection of its valuable ecosystems and rare species.

Index terms: Nematocera, Brachycera, Central Europe, monitoring, conservation

[1136] RESPONSE OF XYLOPHAGOUS BEETLES AND THEIR NATURAL ENEMIES TO INCREASED RESOURCE AVAILABILITY FOLLOWING A SEVERE ENVIRONMENTAL DISTURBANCE

<u>K.L. Rvall</u> & S.M. Smith, Faculty of Forestry, University of Toronto, Toronto, Ontario, M5S 3B3, Canada. Email: krista.ryall@utoronto.ca.

Historically, in eastern Canada, bark beetles have not posed significant problems in the forest landscape and, hence, there is little data available on their population dynamics specific to this region. However, a recent severe environmental disturbance (specifically the ice storm of January 1998) provided a massive input of available resources for these beetles by causing extensive damage to numerous red pine (*Pinus resinosa*) plantations. This has raised concerns over the possibility of future pest outbreaks which could lead to further tree mortality because of increased beetle populations and severe levels of stress in the residual trees at both the stand and regional level. Recent literature on xylophagous beetles and their natural enemies has suggested the importance of scale in detecting pine engraver beetle (*Ips pini*) have increased rapidly at the stand level in response to the large volume of brood material. However, on a smaller scale (i.e. at the level of the log sample), reproductive output and success of individual parental beetles has been negatively influenced by increasing population size at both the log- and stand-level.

The natural enemy complex associated with *I. pini*, particularly the predator *Thanasimus dubius*, has responded positively to higher beetle populations at the stand-level in an apparent delayed density-dependent manner. This type of top-down control has been shown to help control outbreaks of more aggressive bark beetle species and, thus, may help suppress these pine engraver populations. On a smaller scale (the log sample), enemy-caused mortality displays an inversely density-dependent relationship with host density. This research will be discussed in relation to the outbreak cycle and will provide valuable information on the importance of scale, particularly the larger stand- or landscape-level, in the responses of pest populations and their natural enemies to increased

Index terms: Ips, Thanasimus, predation, outbreaks, scale

[1137] IDENTIFICATION OF THE SPATIAL DISTRIBUTION PATTERNS OF INSECT SPECIES BELONGING TO THE HOMNOPETRA-STERNORILYNCA COMPELX IN CITRUS PLANTS (*CITRUS* SPP.) IN THE STATE OF RIO DE JANEIRO THROUGH THE USE OF VARIOUS STATISTICAL AND MATHEMATICAL MODELS

S.S.P. de Souza¹, R. Silva-Filho^{1,2}, W.C. Rodrigues^{1,2}, & O.R.F. Azevedo^{1,2}, Dept. de Entomologia e Fitopatologia, IB, Univ. Federal Rural do Rio de Janeiro, BR 465 Km 07, Seropédica, RJ, CEP 23.890-000, Brasil, ¹E-mail: sousols@ufrrj.br, ²cimp@ufrrj.br.

The spatial distribution of insects has been regarded as one the most important ecological parameters when field experiments and/or observations are conducted, because such can exert an influence upon the dynamics of a species' population, making possible the occurrence of changes in the impact on the part of various mortality agents (either biotical or abiotical) by virtue of the spatial variations in the degree of the individuals' vicinity within each population, thus determining their territory. An interesting and commonly observed feature in various natural or non-natural ecosystems is the high number of unoccupied habitat units, and others densely inhabited, which generates different spatial distributions resulting from births and deaths of individuals. Considering that the prior knowledge of a species spatial distribution constitutes a key factor for a pest monitoring system for the utilization of the MIP which can secure information on changes in tactics and/or strategies for control, optimization of sampling techniques, determination of economical injuries and the incorporation of the spatial dynamics of population models which provide the information on which factors would determine numerical oscillations and even their persistence both in natural and non-natural environments; also, the existence of various statistical models compatible with the biological and/or ecological processes of the species concerned, which would interpret such biological patterns of spatial distribution of insects in their populations, the complexity of their utilization of Homoptera-Sternorhyncha species, mostly those belonging to the, Ortheziidae, Diaspididae, and Coccidae families, prompted the elaboration of this piece of research owing to the existence fo sample data obtained in the period between 1993 and 1999, and also to the lack of such studies on this group of Insecta.

Index terms: Homoptera-Sternorhyncha, spatial distribution, Pinnaspidus aspidistrae, Selenaspidus articulatus, Coccus viridis, Orthezia praelonga. [1139] A SURVEY OF THE ENTOMO-WILDLIFE ASSOCIATED THE GUAVA ORCHARDS (*PSIDIUM GUAYAVA*) CULTUVAR OGAWA 2, WITH THE UTILIZATION OF LURING TRAP MODEL C-47 AND THE (BINOMIAL) 'PRESENCE-ABSENCE' SAMPLING METHOD, IN THE STATE OF RIO DE JANEIRO, BRAZIL

<u>S.S.P. de Souza¹</u>, W.C. Rodrigues^{1,2}, J.B. da Silva^{1,2}, R. Silva-Filho^{1,2} & A.F. Monteiro Junior¹, ¹Dept. de Entomologia e Fitopatologia, IB, Univ. Federal Rural do Rio de Janeiro, BR 465 Km 07, Seropédica, RJ, CEP 23.890-000, Brasil, ¹E-mail: sousols@ufrrj.br, ²cimp@ufrrj.br.

With climate conditions favorable to its expansion not only in north and northwest of the state of Rio de Janeiro, the guava tree culture has shown a great productive potential also in the other regions where it is grown. Usually this happens in small properties and, although there is not any agricultural policy for its commercial exploration, this culture has yielded significant economical returns mostly owing to the excellence of a few cultivars which yield high quality fruits for in natura consumptiom. Even with its potential to generate revenues, this culture has not devoted studies with regard to the bioecological aspects of its entomo-wildlife. As to the insects cited as harmful to the guava tree, only the fruit-fly, trips, borer, and bugs are regarded as harmful, although there are other insects harmful to the culture. The lack of bioecological knowledge of this agroecosystem encouraged the start of this piece of research in the state of Rio de Janeiro, as a way to observe what is actually occurring in terms of insects associated to guava tree in some regions of the state. The work began in July 1999 at the municipality of Japerí, Baixada Fluminense/Rio de Janeiro, in a property with seven culture-lots, with 120 producing trees per to lot, and ages ranging between 6 and 9 years, and a total of 850 trees. Trap Model Carvalho 47 is being tested in this orchard, a trap devised for the capture of species of the families Bostrychidae and Platypodidae, using forest essences. The trap was modified for best suitableness to this study. The traps were distributed in blocks with different colors and luring substances. Each block was made up of two colors and five different lures. The colors being testes are yellow and blue, whereas the luring substances are alcohol, sugarcane whisky, molasses, guava leaf extract and water on witnessing, amounting to 10 traps for each two lots. For the observation of the population dynamics the same methods adpted by Souza (1999) are being utilized. Results of first collections have shown a great possibility of using this technique in population survey of insects occurring in this culture. Index terms: guava tree pests; MIP; alternative sampling method; monitoring; alternative trap.

[1138] MONITORING AND POPULATION DYNAMICS OF THE ENTOMO-WILDLIFE ASSOCIATED TO THE CULTIVATION OF COCONUT PALM (COCOS NUCIFERA) BY MEANS OF TRAPS MODEL C-47: L – MUNICIPALITY OF ITAGUAÍ, STATE OF RIO DE JANEIRO, BRAZIL

S.S.P. de Souza¹, J.B. da Silva^{1,2}, R. Silva-Filho^{1,2}, O.R.F. Azevedo^{1,2} & P.R.R. Silva¹, ¹Dept. de Entomologia e Fitopatologia, IB, Univ. Federal Rural do Rio de Janeiro, BR 465 Km 07, Seropédica, RJ, CEP 23.890-000, Brasil, ¹E-mail: sousols@ufrrj.br, ²cimp@ufrrj.br.

The growing importance of coconut tree cultivation in the state of Rio de Janeiro has awakened the interest on the part of the growers in the planting of orchards with this palm tree owing to the incentives recently offered by the state government in order to expand it to those regions adequate to the growing of the coconut palm. This was motivated by the increase in the consumption of coconut water in natura on the part of the population, thus generating revenues to the state. The need for a better knowledge of the bioecological aspects associated to those relating to the phenology of this culture as well as to the cultural dealings in the management of such orchards have prompted this piece of research in the expectation that a monitoring methodology might be attained on this entomowildlife through the experiments with effective sampling methods and/or techniques, and with ease of utilization, accessible to grower, and that might make possible the decrease of anti-pest chemicals so widely employed. This, of course, would also decrease the harmful impact on the environment, caused by such products in these agroecosystems. This piece of research started in April 1999 at the municipality of Itaguaí, Rio de Janeiro, still regarded as the highest productivity region. The studies are being carried out in a private property with 5-year-old 800 coconut trees; the production is only starting, and this experimentation will be extended to other producing counties in the State. Trap model Carvalho 47 is under test in this orchard, a trap first devised for capturing poliphagous coloptera in forest essence. The original trap was modified for best suitableness to the coconut tree. Traps were allocated in four blocks according to color and five different luring substances. Colors used were, yellow, blue, beige, and pink. Luring substances being used are, namely, molasses, alcohol, sugar-cane whisky, inflorescence extracts and water (witness). The results from first collections have shown that there is a preference for coloration and luring substrate, and the use of this sampling technique can also be effective for the survey of insect populations of Coleoptera, Hymenoptera, and Diptera, amongst others observed in this culture, and also there is possibility of its utilization as a monitoring technique for the culture's MIP.

Index terms: coconut palm; coconut pests; monitoring; alternative luring trap; population dynamics.

[1140] THE OCCURENCE AND BIOLOGICAL ASPECTS OF THE JUMPING PLANT LICE (HOMOPTERA:PSYLIDAE) ON GUAVA PLANTS (*PSIDIUM GUAYAVA*) AND 'SOMBREIRO' TREES (*VICTORIA FAIRCHILDIANA*) IN THE STATE OF RIO DE JANEIRO, BRAZIL

S.S.P. de Souza¹, R. Silva-Filho^{1,2}, R.C.Barbosa^{1,2}, A.L. da Silva^{1,2}, O.R.F. Azevedo^{1,2} & A.F. Monteiro Junior^{1,2}, ¹Dept. de Entomologia e Fitopatologia, IB, Univ. Federal Rural do Rio de Janeiro, BR 465 Km 07, Seropédica, RJ, CEP 23.890-000, Brasil, ¹Email: sousols@ufrj.br, ²cimp@ufrj.br.

The present studies were started in September 1998 in guava orchards at the municipality of Japeri, as well as streets and squares of the West region of the state of Rio de Janeiro, and also on federal and county highways of said state. The observation are being made at 15-days intervals and the methods used for observing the biological, ecological, and/or economical parameters are based upon various monitoring tactics, with the purpose of adjusting them the integrated pest management. In the last three years, the guava orchards have been intensively under attack of psyllida (sap-sucking insects) in almost all Brazilian regions where this fruit is grown. Coincidentally, at these same periods, the problem is being observed in 'sombreiro' trees which decorate the state's streets and highways. Such infestations are caused by different species, as seen by the observation of the injuries caused to the host plants. In guava trees these insects cause the rolling-up of leaves, since they oviposit at the leaf edges, whereas on the 'sombreiro' trees they densely infest the underneath surface of the leaves, forming dense agglomerations; on the upper part of the leaves, they preferably stick to the central nervure. Both species have been causing considerable economical losses possibly resulting from biological unbalances originated by frequent use of chemicals applied and/or by inadequate management practices. The species found on the guava tree leaves belong to the Triozinae sub-family, for they cause the upward rolling-up of the limbus in young leaves and then such leaves rot and fall. The species attacking the 'sombreiro' resemble Chermidae (Psyllinae), but not causing the same one damage on the leaves such as the former ones; however there occur drastic falling of leaves at the end of each cycle. Also, at each cycle there is a observed reduction of the leaf limbus. The results obtained up to present indicates that Triozoida sp. attack guava trees, whereas the 'sombreiro' trees are being attacked by Euphalerus sp., which also infest medicinal plants such as arruda(Ruta sp.) (herb of grace).

Index terms: Psyllidae; Triozida sp.; Euphalerus sp.; sombreiro pests; guava pests; Ruta sp.

[1141] INVASION SEQUENCE DETERMINES PREDATOR-PREY DYNAMICS IN A MULTISPECIES ASSEMBLAGE

<u>S. M. Sait¹</u>, W-C. Liu², D. J. Thompson¹, H. C. J. Godfray² & M. Begon¹, ¹School of Biological Sciences, Nicholson Building, Univ. Liverpool, P.O. Box 147, Liverpool, L69 3BX, UK. E-mail lesait@liv.ac.uk; ²Dept. of Biology and NERC Centre for Population Biology, Imperial College at Silwood Park, Ascot, SL5 7PY, UK.

Recently there has been a trend towards the study of multi-species interactions in ecology. Theory has shown that predator-prey interactions within multi-species communities can exhibit a range of dynamical patterns. There are a number of sequences through which such community assemblages can be constructed, unlike one or two-species systems, but the impact of assembly sequence on predator-prev dynamics has not previously been investigated. Here, we examine census data obtained from experimental three-species systems and demonstrate that the dynamic trajectories of a predator and its prey are determined by the order in which invasion by the third species occurs. The multi-species system comprises a lepidopteran host, the Indian meal moth Plodia interpunctella, and two of its natural encinies; a baculovirus and a predator, the parasitoid wasp Venturia canescens. The dynamics of the component host-pathogen and host-parasitoid systems are characterised by generation cycles of abundance of the host and parasitoid. Replicated three-species systems were constructed by adding the parasitoid to established host-pathogen cultures, or by adding the pathogen to established host-parasitoid systems. Where appropriate adult moths, wasps and infected larvae were monitored and the time series data compared using autocorrelation function analyses. When the parasitoid was the invading species both the host and parasitoid consistently exhibited an immediate and dramatic shift from generation to multi-generation cycles. However, when the pathogen was the invading species, the host and parasitoid exhibited either one of two dynamical patterns; in some replicates the host and parasitoid went through a period of transient dynamics before ultimately exhibiting multigeneration cycles, this gradual shift in pattern contrasting markedly with the immediate change. In the remaining cultures there was no evidence of either a generation or multigeneration cycle in the host and parasitoid. Instead, the transient period persisted for as long as the three-species cultures remained extant. An agestructured model of the three-species interaction supports our results and shows, moreover, that the length of the transient period is sensitive to small changes in pathogen density after invasion. We argue that transient dynamics following species invasions are highly significant ecologically and may be of such duration that they may be as, or more important than equilibrium states that are never effectively attained over timescales typically observed in complex natural systems.

Index terms: baculovirus, cycles, parasitoid, Plodia interpunctella, Venturia canescens

[1142] A SURVEY OF FECAL FIRING AND HOUSECLEANING IN LEPIDOPTERAN CATERPILLARS

B.A. Salazar, J.D. Hatle & D.W. Whitman, 4120 Dept. of Biological Sciences, Illinios State Univ., Normal, IL 61790-4120, USA, E-mail basalaz@ilstu.edu.

Fecal firing and fecal housecleaning are two behaviors employed by Lepidopteran caterpillars to distance themselves from their feces. We tested 73 caterpillar species (18 families) from a deciduous forest in eastern Maryland, and various desert habitats in southeastern Arizona for fecal firing and fecal housecleaning in order to address the following four questions: are these two behaviors associated with shelter building; are they negatively associated with morphological defenses (hairiness, spines, etc.); are they negatively associated with aposematic coloration; and how are they distributed phylogenetically? We found 12 out of 73 species of caterpillars fecal fired. Our results indicate that fecal firing appears to be associated with shelter building. Fecal firing does not appear to be associated with any particular caterpillar surface morphology, and it appears to be negatively associated with aposematic coloration. Fecal firing also appears to be restricted phylogenetically and is common only within the family Hesperiidae. We observed repeatable fecal housecleaning behavior in only 2 out of the 57 caterpillar species tested. One of these caterpillars was a member of the family Noctuidae and the other was Panopoda rufimargo (Noctuidae). Overall, we found little evidence that fecal firing functions to distance caterpillars from their feces in order to avoid either visual or chemical detection by predators and/or parasitoids. We also hypothesize that fecal firing probably evolved in shelter building caterpillars to conserve space.

Index terms: aposematic, phylogenetically, Hesperiidae, Noctuidae, Panopoda rufimargo

[1143] OBSERVATIONS ON THE AQUATIC HEMIPTERA (GERRIDAE) DIVERSITY FAUNA FROM DISTURBED AND NON-DISTURBED ENVIRONMENT OF AMAZÔNIA CENTRAL, BRASIL

<u>R. T. M. Sampaio</u> & I. R. Brandão, Instituto Nacional de Pesquisas da Amazônia, P. O. Box 478, 69011-970, Manaus/AM, BR. rsampaio@inpa.gov.br. Funding: PPG7/FINEP/ PPI/INPA-MCT.

The aquatic Hemiptera: Heteroptera mainly colonize continental water bodics. The crescent interest on the aquatic entomofauna in the last years, is due mostly by the potencial bioapplication of these insects on the evaluation of the water quality after environmental disturbance. Information on either disturbed and non-disturbed types of environment are precious if one wishes to understand the antropogenic effects over some region.. Manaus and surrounding warters are being pressed by the iminent urban development, causing areas to be highly disturbed, along preserved areas around roads and the city. Data from about ten years collecting on disturbed and non-disturbed streams of Manaus and adjacent areas were evaluated and showed a tendency of some Gerridae genera and species, even belonging to the same genera, to be present only on nondisturbed areas. The survey is a result of 26 collection travels around Manaus city. Richness from three streams of disturbed environment were selected to compare to non disturbed ones. A total of 277 Gerridae specimens were collected where 154 (8 genera and 12 species) from the non-disturbed areas and 123 (6 genera and 7 species) from the disturbed one. Limnogonus hyalinus, Brachymetra albinerva, Tachygerris surinamensis, Neogerris lotus and Metrobates laetus have been collected only on non-disturbed areas. Otherwise Neogerris celeris and Brachymetra lata have been collected on both areas, the last one doubled the number of specimens presented. Brachymetra shawi and Neogerris visendus were mostly collected from non-disturbed and disturbed areas respectively. Also the presence of males and females different numbers on both types of environment has shown differences. The significance of these results as possible application on biotecnology as bioindicators of quality of water will be discussed. The relevance of these studies is in considering the Amazon area as a great water resource and Gerridae a tropical family, as 54 from the 57 existing genera are endemic on this area althoug little is known about its diversity.

Index-terms: Aquatic Insects; Hemiptera; Heteroptera: Gerridae.

[1144] AN AQUATIC INSECT FAUNA FROM THE SUNDANCE FORMATION (LATE JURASSIC), NOR'THERN WYOMING AND SOUTHERN MONTANA, U.S.A.

J.A. Santingo-Blay¹, <u>C.C. Lebandeira</u>^{1,2}, L. J. Pribyl¹ & L.D. Martin⁴, ¹Department of Paleobiology, National Museum of Natural History, Smithsonian Institution, Washington, DC, 20560, USA, e-mail: *labandeira.conrad@nnnh.si.edu*; ²Department of Entomology, University of Maryland, College Park, MD, USA 20742; ⁴University of Kansas Natural History Museum, Lawrence, KS, USA 66045

The Late Jurassic Sundance Formation, of Oxfordian to Kimmeridgian age and corresponding to a date of about 155 million years, is a lowland basinal or perhaps marginal marine deposit consisting of finely-laminated, platy lithographic limestone that once bore a benthos of lime mud. This deposit bears an allochthonous palynoflora consisting of probable schizeacean fern spores; bennettitalean Eucommiidites pollen; and conifers that include Araucarites pollen, cheirolepidacean Classopollis pollen, and possible podcearpaceous wood fragments. The vertebrate fauna consists of one fish species whereas the nektonic insect fauna contains 15 species of mostly Hemiptera and Coleoptera. Sedimentological, paleobiological, and geochemical evidence indicates a shallow basin near sea level that periodically infilled with terrestrial clay sediment from influxes of fresh water. Evidently bottom conditions were inhospitable to respiring organisms. Unlike other mid-Mesozoic deposits of similar age, such as Solnhofen in southern Germany, the Sundance Formation lacks land-derived taxa. Major insect taxa include the heteropterous Belostomatidae, Corixidae, Naucoridae, and extinct The Coleoptera are represented principally by Dytiscidae and possible Enicocoridae. extinct Parahygrobiidae. Rare caddisfly cases constructed of quartzose sand grains are also present. Adult and subadult taxa occur in abundance, allowing some taxa to be evaluated by bivariate morphometric analyses. Soft-bodied preservation of insects by carbonate minerals, principally calcium phosphate, reveals segmented appendages, spines, mouthparts, surface ornamentation, and even premortem color patterns of elytra revealed by variable gray hues. These exceptional details are photographically documented under alcohol immersion at long exposures with fluorescent light. Preparation of fossil material involves careful and repeated surface etching in dilute acetic acid, followed by water rinses and removal of microcrystalline lime matrix by camelhair brushes. This deposit and the Todilto fauna in New Mexico are the only diverse, mid-Mesozoic, North American, fossil insect deposits. As Sundance taxa become better known, their taxonomic affinities to contemporaneous deposits in Eurasia and Brazil should reveal important biogeographic patterns. We are evaluating the Late Jurassic response of continental aquatic insects to north/south distributions of land masses separated by an east/west Tethyan Sea, prior to formation of the Atlantic Ocean. Index: Late Jurassic, fossils

[1145] THE STUDY OF ABUNDANCE, BITING BEHAVIOR AND PARITY OF ANOPHELINE IN ENDEMIC MALARIA AREA IN PORTO VELHO – RONDONIA – BRAZIL

F. Santos¹, A. E.F.L.Cunha¹, A. O. Maia¹ & O. L. Silva¹, ¹ Health National Foundation

Studies of abundance, biting behavior and seasonal distribution of Anophelines are essential for malaria control programs. The strategy of selective control is based on the need to use selective tools for vector control. Therefore it is necessary that studies are conducted, to understand the population dynamics and seasonal variation of vectors. That way, control measures can be targeted to priority sites, and resources optimaly used. To conduct this study, 11 localities in a peri- urban area of Porto Velho were selected, where adults and larvae were collected monthly from January to December 1997. Larval collections were done at 100 different sites, using a dipper (350 ml) in previously selected permanent breeding sites. Collected larvae were counted and 3rd and 4th instars were transported to the laboratory for species identification. Adults were collected at intra- and peridomiciliary surronding during 4 hours using human bait, with the help of na oral aspirator and stored in plastic cups for transport to the laboratory to identification. The ovaries of Anopheles darlingi females were dissected to determine parity. In total 2,243 adults mosquitoes were collected and, of the species collected, Anopheles darlingi was the predominant species in the peridomiciliary site and, of the parous females. A higher number of mosquitoes was collected at sites with more malaria cases. During the study period, 765 larvae were collected, with An. darlingi as the predominant species. It has been demonstrated that Anopheles darlingi is the principal vector of malaria in the periurban area of Porto Velho town, because it was encountered at high densities. It is also said the density and presence of this is directly related to the number of malaria cases in the localities. More detailed studies have to be done, because we assumed that the faillure in the malaria control programs is due to the change in the resting behavior.

[1147] ANT-HERBIVORES INTERACTIONS IN TOCOYENA FORMOSA (RUBIACEAE) IN CERRADO VEGETATION

J. C. Santos¹ & K. Del-Claro¹, ¹Inst. de Biologia, Univ. Fed. Uberlândia – Uberlândia, MG, CP 593, Cep 38400-902, Brazil. e-mail: jcsantosbio@hotmail.com.

Extrafloral nectar is one of the most common reward that plants offer to animals, specially ants. Although Tocoyena formosa K. Schum. (Rubiaceae) is a cerrado plant without extrafloral nectaries, ants feed on its nectar. After flowers were visited by its pollinators (hawkmoths) the corolla drops but the floral nectary continues active producing nectar on the top of fruit in development and attracting visiting ants. In this study we investigated if ants visiting the "floral nectaries" of Tocoyena can produce some benefit to the plant. Field work was conduced between July 1997 and january 1998 in a cerrado reserve (cavanna neotropical vegetation) at Clube de Caça e Pesca Itororó de Uberlândia (CCCPIU). We tagged 50 individuals of T. formosa, all of similar height (0.5-1.5m) and developmental state, each one without leaves or reproductive structures in the beginning of study. Treatment plants (N = 15) received an ant exclusion resin (Tanglefoot R) in their basis and control plants (N = 35) were maintained in their natural state, with free access to ants. We visited weekly each plant to verify the integrity of the resin barrier and species visiting the "floral nectaries". We quantified data on leaf herbivory, fruit production, presence of ants and herbivores on plants. The results showed that there was not statistical difference in folivory between groups or ant species. Although ant excluded plants presented a lower proportion of fruits formed by buds produced, and plants with ants have also presented heavier fruits, these differences were not statistically significant. The *Ectatomma* genus was more efficient in protection of buds and fruits than ants absence and between the second state of the second state investigating benefits of ant visitation to floral nectaries of a cerrado plant. Although, our results did not present statistical difference between plants with and without ants, we suggested that benefits, mainly in fruit production and development may exist with ant presence and other experiments conduced in other years with a major sample size will demonstrated it definitely.

Index terms: Tocoyena, Rubiaceae, ants, herbivory, ant-plant interaction

[1146] COMPARISON OF FOUR METHODS FOR COLLECTING ADULT ANOPHELINE MOSQUITOES IN AN ENDEMIC AREA IN PORTO VELIIO – RONDONIA – BRAZIL

<u>F. Santos¹</u>, J. B. P. Lima² & I. A. Braga¹, ¹ Health National Foundation; ² Army Biological Institute

For many years, the most representative method to collect Anopheline mosquitoes is the human biting catch, but this method is expensive, laborious, and exposes collectors to the risk of contracting malaria. Four collections methods were compared in the malaria endemic area of Porto Velho -- Rondonia -- Brazil. The Shannon trap, the Shannon modified trap, human biting catch with the collector using cotton black socks and the regular human biting catch. On exposed legs and the protectes them, to collected mosquitoes, oral aspirator was used, and on shannon traps, the oral and mecanic aspirators were used. The experiment was conducted at four different locations with equal distance between them and was repeated four times at each location. The randomized design experimental was used. The ovaries of female Anopheles darlingi were dissected to determine parity. The results showed the most abundant species was Anopheles darlingi, that is the principal species involved in the malaria transmision, and the best collection methods the regular human biting catch. In the paity rate by all methods, the proportion of nulliparous females was not significantly higher than the proportion parous. In spite of a questionable method, the human biting catch is the best and the most representative compare to others for monitoring the anophelines populations in endemic malaria areas. However, studies should continue search the alternative methods for monitoring the malaria vectors without risking the volunteers life.

[1148] INTERPLAY OF VEGETATIONAL FEATURES AND MICROCLIMATE ON BOLL WEEVIL CAPTURE IN PHEROMONE TRAPS

T. W. Sappington¹ & K. R. Beerwinkle², ¹USDA-ARS, IFNRRU, 2413 E. Hwy. 83, Weslaco, TX 78596 USA, E-mail tsapping@weslaco.ars.usda.gov; ²USDA-ARS, APMRU, 2771 F&B Road, College Station, TX 77845 USA, E-mail kbeerwinkle@tamu.edu.

Traps baited with the synthetic pheromone of the boll weevil (Anthonomus grandis) are used extensively to monitor local and long-range movement, to detect and monitor local populations and potential problem fields, and to guide treatment decisions in cotton. Quantification of the effects of environmental factors and their interactions on boll weevil trap captures is important to efforts to optimize trap deployment, and to appropriate interpretation of capture data. Paired trap lines were placed on opposite sides of a brush line at six different sites on a plantation in the Lower Rio Grande Valley of Texas, USA. A strong negative relationship between mean daily wind speed and total daily capture of boll weevils accounts for about half of the observed day-to-day variation in trap captures. In addition, our data indicate that much of the variation between traps within days may arise from differences in local wind speed as governed by local vegetation depending on wind direction. Brush lines in this study slowed the wind by 40-70% and mitigated its effects such that traps on the leeward side averaged 2.5-2.9 fold higher captures than traps on the windward side. The magnitude of the effect of windward or leeward placement of traps on weevil captures depended on the relative strength of the wind and density of the brush. Under light winds (< 10 km/h), there were no increases in leeward trap captures. However, on days of moderate (10-20 km/h) or strong (> 20 km/h) winds, leeward trap captures averaged 3.9- or 2.4-fold greater than windward captures, respectively. Traps on the leeward side of a heavy brush line captured ~4.5-fold more weevils than on the windward side on days with moderate winds. Mechanisms of the effects of brush lines on differential weevil captures are being investigated with the use of four automated pheromone traps. These log the entry times of boll weevils into the trap, as well as temperature, wind speed, and wind direction from a small weather station associated with each trap. Thus, fine scale microclimatic measurements can be correlated with weevil captures within narrow windows of time. By taking into account the ability of brush lines to dampen the effects of wind on boll weevil trap captures, researchers and producers can dampen some of the daily and positional variation in trap captures by more careful placement of traps relative to windbreaks. Our results also have implications for situations in which detection of very low populations of local or immigrant weevils is critical, such as in boll weevil eradication and post-eradication zones.

Index terms: Anthonomus grandis, flight, movement, wind, sampling.

[1149] INSECTIVOROUS BIRD COMMUNITY DEPENDING ON FORESTS

<u>S. Sato</u>, Shikoku Res. Ctr., For. and Forest Prod. Res. Inst. 2-915, Asakura-nishimachi, Kochi, 780-8077, Japan. E-mail shigeho@ffpri-skk.affrc.go.jp

To preserve an animal community on reduced and fragmented natural forests, we need to understand the mechanisms sustaining the animal community. It is necessary to know not only the structure of the community but also the interactions with other creatures. The interactions between forest bird communities and insect communities, which are major food resources for birds, have been studied only a little. Here the author analyzed the bird communities of differently treated forests to understand the effects of the modification of forest vegetation on insectivorous bird communities through the insect communities. The author surveyed the bird communities in early summer, which was the breeding season of most birds, on 11 sites including primary forests, secondary forests and coniferous plantations in warm-temperate zone of Shikoku, southwestern Japan. According to their food guilds, the insectivorous birds were classified to the predators of leaf-eaters on crown layer the predators of leaf-eaters on hush layer, the predators of wood-borers and phloemborers and the predators of ground wanderers. The reactions of bird community to the vegetation change were different among the food guilds. The predators of leaf-eaters on crown layer were poor in species on young secondary forests and young plantations, while the predators of leaf-eaters on bush layer were rich on secondary forests and young plantations. The predators of wood-borers and phloem-borers were few on plantations. Those results suggest that human impacts on forests affect the structure of bird community through the change of insect community.

Index terms: food guild, warm-temperate forest, ecological interactions, Japan.

[1151] HOST RECOGNITION IN XIPHYDRIID WOODWASPS

N. M. Schiff¹, <u>L. II. Williams</u>, <u>III²</u>, A. D. Wilson¹ & L. D. Price², ¹Center for Bottomland Hardwoods Research, Southern Research Station, U.S. Forest Service, P.O. Box 227, Stoneville, MS 38776-0227, USA, E-mail nschiff@asrr.arsusda.gov; ²USDA-ARS SIMRU, P.O. Box 346, Stoneville, MS 38776-0346, USA, E-mail livy@ars.usda.gov.

There are approximately 22 genera and 100 species of woodwasps in the family Xiphydriidae. The family has a worldwide distribution, but only the genus Xiphydria, with 9 described species, occurs in the United States. Xiphydriids are medium-sized wasps that are uncommonly collected. Larvae bore through hardwood hosts and consume wood decayed by ascomycetous, symbiotic wood-decay fungi. Most U.S. species are relatively oligophagous but at least one species, X. *tibialis*, has been reared from a wide range of hardwoods. There is little information about how xiphydriid woodwasps locate and accept hosts. Observations of Xiphydria species engaged in host searching behavior suggest that wasps may use both chemical and physical stimuli to find and recognize host woods. We recorded electroantennogram (EAG) responses of xiphydriid wasps to plantproduced terpenes and alcohols, and to fungal symbionts. Xiphydria antennae responded significantly to all stimuli, and a dose response was observed for plant-produced compounds. Behavioral assays were conducted which allowed wasps to choose between host and non-host woods. Parallel assays that eliminated physical and contact chemical cues from the host, but allowed passage of olfactory cues were also conducted. Results of EAG and behavioral studies suggest that Xiphydria sawflies use their antennae to recognize olfactory and/or contact chemical stimuli from their hosts. Physical cues also appear to play a role.

Index terms: Xiphydria, sawfly, fungi, electroantennography, olfaction.

[1150] BIODIVERSITY OF *FAGUS* GALL MIDGES: COEXITENCE AND LIFE HISTORY STRATEGY

<u>S. Satou¹</u>, K. Tsuda² & J. Yukawa³, ^{1,3} Entomological Laboratory, Faculty of Agriculture Kyushu University, Fukuoka, 812-8581 Japan, E-mail: shin@agr.kyushu-u.ac.jp; ² Kinpo-Kagoshima

At least 26 species of gall midge produce leaf galls on *Fagus crenata* [Fagaceae] in Japan. Most of them are widely distributed in Japan, except a few which are found in restricted areas. Such diversified conditions on a single host species enable us to study mechanisms maintaining biodiversity and interactions between organisms belonging to a same and different trophic levels. Periodical dissection of galls, rearing experiments, and host plant phenological data indicated that respective species of gall midge emerged differently in spring to summer seasons, corresponding to the changes of leaf opening phenology. Their life histories can be divided into three patterns according to overwintering stages, emergence seasons, and oviposition sites. Each pattern was adopted by a species group of gall midges belonging to one or two related genera. Population density expressed by the number of galls per leaf was extremely low for almost all species, and the spatial distribution pattern of their galls were contagious. These phenomena were considered to be caused by the oviposition concentrated on particular fresh leaves that were synchronized with gall midge emergences.

Index terms: Fagus crenata, leaf opening phenology, spatial distribution pattern

[1152] ATTACK DYNAMICS OF THE SPRUCE BARK BEETLE *IPS* TYPOGRAPHUS IN STANDS WITH AND WITHOUT REMOVAL OF WINDTHROWN TREES AFTER A STORM FELLING

<u>M. Schroeder</u> & Å. Lindelöw, Dept. of Entomology, Swedish Univ. of Agricultural Sciences, P. O. Box 7044, SE-750 07 Uppsala, Sweden, E-mail Martin.Schroeder@entom.slu.se.

The spruce bark beetle, Ips typographus, is one of the economically most important pests of mature spruce forests in Eurasia. At high population levels the risk for successful attacks on standing trees increases. One factor promoting high population levels in I. typographus is windstorms by providing a surplus of defenceless breeding material in form of fallen trees. An increase of the amounts of breeding material results in low attack densities which releases the beetle population from the usually strong intraspecific competition. Thus, removal of downed spruce trees, to prevent *I. typographus* reproduction has for a long time been the most important measure to reduce the risk for bark beetle attacks on standing trees in the managed forest. But for nature conservation reasons efforts are now being made to increase the amounts windthrown trees left in the managed forests. In the present study the attack dynamics of I. typographus were studied for four years in a number of stands damaged by a storm felling in November 1995. Both stands with removal (managed stands) and without removal (unmanaged stands) of windthrown trees were included in the study. In the four summers following the storm disturbance 50 - 322 standing trees were killed by *l. typographus* in the five unmanaged stands which corresponds to 53 - 86 % of the numbers of attacked windthrown trees. In the first summer after the storm disturbance 531 windthrown trees were attacked by I. typographus in the five unmanaged stands. In contrast, only one standing tree was killed by I. typographus this year in the same stands. Also in the second summer many windthrown trees were attacked while in the third summer no windthrown trees suitable to I. typographus remained. The number of trees killed by I. typographus in unmanaged stands where all the windthrown trees had been left peaked in the second or third summer after the storm felling. In the four summers following the storm felling about two to four times as many standing trees were killed per ha in the unmanged stands compared with in the managed stands.

Index terms: bark beetle killed trees, Picea abies, forest management

[1153] SPIDER COMMUNITY OF AGRICULTURAL ECOSYSTEMS IN CENTRAL AND SOUTH RUSSIA

R. R. Seifulina, Department of Entomology, Biological faculty, Moscow State University, 119899, Moscow, Russia, E-mail: raviljevna@yahoo.com

The investigations were carried out in the agricultural landscape in Moscow region in 1994-1997 and in Krasnodar region (the South of Russia) in 1998. The species composition, spatial distribution and seasonal dynamics of spiders were studied in the different crop fields, on their margins and in adjacent biotopes. The areas of fields were 12-14 ha in Moscow and 60 ha in Krasnodar. Spiders were regularly collected with entomological sweeping and pitfall traps during the crop vegetation season. Samples were taken in the centre of the field, on the field edges (7-10 m into the field), on the field grassy margins and in adjoined biotopes. The distance between the nearest edge and centre in Moscow was about 150 m and in Krasnodar - 400 m. A total 234 species of 121 genera of 20 families were found. 168 species captured in the fields and their margins. Most of these species (about 90%) were collected on the margins. Number of species decreased from the margins to the field centre. The analysis of spider species composition suggests that only some species are able to penetrate into the field. On the contrary, practically all the species inhabiting fields occurred in the margins as well. Therefore the margins are regarded as the main source and refuge for spiders in the agroecosystem. About 95% of all collected epigeic specimens belong to Linyphiidae and Lycosidae families according to pitfall traps. Oedothorax apicatus (Linyphiidae) dominated in the studied agrocenoses in Moscow (29%) and was mass in Krasnodar regions (10%). Four species of Pardosa (Lycosidae) and two of Erigone (Linyphiidae) were mass in Moscow regions as well. P. agrestis dominated (68%) and Trochosa spp. (Lycosidae) were abundant in winter wheat fields in Krasnodar region. P. agrestis occured more frequent in the field central zone at the end of spring. On the contrary, O. apicatus was more ample on the edge of field. According to sweeping, Xisticus ulmi (Thomisidae), Tetragnatha extensa (Tetragnathidae) and Microlinyphia pusilla (Linyphiidae) dominated in field vegetation in Moscow region, while Hypsosinga pygmaea (Araneidae) in Krasnodar region. Eurytopic, widespread, opened space species constitute the basis of studied spider communities. Species composition actually does not depend on the cultivated crop. However, the latter is sure to influence the number, dominance structure, spatial distribution and seasonal dynamics of mass species.

Index terms: Araneae, Lycosidae, Linyphildae, agrocenoses, species composition.

[1154] MODELLING THE POPULATION INTERACTIONS BETWEEN THE CROWN WEEVIL MOGULONES LARVATUS AND ITS HOST PLANT ECHIUM PLANTAGINEUM

<u>A.W. Sheppard¹</u>, M. Rees² & K. Grigulis¹, ¹CRC for Weed Management Systems, CSIRO European Laboratory, Baillarguet, 34980 Montferrier-sur-Lez, France; ²Imperial College, Silwood Park, Ascot, Berks, SL5 7PY, UK

Population models are used to understand the ecological mechanisms involved in interactions between insects and their food resources. In host-parasitoid systems these have achieved levels of complexity, which have provided detailed evidence of some subtle stabilizing mechanisms in the interactions between populations of predator and prey. Such models in herbivore-plant systems have, in general, been quite simple by comparison. In most cases the models used have been based on the dynamics of the host plant incorporating the impact of the insect herbivore as a constant or stochastic variable within a range defined from field observation. Such modeled systems are either unregulated (matrix models) or regulated by density dependence only in the host plant. We have been constructing and exploring a suite of models for the interactions between a root-crown boring weevil, Mogulones larvatus, introduced into Australia and locally wiping out populations of the annual pasture weed, Echium plantagineum. A simple cohort-based model, like others in the past, incorporates weevils simply as a constant impact change in survival and/or fecundity of the host plant. The results are over-optimistic about the impact of the weevil on the populations of its host. A more complex individual-based model incorporates a) variation in weevil impact and b) integrates the dynamics associated with how the adult egg-laying weevil population responds to changing sized and density of its host and c) incorporates larval competition within individual hosts. Density dependence is present therefore in both weevil and host plant components of this model. Outputs from this model highlight the following conclusions. Firstly, including a seedbank-refuge in the model increased host-plant population stability in the face of impact from the weevil. Secondly, including variation in weevil impact amongst plant individuals greatly decreased the effects of the weevils at the population level and this critically depended on the form that this variation took (i.e poisson or negative binomial). Finally, including density dependence in the both the weevil and host plant populations in the model increased the stability of the interactions between them. This study shows that it is valuable to move beyond simple population models for understanding the interactions between insect herbivores and their host plants, but it is vital in this process that field data on herbivore impact assesses variation as well as the mean of the impact and attack levels they cause.

[1155] INSECT COMMUNITY ON RUMEX OBTUSIFOLIUS AS A HOST PLANT

M. H. Shim¹, O. S. Kwon² & <u>S. H. Nam¹</u>, ¹Dept. of Biology, Taejon University, 96-3, Yongwun-tong, Tong-gu, Taejon, 300-716, Republic of Korea; ²Dept. of Sericulture and Entomology, National Institute of Agricultural Science and Technology, 61, Seodun-tong, Kwonscon-gu, Suwon, 441-100, Republic of Korea.

This study was conducted to investigate the insect community on *Rumex obtusifolius* which is a naturalized plant in Korea. The study was started on October 1998 and finished on September 1999. Five study sites were chosen near Samsan stream, near Daecheong lake. Data collection was done onsite every other week during the study period. A total of 5 orders 33 families 85 species was identified to live on the plant. Insects belong to Coleoptera showed highest occurrence in July. Population dynamics of insects at each study site was analyzed. It is concluded that *R. obtusifolius*, a newly naturalized plant in Korea, has successfully established itself as a host plant.

[1156] DISTRIBUTION OF SCAPTOCORIS CASTANEA (HEMIPTERA: CYDNIDAE) POPULATION IN THE SOIL IN FLORÍNEA COUNTY, STATE OF SÃO PAULO, BRAZIL

R. C. Siloto, A. Raga & M. E. Sato, Inst. Biológico, P.O. Box 70 - 13.001-970, Campinas, SP, Brazil. E-mail: resiloto@carpa.ciagri.usp.br

The burrowing bug, Scaptocoris castanea, causes serious damage in several crops in Brazil, mainly soybean, corn, cotton and pasture, sucking the roots of the plants and affecting their development and production. The ability of this insect to move deeply in the soil, associated with their irregular distribution, makes the chemical control of this pest very difficult. In this study, we have evaluated the distribution of the insect in the soil, making correlation with the weather conditions, especially rainfall. The study has been carried out in Florínea county for a period of 18 months. The evaluations have been realized monthly, counting the number of nymphs and adults in soil samples of 25 cm by 25 cm (area) by 50 cm (depth). The sample of soil was separated into two parts: 0-25 cm and 25-50 cm deep. During all the evaluated period, the number of nymphs was higher the number of adults (4:1). This higher proportion of nymphs was more clearly observed during the dry periods (rainfall lower than 70 mm a month) when the nymph/adult ratio reached 11:1. The highest percentage of nymphs (67.4) in the layer of 0-25 cm was registered in Jan/99, which was correspondent to the month with the highest rainfall (551 mm). On the other hand, the lowest percentage (21.0) of nymphs in this layer was in July/99, which was one of the months with the lowest rainfall (48 mm). The highest population of adults in the lower layer was observed during Dec/98 and Jan./99, while the highest population of adults in the upper layer was in Mar./99 and Apr./99. Considering the total population of burrowing bugs (nymphs + adults), the highest number of insects (62.2 insects; with 60% of them in the layer of 0-25 cm) was observed in Apr./99 after five months with high rainfall (average: 390 mm a month). The lowest number was registered in Apr./99 (16.2 insects; with 79% of than in the layer of 25-50 cm), after a six month period with low rainfall (average: 67 mm a month). These data indicate that the rainfall (and consequently the soil moisture) has influence on the number and distribution of S.castanea in the soil.

Index terms: burrowing bug, rainfall, population dynamics.

Index terms: Biological control of weeds, Boraginaceae, Curculionidae, Australia.

[1157] FEEDING TIME OF *PHTHIA PICTA* (HEMIPTERA: COREIDAE) IN DIFFERENTS AGES ON FRUITS OF TWO CULTIVARS OF TOMATO

R. A. da Silva¹ & <u>G. S. Carvalho</u>^{1,2}, ¹Dept. Fitossanidade, Univ. Fed. do Rio Grande do Sul, P.O. Box 776, Porto Alegre, RS 90001-970, Brazil; ² Dept. Biologia, Pont. Univ. Católica do Rio Grande do Sul, P.O. Box 1429, Porto Alegre, RS 90619-900, Brazil, Email: gervasio@pucrs.br.

Among the pests of the tomato culture (Lycopersicon esculentum) is Phthia picta, a bug that make punctures on fruits when feeding. This study was carried out in the Laboratório de Entomologia, Departamento de Fitossanidade, Faculdade de Agronomia, UFRGS, Porto Alegre, RS, with the following objectives: to register the number of punctures per insect, the feeding time per puncture and the total feeding time of males and females of P. picta in differents ages, in two commercial cultivars of tomato (Empire and Santa Clara). Twelve insects fed with fruits of Empire since the first nymphal stage were used in this assay. The bugs were divided in four groups: A1 (3 females), A2 (3 females), B1 (3 males) and B2 (3 males). The insects of each group were individualized in pot of plastic (8cm of diameter x 12cm of height) covered with voil, under controlled conditions (26 ± 1°C; 70 ± 10% RH and photophase of 14 h). Each group was observed four times, when the insects were 13, 16 and 19 days of adult life. The observations consisted in to submit the bugs of the groups for a period of 24 hours without food, under controlled conditions, after to offer fruits of Empire (to groups A1 and B1) or Santa Clara (to groups A2 and B2) cultivars and to observe under environmental temperature the bugs for three hours, registering the number of punctures maked per insect and its duration. The feeding time was considerated the period between the beginning of insertion of the bug's stylets on fruit and the moment that its are retired. In the period among the observations, each insect received a fruit of the group correspondig cultivar. In the first observation only the insects of group B1 fed on fruits. Among the other insects the following behaviors were observed: resting, moving and sometimes food-touching. So, the first observation was not used for statistics analysis. The Analysis of Variance showed that the number of punctures per insect (4,00 in Santa Clara and 4,14 in Empire) and the feeding time per puncture (17,25 minutes in Santa Clara and 22,91 minutes in Empire) are not differents between cultivars. In the same way, no significants differences were found in the total feeding time of the insects: among differents ages (54,82, 36,30 and 61,83 minutes, respectively in 13, 16 and 19 days); between cultivars (42,15 and 59,81 minutes, respectively in Santa clara and Empire); between sexes (43,90 and 58,06 minutes, for females and males, respectively). Index terms: Lycopersicon esculentum, insecta, bug, puncture.

[1158] DAMAGE CAUSED BY SNOUT BEETLES OF THE GENERA PANTOMORUS AND NAUPACTUS IN THE "TAHITI" TRUE LIME IN ARARUAMA CITY, RJ - BRAZIL

R. Silva-Filho¹, O.R.F. Azevedo¹, P.R.R Silva^{1,2}, W.C. Rodrigues^{1,3}, P.C.R. Cassino^{1,4} & S.S.P. Souza¹, ¹Dept. de Entomologia e Fitopatologia, IB, Centro de Manejo de Pragas "Cincinnato Rory Gonçalves", UFRRJ, BR 465 Km 07, Seropédica, RJ, Brazil, CEP 23890-000, Brazil, E-mail: cimp@ufrrj.br, ²E-mail: pramalho@fst.com.br; ³E-mail: wcosta@ufrrj.br; ⁴E-mail: pr.cassino@uol.com.br.

The snout beetles of the genera *Pantomorus* and *Naupactus* (Brachyderinae) are extremely commun in association with citrus in the majority of the Brazilian regions that produce citrus. They attack flowers, roots and leaves of citrus plants. These snout beetles never were observed in so high population density as were observed in the period of October, 1998 to December, 1999, in São Vicente de Paulo, Araruama (RJ) where they are damaging seriously the leaves of "Tahiti" true lime plants. A monitoring was carried out in a plot of 210 plants. The results showed a great occurrence of those species caused a reduction of leaf limb area, and significant loss of plant photosynthetic surface results in reduced yield and quality of fruit. Those species were also found in higher density than the other insect species that feed on the citrus trees in the study area.

Index terms: Coleoptera; Curculionidae, Pantomorus; Naupactus; Integrated Management.

[1159] ORIENTATIONAL RESPONSES OF HELICOVERPA ARMIGERA LARVAE TOWARDS LEAVES OF DIFFERENT LEGUMINOUS CROPS

A. K. Singh & S. Mullick, Dept. of Zoology, Univ. of Delhi, Delhi-110007, India.

Orientational bioassays of first instar Helicoverpa armigera (Lepidoptera: Noctuidac) larvae towards the leaves of four leguminous crops viz. chickpea (Cicer arietinum), pigeonpea (Cajanus cajan), blackgram (Vigna mungo), and cowpea (Vigna unguiculata) were conducted in the laboratory. The larvae showed positive orientational responses towards the whole leaves of all the test plants. In no-choice tests, the orientational preferences of larvae were statistically equal for chickpea, pigeonpea, and blackgram but these were significantly higher than the orientational preference for cowpea leaves. The orientational responses of larvae for the crushed leaves of pigeonpea were found to be significantly lower, as compared with the crushed leaves of chickpea, blackgram, and cowpea. Larval attraction for the crushed leaves of chickpea, blackgram, and cowpea was statistically identical in no-choice tests. The orientational responses of gram podborer larvae for crushed leaves of cowpea were significantly higher than the whole leaves. However, the whole pigeonpea leaves elicited higher orientational responses than the crushed leaves. Maceration was not observed to affect the attractancy of chickpea and blackgram leaves, as the orientational responses of larvae to the crushed and whole leaves were statistically equal in no-choice tests. Foliage extracts in hexane of all the test plants elicited significantly higher responses of larvae than the control. Also, methanol extracts of leaves of all the test plants attracted significantly higher percentage of larvae in nochoice tests (p<0.05). However, in two-choice tests, hexane extracts of leaves elicited significantly higher orientational responses of larvae compared to the methanol extracts of same leaves (p<0.01). The results indicated that all the test plants contain stimuli, which elicit positive orientational responses of larvae. These positive factors are extractable in hexane and methanol, which is higher in former than the latter.

Index terms: Pulses, foliage extracts, larval attraction, olfactory responses.

[1160] BIOLOGICAL ATTRIBUTES OF SPOTTED STEM BORER, CHILO PARTELLUS FED ON MAIZE CULTIVARS

A. K. Singh & A. K. Varshney, Dept. of Zoology, Univ. of Delhi, Delhi-110007, India.

Effects of two maize cultivars, Basilocal and Kisan, on the biological attributes of Chilo partellus, were studied in the controlled conditions. Average larval mortality was higher on Kisan leaves (71%) in comparison with that on Basilocal leaves (55%). Also, growth of larvae was significantly lower on the former than on the latter (P < 0.05). The stem borer larvae were reared on artificial diets, incorporated with fresh foliage paste of these cultivars. Survival rate was found to be significantly higher on the diet incorporated with Basilocal foliage than on that containing the Kisan foliage. Sexwise pupal weights were statistically similar on both the test diets. However, significant differences were observed in the weights of male and female pupae. The female pupae were significantly heavier than the male pupae obtained on each diet. The percentage of larvae completing development and emerging as adults on the Kisan and Basilocal foliage diets was 40% and 60%, respectively. The proportion of males to females was almost equal in the population reared on the Basilocal diet. However, the ratio of males was significantly lower than the females in the population reared on the Kisan foliage diet. The developmental period of the insect was statistically identical on both the test diets. But its growth index was higher on Basilocal foliage diet than on the Kisan foliage diet. Longevity, oviposition period, and number of eggs laid were similar for the females reared during larval stages on both the diets. However, hatchability of the eggs delivered by the females reared on the Basilocal foliage diet was significantly higher when compared with those laid by the females reared on Kisan foliage diet. These results indicate that Kisan maize cultivar contains some factors, which cause antibiosis to *C. partellus* larvae and restrict the build up of its population on the Kisan cultivar, as compared with the Basilocal. Index terms: Hatchability, development, sex ratio, oviposition.

[1161] FURTHER OBSERVATIONS ON THE NOCTURNAL OVIPOSITION BEHAVIOR OF BLOW FLIES (DIPTERA : CALLIPHORIDAE)

D. Singh¹ & M. Bhartl², ¹²Department of Zoology, Punjabi University, Patiala - 147002, India, E-mail devinder@pbi.ernet.in.

It had generally been believed that blow flies do not oviposit at night before Greenberg (1990) reported that blowflies do lay eggs at night as well. This observation had wide applications since it may alter the calculated minimum postmortal interval by several hours. Though Greenberg's experiment was meticulously planned, it did have one major shortcoming. In this experiment he put the oviposition medium under the bushes on the ground. So the flies could have actually crawled rather than fly to this piece of meat. Hence one question still remains unanswered i.e. can the flies lay eggs on a dead body after getting attracted from some distance? To put it in a simple way the question is - do blow flies fly at night? The present studies have been undertaken to find an answer to this question. The details will be discussed during the presentation of the paper. Index terms: Night oviposition, Calliphoridae, forensic entomology

[1163] SOIL MACROFAUNA AND MESO UNDER DIFFERENT VEGETATION COVERING

M.LJ. Soares¹; <u>E.C.Costa²</u> & M.A.G.Costa², ¹ Rua Álvares de Azevedo, 02/306-C – CEP 97010-010 – Santa Maria, RS – Brasil; ² Depto. de Defesa Fitossanitária, Centro de Ciências Rurais – Universitáde Federal de Santa Maria, Campus Universitário, prédio 42, 1° andar, 3225 – CEP 97105-900 – Santa Maria – RS – Brasil – e-mail: eccosta@ccr.ufsm.br.

The relationship among soil plant communities might be indicated by studies on soil fauna. Representants for Phylum Annelida and Arthropoda. Determination of productive and fertile situation for areas with economical relevance into rural sector, could be associate with the presence representants of Phylum Annelida and Arthropoda whose constitute the soil macrofauna and meso were determined. The extraction of meso and macrofauna was done from soil samples collected on the experimental field of University, Santa Maria,(USIM). Using an extractor of soil were collected during spring of 1996, summer, fall and winter of 1997. They were extracted on 0-5, 5-10, 10-15 and 15-20 cm of soil depth. Also, in this areas, soil was sampled for chemical and fisical analysis. Another relation is associated to kind of vegetation covering whose it's possible to observe the faunal population density and quality. Representants of soil macrofauna and meso are recognized. The predominance of the Class Insecta and the variety of orders were related with vegetation covering. Was obtained the total individual quantity in relation to percentile and number of individual for square meter in agree to order was obtained. The variables were statistical analyzed to the determination of mathematical models to demonstrated the situation.

[1162] BIOLOGY OF ISODONTIA FUSCIPENNIS COMPLEX IN TRAP-NESTS (IIYMENOPTERA: SPHECIDAE)

L. A. Soares⁴, H. R. Pimenta², R. P. Martins³ & <u>L. R. S. Zanette⁴</u>, ² in memorian ^{1.3,4} Lab. of Insect Behaviour and Ecology, Biological Science Inst., Fed. Univ. of Minas Gerais, P. O. Box:486, Belo Horizonte, MG, 31140-390, Brazil, E-mail: ³wasp@mono.icb.ufmg.br; ⁴enzo@mono.icb.ufmg.br

During two years (X/92-X/93 and X/95-X/96), nests of Isodontia fuscipennis were collected using trap-nests (n=4800) in four distinct areas, two of secondary forest and two of grassland, at 1 and 2 m. high, in the UFMG's Campus, at Belo Horizonte, M.G., Brazil. The trap-nests were made of bamboo canes, 84 to 190 mm long ,with 76 to 241 mm of internal diameter and with an opening at one extremity. Among the available nests, 113 were used by *Isodontia fuscipennis*. These nests consisted of linear series of one to six brood cells, weakly separated by wads of grass stems and filled with plant material (grass stems and fibres). The final closure of the nest entrances was done by the females, with tufts of small dry brushwood and grass stems which can protrude from the opening by as much as 30mm. The cells were provisioned with adults and nymphs of grasshoppers (Tettigoniidae). The wasp's eggs were laid on the cephalothorax junction of the prey. The number of preys per cell varied from 3 to 6. From the collected nests, 156 adult wasps emerged, 56,2% were females and 43,7% males. The order of emergence was not related to sex. Females were larger than males (width of the thorax- females = $2,63 \pm 0.22$ mm / males = $2,37 \pm 0,20$ mm). The only natural enemy found was an Ichneumonidae wasp. The majority of nest's occupations (60,1%) occurred during the dry season (June to September).

Index terms: solitary wasps, nesting behaviour, grasshoppers.

[1164] DIVERSITY OF NATIVE BEES (HYMENOPTERA: APOIDEA) AND USE OF FLORAL RESOURCES IN A SECTION OF THE CHACO SERRANO (BOSQUE SERRANO) IN CENTRAL ARGENTINA

C.A. Sosa & M. Manfrini de Brewer, Centro de Inv. Entomol. F.C.E.F. y N. Univ. Córdoba. Av. Vélez Sársfield 299 C.P. 5000. Córdoba. Argentina. E-mail: csosa@com.uncor.edu

The diversity of natives bees in a section of the Bosque Serrano in Córdoba (31°10' S, 64°20° O) was determined and the utilization of floral resource by them in this area was analized. Eight samples monthly were made during september to march between 1996 and 1999. The Candfield's transect method was used (1 m. of large by a band of 2 m. of width) and the activity of bees was observed during 10 minutes. Diversity of plants presents, numbers of flowers availability, diversity of flowers visitors and its pattern of activities, mechanisms of search and obtaining the flower's resources availability were registered. 3994 specimens corresponding to 38 genera and 68 species included in 5 families were sampled. Bombus bellicosus (n= 594; 14.87%), B. morio (n=718; 17.97%), B. opifex (n=872; 21.83%), Dialictus sp. 2 (n=158; 3.95% at total) y Xylocopa ordinaria (n=342; 8.56%) were the dominant species. Period between '96-'97 was the most important in relation to the diversity and abundance of native bees. During others periods few differences in relation to the first years were established. During the study specimens of Bombus and Halictidae were the first species to appear at the beginning of spring that continued until the summer was finished. Anthophoridae and Megachilidae predominated at finish of spring, but Andrenidae and Colletidae were more important at beginning of summer. Angiosperms (principally Apiaceae, Asteraceae, Fabaceae, Lamiaceae, Malvaceae, Solanaceae and Verbenaceae) including 34 families and 129 species, were used by bees as floral resources. During the study there were not differences about the diversity of plant species. Important differences between years in relation to the utilization of resources was established. We can conclude that in the three years the families more abundant was Apidae y Halictidae. In relation to the utilization of resources, we established an important differences between years. Dominant species to select the resources were the most generalist bees.

Index terms: Bombus, Xylocopa, Dialictus, Colletidae, Andrenidae.

[1165] RELATIONSHIP BETWEEN CARPENTER BEES (HYMENOPTERA: APIDAE) AND THE FLORA OF THE CHACO SERRANO IN CENTRAL ARGENTINA

C.A. Sosa & M. Manfrini de Brewer, Centro de Inv. Entomol. F.C.E.F. y N. Univ. Córdoba. Av. Vélez Sársfield 299 C.P. 5000. Córdoba. Argentina. E-mail: csosa@com.uncor.edu

The fauna of carpenter bees (Xylocopinae) and the relationship with the flora of the Bosque Serrano in Córdoba (Argentina) was analyzed. Four samples monthly were made during october to march between 1994 and 1995, at two localities in Córdoba: Cabana (30°20'S, 64°10'O) and Quebrada Los Hornillos (31°10'S, 64°10'O). Both sites are in the Chaco Serrano area. The carpenter bees were captured during the period of more activities (between 9-13 Hs.) and when were on the flowers. The patterns of activities and the diversity of plants that they visited were observed. Five species of carpenter bees were registered: Xylocopa ordinaria (84,27%), X. splendidula (10,110%), X. artifex (2,25%), X. subcyanea (2,25%) and X. ciliata (1,12%). Females were predominant (96,63%), all specimens of X. ordinaria and splendidula were female. Males (3,37%) were registered in X. artifex, X. ciliata and X. subcyanea only. The bees visited 22 species of plants including in Acanthaceae, Asteraceae, Apiaceae, Fabaceae, Lamiaceae, Lythraceae, Solanaceae and Zygophillaceae. Three patterns of behavior were established: lodging on flower (principally in the visits to Asteraceae and Apiaceae), entering into the corolla (in Fabaceae and Lamiaceae) and vibrating the anthers (exclusive on Solanaceae's flowers). At 60% of the visits, the bees tacked nectar, at 47% collected pollen and the 23% without resources. The results show that each species of Xylocopa presented a specific behavior when a particular plant was visited: X. ciliata will be monolectic on Asteraceae; X. artifex, X. subcyanea and X. splendidula will be oligolectic on Asteraceae, Fabaceee and Solanaceae; and X. ordinaria will be polilectic on all families of plants observed. During this periods of studies there are no differences in the relationship carpenter bees-plants between localities and years.

Index terms: Xylocopa, floral resources, behavior.

(1166) POPULATION BEHAVIOUR CHANGES OF THE PROCESSIONARY MOTH (*THAUMETOPOEA PITYOCAMPA*) IN PORTUGAL

E. Sousa, M. Moreira & M.L. Inácio, Dept. Protecção Florestal. EFN. Quinta do Marquês 2780 Oeiras. Portugal E-mail: dpf.efn@mail.telepac.pt.

The Leiria National Forest is a 28 acres state propriety in the middlewest of Portugal of maritime pine (*Pinus pinaster*), considered to be a climax area for this forest species. Normal processionary moth defoliation is being detected every year in these pine stands. However, since 1997 abnormal intensive defoliations were observed during summer periods causing a new considerable tree damages, and the agent was identified as *Thaumetopoea pityocampa*. These observations reveal a change in the population behaviour which seems to by related to a bio-ecological readjustment induced probably by biotic and/or abiotic factors. The previous documented knowledge of the *T. pityocampa*, such as thermal requirements and thresholds, and the data from captures of light and sexual feromone bailed traps placed in some pine plots were analysed by degree-day methods in order to develop an adult emergencies predictive model. This forecast model will be an important tool to prevent future abnormal population outbreaks.

Index terns: Thaumetopoea pityocampa, Pinus pinaster, biological cycle changes, Portugal

[1167] HOST PLANTS OF ZAPRIONUS INDIANUS IN THE STATE OF SÃO PAULO, BRAZIL

M. F. S. Filho¹, D. A. O. Prestes¹, M. E. Sato¹ & A. Raga¹, ¹Inst. Biológico, Caixa Postal 70, Campinas, SP, Brasil, 13001-970, E-mail: miguelf@dglnet.com.br.

Zaprionus indianus (Dip.: Drosophilidae) was detected in Brazil in February 1999 infesting fig fruits (Ficus carica), in Valinhos County, State of São Paulo. Losses of 40% were estimated in the fig orchards without including decaying vegetable matter. The females oviposite in the superficial ostiole and the larvae move into the syconia for feeding. Probably fungus and yeast are inoculated in the fruit. The cavity of ripening figs bears a big number of adults which can be found in foraging and mating. In that County, adults of Z. indianus infest also fresh figs in summer period where the high relative humidity and temperature are characteristical conditions. Zaprionus. indianus is considered a polyphagous species and it is abundant in ripe fruits. Adults were found in rotten vegetables on the soil. In the field several fruit samples were collected to identify the main hosts of Z indianus in the State of São Paulo. Fruits hanging on the tree and from the ground were collected and kept in the laboratory. Adults emerged from 22 botanical species (14 exotics and 8 natives) belong to 10 families as follow: Anacardíaceae (Mangifera indica, Spondias purpurea), Combretaceac (Terminalia catappa), Ebenaceae (Diospyrus kaki), Malpighiaceae (Malpighia glabra), Mimosaceae (Inga affinis), Musaceae (Musa spp.), Myrtaceae (Eugenia involucrata, E. pyriformis, E. schomburgkii, Janbosi, Oxalidaceae (Averritoa carambola), Rosaceae (Eriobotrya japonica, Prana mume, P. persica, Fragaria x ananassa, Pyrus communis) e Sapotaceae (Achras sapota). Index terms: Drosophilidae, Ficus carica, hosts.

[1168] EFFECT OF NYMPHAL DENSITY ON DEVELOPMENT AND PERFORMANCE OF *LEPTOGLOSSUS ZONATUS*, THE LEAF-FOOTED BUG (HETEROPTERA:COREIDAE) ON CORN (*ZEA MAYS*)

C. E. P. Souza^{1, 2, 3}, B. F. Amaral-Filho^{1, 3} & A. Mafra-Neto^{1, 2}, 1- Fac. Filos. Ciênc. e Letras de Ribeirão Preto, Univ. de São Paulo, Av. Bandeirantes, 3900, Ribeirão Preto São Paulo, Brazil, 14040-901; 2- 100A Chapman Hall Univ. of California-Riverside, Riverside, United States, 92521; 3- Univ. Est. de Campinas – Depto. de Zoologia, caixa postal: 6109, Campinas. São Paulo, Brazil.

The duration of nymph stage, percentage of mortality, weight of the adults (male and female), the sexual ratio and reproductive activities of the leaf-footed bug *L. zonatus* fed on corn were studied under controlled laboratory conditions. The experiment consisted of the standardization of size of the rearing space and the amount of food to supplied to *L. zonatus* fed on (T1), 10 nymphs (T2), 15 nymphs (T3), 20 nymphs (T4) and 25 nymphs (T5). The duration of the nymph stage was shortest at the lowest density (T1= 31.25 \pm 0.25 days). The rate of survivorship was highest for T4 (51%) and lowest for T5 (38.28%). The sexual ratios varied among treatments: T1=0.6; T2=0.23; T3=0.54; T4=0.45 and T5=0.53 (ratio=females/males). Mating significantly reduced the longevity of females: the longevity of unmated females was 114,8±15.0 days whereas mated females lived only 50.20±10.1 days. Females had higher fresh body weight than males, except for those in treatment T1. We discuss some of the possible adaptive and developmental advantages of aggregation for *L. zonatus*.

Index terms: Leptoglossus zonatus, nymphal density, leaf-footed bug, coreid, corn

[1169] CONTRIBUTIONS TO THE BIOLOGY AND ECOLOGY OF NEOLEUCINODES ELEGANTALIS (LEPIDOPTERA: CRAMBIDAE)

C. M. de Souza¹, <u>J. L. Blackmer</u>² & A. M. Viana-Bailez¹, ¹Lab. de Proteção de Plantas, Univ. Estadual do Norte Fluminense, Campos dos Goytacazes, RJ, Brazil, CEP: 28015-620, E-mail: claudio@uenf.br. ²Current address: USDA-ARS, 4135 E. Broadway Rd., Phoenix, Arizona, USA 85040-8803.

Neoleucinodes elegantalis, the small tomato borer, is one of the most important tomato pests in South America. Localization of the preferred oviposition sites, as well as a better understanding of the life cycle of this moth could facilitate field monitoring and/or improve pest management methods. From 1998 to 1999, in the region of São José de Ubá, Rio de Janeiro, Brazil, several commercial tomato fields were monitored for eggs of N. elegantalis. Eggs were detected on adaxial (4.3%) and abaxial (15.8%) calyx surfaces, petiole (2.5%), fruits (77.0%), and rarely on flowers. Most eggs (67.2%) were oviposited on fruits 21-35 mm in diameter. A large percentage (78.00%) of egg masses had fewer than 1-4 eggs, which suggests that N. elegantalis may use an egg-spacing or ovipositiondeterring pheromone. Laboratory assays were used to gain a better understanding of the basic biology of N. elegantalis. Eggs were obtained using paraffin-coated artificial fruit (35 mm diameter, dark green or red). At 15, 20, 25, and 30 °C egg hatch occurred between 8-12, 7-10, 7-10, and 5-6 d, and egg viability was 83, 99, 100, and 90%, respectively. Most eggs (70.0%) hatched during the first hour of photophase. The larval to pupal period ranged from 28-35 d and pupal weights were 51.3 ± 8.0 and 59.8 ± 7.0 mg for males and females, respectively. A large percentage of adults (51%) emerged within 4 to 6 h after the initiation of scotophase. The majority of copulations (65.5%) occurred 24 to 48 h after emergence, and 5 to 7 h after the initiation of scotophase (56.5%).

Index terms: small tomato borer, oviposition, life cycle, tomato, artificial oviposition substrate

[1171] TOXICITY OF TOMATO ALLELOCHEMICALS TO EGGS AND NEONATE LARVAE OF Neoleucinodes elegantalis (LEPIDOPTERA: CRAMBIDAE)

C. L. M. de Souza¹, A. M. Viana-Bailez¹ & <u>J. L. Blackmer</u>², ¹Lab. de Proteção de Plantas, Univ. Estadual do Norte Fluminense, Campos dos Goytacazes, RJ, Brazil, CEP: 28015-620, E-mail: claudio@uenf.br. ²USDA-ARS, 4135 E. Broadway Rd., Phoenix, Arizona, USA. 85040-8803.

Neoleucinodes elegantalis, the small tomato borer, is one of the most important pests of tomatoes in South America. The wild tomato genotypes, Lycopersicon hirsutum f. hirsutum and L. hirsutum f. glabratum, are the main sources of resistance genes against several insect pests of tomato. These genotypes possess high densities of glandular 2-tridecanone (2TD), 2-undecanone trichomes, which have high concentrations of (2UD) and zingiberene (ZIN). The objective of this work was to evaluate the toxicity of these substances to the eggs and neonate larvae of N. elegantalis. The eggs and larvae were exposed to filter paper that had been treated with increasing concentrations of these compounds, which were first dissolved in acetone, and then allowed to evaporate. The average concentrations corresponded to those detected in wild genotypes (12.5, 60 and 125 mg/ml for 2UD, 2TD and ZIN, respectively). The methyl ketone, 2TD, was extremely toxic to eggs and resulted in 62.5 and 97.5% mortality at 40 and 120 [g/[], respectively. 2UD and ZIN were less effective, even at the highest concentrations (20 and 200 De/11, respectively), only resulting in 17.5 and 20% egg mortality. Egg viability for control treatments (water and acetone) was 92.5 and 90.0%, respectively. For neonate larvae, 40 and 120 g/01 of 2TD resulted in 72.5 and 95% mortality, respectively. ZIN at 200 □g/□l and 2UD at 20 □g/□l resulted in 67.5 and 20% mortality, respectively. Survival of larvae, 5-6 h after the initiation of tests, for control treatments (water and acetone) was 100 %. These findings indicate that 2TD, a methyl ketone present in type VI trichomes of L. hirsutum f. glabratum, holds promise as an alternate means of controlling both eggs and neonate larvae of N. elegantalis.

Index terms: 2-tridecanone, 2-undecanone, zingiberene, Lycopersicon hirsutum, small tomato borer

[1170] OVIPOSITION PREFERENCE AND DEVELOPMENT OF NEOLEUCINODES ELEGANTALIS (LEPIDOPTETRA: CRAMBIDAE) ON TOMATO GENOTYPES

C. M. de Souza¹, <u>J. L. Blackmer</u>² & A. M. Viana-Bailez¹, ¹Lab. de Proteção de Plantas, Univ. Estadual do Norte Fluminense, Campos dos Goytacazes, RJ, Brazil, CEP: 28015-620, E-mail: claudio@uenf.br. ²Current address: USDA-ARS, 4135 E. Broadway Rd., Phoenix, Arizona, USA 85040-8803.

The wild tomato genotypes, Lycopersicon hirsutum f, hirsutum (Hir) and L, hirsutum f. glabratum (Gla) have been shown to be resistant to several insects, primarily due to their high densities of glandular trichomes and defensive allelochemicals. Despite the economic losses caused by Neoleucinodes elegantalis, the small tomato borer, limited effort has gone into screening cultivars for resistance against this pest. A moderate level of resistance against N. elegantalis has been reported for the cultivars Angela Hiper (Ah) and Roma VF (Rvf); however, a susceptible cultivar, Santa Clara (Sc) is widely planted throughout Brazil. The presence of either antixenotic and/or antibiotic resistance to N. elegantalis was examined under greenhouse conditions using choice and no-choice tests with the genotypes Hir, Gla, Ah, Rvf and Sc. Choice tests were setup in a randomized block design with 5 genotypes, 4 blocks, and 3 plants/genotype/block. No-choice tests were setup in a randomized entirely design with 5 genotypes and 6 repetitions. Oviposition preference and development of N. elegantalis were used to characterize resistance. N. elegantalis did not deposit eggs on Hir or Gla, suggesting that these two genotypes may possess traits (chemical or mechanical in the form of trichomes) that interfere with oviposition. Among the cultivars tested, *N. elegantalis* exhibited a significant preference, at least with regards to oviposition, for Ah over either Sc or Rfv fruits. Significant differences were also observed among these cultivars for the larval-pupal period and pupal weights. The larval-pupal period was significantly longer and pupal weights were lower for insects reared from Rfv (23.5 d; 40.8 mg) than for either Ah or Sc (20.96d; 49.2 mg and 20.57 d; 44.6 mg, respectively). No differences in egg hatch or viability, larval viability, pupal period or viability, sex ratio or adult viability were observed among the cultivars tested. These findings suggest that the wild genotypes possess traits, probably antixenotic in nature, that interfere with the initial stages of host finding and/or acceptance, while the cultivar Rfv possess traits, probably antibiotic in nature, that interfere with normal development.

Index terms: Host-plant resistance, antixenosis, antibiosis, Lycopersicon esculentum, Lycopersicon hirsutum

[1172] OCCURRENCE AND BIOECOLOGICAL ASPECTS OF WHITEFLIES (HOMOPTERA; ALEYRODIDAE) ON CITRUS ORCHARDS IN THE STATE OF RIO GRANDE DO SUL, BRAZIL

<u>S.S.P. Souza</u>¹ & P.C.R. Cassino¹, ¹Dept. de Entomologia e Fitopatologia, IB, Univ. Federal Rural do Rio de Janeiro, BR 465 Km 7, Seropédica, RJ, CEP 23.890-000, Brasil, E-mail sousolsp@ufrj.br, pr.cassino@uol.com.br.

A field work was conducted with the aim of studing the bioecological aspects of Aleyrodidae in order to develop a binomial sampling plan of presence-absence for Aleurothrixus floccosus, Dialeurodes citrifolii, Aleurotrachelus cruzi, and Paralyrodes bondari. Insect samples were taken randomly from September, 1995 to March, 1998 in 23 cities of the state of Rio Grande do Sul, in the south of Brazil. The samples were taken in two citrus orchards of 'Valência' localized in the counts of Butiá e Viamão, with the purpose of monitoring aleirodids species. In the others 21 cities visited, the principal aspects observed it was the occurrence of the species of 'whiteflies' in order to obtain the geographical distribution of them in this state. Sixteen citrus trees were sampled, and 4 opposite branches/tree in two height's levels were evaluated weekly. The population dynamics of those species were established using the degree of infested leaves estimated by the binomial sampling plan. The patterns of distribution of the aleirodids species were by the binomial sampling plan. The platents of the interaction of the interaction of the properties of infested leaves were estimated through the Wilson & Room's mathematical model. The number of samples needed to evaluate the population density was calculated ($\infty = 0.2$ and D = 0.1 - 0.2). The results showed that sample sizes with standard error 0.2 were more feasible for monitoring whiteflies in citrus orchards. The efficacy of the methods used, in this experiment demonstrated that they should be used in monitoring program of Aleyrodidae in citrus IPM systems. However, it is necessary to be aware, because these results may not be applicable to other regions due to the own behaviour of the alcirodids species, cultivars and localities. The degrees of frequency (occurrence) for each specie in the 23 cities visited for this purpose were: A. floccosus (100%), D. citrifolii (87.50%), P. bondari (66.17%), A. cruzi (50%), Bemisia tabaci (41.67%), Trialeurodes vaporariorum (29.17%) as well as P. crateraformans.

Index terms; Citrus whiteflies; citrus pests; Aleurothrixus floccosus; Dialeurodes citrifolii; Aleurotracheulus curzi; Paraleyrodes bondari; Bemisia tabaci.

[1173] DETERMINATION OF THE SPATIAL DISTRIBUTION OF CITRUS WHITEFLEIS' BY OF TAYLOR'S POWER LAW COEFFICIENTS AND WILSON & ROOM'S MATHEMATICAL MODEL ON 'VALÊNCIA' CITRUS ORCHARDS, STATE OF RIO GRANDE DO SUL, BRAZIL

S.S.P. de Souza¹ & P.C.R. Cassino^{1,2}, ¹²Dept. de Entomologia e Fitopatologia, IB, Univ. Federal Rural do Rio de Janeiro, BR 465 Km 07, Seropédica, RJ, CEP 23.890-000, Brasil, E-mail: sousols@ufrrj.br, 2pr.cassino@uol.com.br.

Prior knowledge of the model of spatial distribution of species, pest, and natural plant enemies is a key factor which should be taken into account in developing sampling methods in agroecosystems, since the position occupied by an specimen in relation to one another within a population is the most important ecological characteristics of the species because of their bearing on birth and deaths of individuals. In the identification of the organisms distribution within their populations various biological patterns of mathematical models can be used for frequencies distributions, and the Poisson's function most properly describes the randomness of such organisms. However, the pieces of research conducted in this field have shown that the insects spatial distributions usually do not follow that pattern, and such distributions are most precisely described by some of the existing contagious distributions. On observing the importance of this feature, and the lack of studies on Aleyrodidae on Citrus spp., the option was to conduct such studies by using the Taylor's power law, by means of the calculation of the relation variance/average of data at each sampling, and then the mathematical model proposed by Wilson & Room (1983) was tested. This piece of research was conducted at the municipalities of Butiá and Viamão, state of Rio Grande do Sul. Samplings were made weekly for and two years and six months (September, 1995 to March, 1998), on orange tree leaves cv. Valência'. Species observed were: Aleurothrixus floccosus, Dialeurodes citrifolii, Paraleyrodes bondari, and Aleurotrachelus cruzi. Results showed that the models adopted for the identification of the spatial distribution of these species under the specific conditions in those regions were effective for species showing higher population density per leaf (for instance, A. floccosus, on both sites) and, inadequate for those which showed low population levels (such as A. cruzi, D. citrifolii, and P. bondari, at Butiá, and P. bondari and D. citrifolii at Viamão). It was also observed that every species shows a tendency to follow a differentiated mathematical model according to its spatial distribution.

Index terms: A. floccosus, D. citrifolii, P. bondari, A. cruzi, distribution.

[1174] A REGRESSION METHOD FOR IN SITU ESTIMATION OF APHID NUMBERS

J. Srikanth, Sugarcane Breeding Institute, Coimbatore 641007, India

In situ estimation of aphid numbers in aggregations on plant parts demands consideration of colony characteristics, such as the extent of plant surface colonized and the intra-plant variation in colonization rate relative to surface area. Using Aphis craccivora Koch (Homoptera : Aphididae) on cowpea as case study and regression analysis between aphid number (colony size) and the three colony dimensions, viz. length (colony length), circumference (colony thickness) and surface area (colony area) of colonized portions, I show that colony area as the predictor gives the best estimate of aphid numbers on stems and pods. In three arbitrary infestation classes, namely heavy, medium and low, colony size showed the highest correlation coefficient with colony area followed by colony length and colony thickness, in both stem and pod. Standard partial regression coefficients of colony dimensions also indicated the relative importance of colony area as predictor of colony size. Simple linear regression between colony size and colony area was adequate for aphid number estimation, as multiple regression with combinations of colony characteristics did not significantly improve prediction. Significantly different colonization rates in stem and pod, particularly at high densities, necessitate estimation of different regressions for colony size estimation on these parts. In situ estimation of aphid numbers on stem or pod involves two steps: laboratory standardization of regression equations between colony size and colony area in different infestation classes for these parts separately; in situ estimation of aphid number on sampled plant part by predicting from colony area using the regression equations. By assigning 100 % coverage of colony area to the sample colony with the highest density cm2, and sorting the sample colonies in the descending order, I generated colony data for five proposed infestation classes in stem and pod. With correlation and regression analysis of these simulated colony data, I demonstrate that estimation of aphid numbers can be improved further by increasing the number of classes as well as defining them more objectively on the basis of per cent coverage of colony area. I also discuss the extension of the method to other hosts of the aphid and to other homopteran insects that aggregate or form dense sedentary colonies.

Index terms: Aphis craccivora, estimation of numbers, infestation classes, correlation and regression

[1175] DEMOGRAPHIC ECOTOXICOLOGY: AN ACTUARIAL PERSPECTIVE ON PESTICIDE EFFICACY

D. Stark, Ecotoxicology Program, Dept. of Entomology, Washington State Univ. Puyallup, Washington 98371 USA, E-mail stark@puyallup.wsu.edu.

Demography is a powerful tool that can be used to develop estimates of the total effect of toxicants (lethal and sublethal) at the population rather than the individual level, something that traditional toxicological assays can't do. Here I will present several examples of demographic ecotoxicology, showing the advantages and disadvantages of this approach. I will also examine alternate methods for estimating population growth rate that are faster and less expensive than developing life tables yet provide a good approximation of r. An example will be presented using a matrix modeling approach based on life table data, that determines the combinations of pesticide-induced mortality (lethal effect) and reduction in fecundity (sublethal effect) that result in positive, negative, and stable population growth rates (r) for the Seven-Spot lady beetle, Coccinella septempunctata L. and its prey, the pea aphid, Acyrthosiphon pisum Harris. The level of mortality and reduction in fecundity that populations of each of these species can withstand is very different and appears to be dependent upon intrinsic life history variables. Differences in life history variables among species should therefore be a major consideration in risk assessment and when considering integrating pesticides and biological controls.

Index terms: matrix models, life history variables, risk assessment

[1176] THE BLACK SCALE OF GRAPES TARGIONIA VITIS IN GREECE

G. J. Stathas & D.C. Kontodimas, Dept. of Entomology, Benaki Phytopathological Inst., 8 S. Delta Str., 145 61-Kifissia (Athens), GREECE, E-mail bpilibr@otenet.gr

The phenology and natural enemies of the diaspidid, Targionia vitis, were studied in ifested vineyards in Greece in 1998-99. In Southern Greece, this viviparous species, develops one generation per year and overwinters as a mated female. Fecundity was estimated by dissecting not yet-reproducting females collected during the first 10 days in May and recording the eggs inside, was found to be 82 - 105 eggs. The neonate crawlers appeared in mid - May. First and second instar nymphs appeared in June and developed to male and female nymphs by mid - July. The flights of males were observed from mid -July until the end of August. By the beginning of September the whole population consisted of mated females. The aphelinid parasitoid, Aphytis abnormis was observed to parasitise second instar nymphs and adult females of the scale. The parasitisation percentage reached 7% by the end of August – beginning of September. Larvae and adults of the nitidulid predator Cybocephalus fodori were also recorded. Index terms: Aphytis abnormis, Cybocephalus fodori, diaspidid, phenology, fecundity.

[1177] BIOLOGICAL ASPECTS OF ZAPRIONUS INDIANUS, A NEW PEST OF FICUS CARICA IN VALINHOS, SÃO PAULO, BRAZIL

C.P. Stein¹ & E.P. Teixeira¹, Centro de Fitossanidade, Instituto Agronômico de Campinas, Caixa Posta 28, 13001-970, Campinas, São Paulo, Brasil, E-mail: cpstein@cec.iac.br, edson@cec.iac.br

Zaprionus indianus (Diptera: Drosophilidae) was registered for the first time in Brazil as a pest of fig (Ficus carica var. roxo-de-valinhos) in March of 1999 in Valinhos, São Paulo State. At this time, this fly caused a loss on prodution and exportation of fig around 40% and 80%, respectively. This species is common in Africa and was fist described from material collected in the India. Apparentely it has rapid progression in the tropical region. The female lays its eggs inside the ostiole. After enumerging, the larvae reachs the interior of the fruit which becomes inapropriate for the consumption. Besides two native species of the Brazilian Cerrado, lobeira (Solanum licocerpum) and araticum (Annona crassiflora), 74 botanical species belonging to 31 families were registered as hosts for Z. indianus. The species has been observed in Santa Catarina, Rio de Janeiro, Minas Gerais, Mato Grosso do Sul and Goias States. Experiments to elucidate biological aspects of this fly were carried out in laboratory. Samples of the fly were kept at 25 ± 1° C, 14-hour photophase, in artificial diets (banana, yeast) with or without dietary supplement (Saccharomyces cerevisiae). The observations demonstrated that the incubation period ranged from 24 to 36 hours; larval period from 8 to 15 days; pupal period from 4 to 9 days. The longevity of adults mated ranged from 24 to 83 days and 21 to 96 days, with and without dietary supplement, respectively. The adults life span individualized with dietary supplement ranged from 5 to 56 days. There were no significant differences between the longevity of males and females in all the cases. The average number of adults originated from a couple without dictary supplement was 75,87 (33 - 134) while those ones with dietary supplement produced 313,50 (93 - 698) adults. The sex ratio has 0,5607. Index terms: Diptera, Drosophilidae, biology, damage.

Symposium and Poster Session

[1179] ALTITUDINAL MIGRATIONS OF BUTTERFLIES AND OTHER INSECTS IN NORTHWESTERN COSTA RICA: ECOLOGY AND CONSERVATION

R. D. Stevenson¹ & W. A. Haber², ¹ Dept. of Biology, Univ. of Massachusetts, Boston, MA, 02125, USA, ²Missouri Botanical Garden, P.O. Box 299, St. Louis, MO 63166, USA; E-mail robert.stevenson@umb.edu

Over the past 15 years, a variety of studies and approaches (direct observations, flight traps, censuses of forest fragments and extensive forest tracts) centered at Monteverde, have established altitudinal and cross-country migrations of butterflies over the Tilarán mountains (Puntarenas, Alajuela, and Guanacaste Provinces). Approximately 60% of the 263 butterfly species censused (many more occur) in the dry forests of the Pacific lowlands below Monteverde migrate to the highlands or the Atlantic coast. A higher proportion, 75% of the 594 species recorded in Monteverde, leave or pass through the region (1200-1800 m). Beetles, wasps, and dragonflies have also been observed to migrate. The migrations have complex seasonal patterns that are correlated with climate and phenological changes. Rainfall ceases from mid November to mid May in the Pacific lowlands, and many species leave during this time of year. The F1 generation produced in the Pacific lowlands by adults that came from the Atlantic side in April and May, migrates back to the Atlantic side from late June through July creating another peak in migration intensity. Examples of specific species will illustrate the complexity of the patterns. Seasonal migration is clearly an important ecological phenomenon for Costa Rican butterflies and other insects, but our current knowledge of the biology of many rare species is too incomplete to assess their conservation status. Nevertheless, the effect of deforestation, fire, and use of pesticides probably reduces lowland populations and threatens some species. In the context of the likely historical changes in the butterfly fauna, alternative hypotheses about the vulnerability to extinction of Pacific lowland migrant and resident butterflies are presented.

Index terms: Butterflies, insects, tropics, migration, conservation.

[1178] SURVEY OF VECTORS SHARPSHOOPERS OF XYLELLA FASTIDIOSA IN COFFEE PLANTATIONS IN SÃO PAULO STATE, BRAZIL

<u>C. P. Stein</u>, Centro de Fitossanidade, Instituto Agronômico de Campinas, Caixa Posta 28, 13001-970, Campinas, São Paulo, Brasil, E-mail: cpstein@cec.iac.br

The bacteria Xylella fastidosa is a plant parasit that in Brazil has been observed mainly in cultures of plum and citrus. This bacteria was registrated for the first time infecting coffee plants causing the "coffee branch atrophy" disease, in cultures in Macaubal and São José do Rio Preto, São Paulo State, in 1995. The sharpshoopers of the family Cicadellidae (Cicadellinae) and Cercopidae which feed on xylem are known as the major vectors of the X. fastidiosa. A survey to verify the occurring especies of sharpshoopers in coffee plantations in São Paulo State, was carried out in 8 differents sampling dates at plantations of Coffea arabica var. Mundo Novo in Pindorama, Mococa (feb – jun/99) and Campinas (mar – jul/99). Samples were performed using yellow strick traps (10 x 24 cm) hung on the plants at height of 1.5 m from the ground. In this way, 2135, 1004 and 1330 specimes were trapped, respectively in Pindorama, Mococa and Campinas. From these, Cicadellidae represented 80.70, 75.00 and 88.95% of the total sharpshoopers trapped. The major species trapped in Pindorama, Mococa and Campinas were Oncomotopia fascialis (24.59; 24.00; 61.13%), Dilobapterus costalimai (3.37; 2.23; 18.20%) and Acrogonia terminalis (9.23; 2.69; 2.48%), that belong to Cicadellinae subfamily. These three trapped species of Cicadellinae represented 55.36% (Pindorama), 27.09% (Mococa) and 83.92% (Campinas) of the total of shapshoopers trapped.

Index terms: Coffea, Cicadellidae, Oncomotopia fascialis, Dilohopterus costalimai, Acrogonia terminalis. [1180] FEEDING AND METABOLIC RATE OF GALUMNA ELIMATA (ACARI: ORIBATIDA) UNDER DIFFERENT TEMPERATURES

V. Šustr¹ & J. Huberl², ¹Academy of Sciences of the Czech Republic, Inst. of Soil Biology, Na sádkách 7, České Budějovice, 370 05, Czech Republic, E-mail sustr@upb.cas.cz; ²Research Inst. of Plant Protection, Drnovská 507, Praha 6, 161 06, Czech Republic.

The oribatid mite Galumna elimata was reared under laboratory conditions on algae (*Protocccus* spp.) at different temperatures (5-30°C) for 21 days. The ability of the physiological compensation of feeding activity for temperature was tested. Oxygen consumption of mites increased with temperature. This relationship was similar before and after acclimation, no compensation was observed. Presence of animals on algae food increased exponentially with temperature before acclimation, but it was higher at 15°C after acclimation at constant temperature. Defecation increased exponentially with temperature, the relationship was similar before and after acclimation. The food boluses contained algae or algae mixed with unknown fungal hyphae in individuals acclimated to 15 and 20°C. The concentrated mucoid substances prevailed in animals exposed to cold, indicating lower feeding activity at 5°C. However, the higher weight-specific amylolytic activity was found in the whole body homogenates of mites exposed to cold acclimation (5°C) in comparison with individuals acclimated to 15 and 20°C. The acclimation response of weight-specific amylolytic activity was accompanied by elevation of protein-specific amylolytic activity. Microanatomical features did not confirm any increased secretion activity of mesenteric and caecal cells in cold acclimated animals. Granulation and apocrine secretion of these cells increased with increasing temperature as with food ingestion. Based on these findings, we concluded that specific amylolytic activity reflected passively the different changes in protein composition of the body at different temperatures and its elevation is without direct adaptive importance. The results were used for preliminary estimation of production of fecal pellets during the year in natural conditions

Index terms: mites, respiration, defecation, amylase, acclimation.

[1181] INTERACTIONS OF MICROFLORA AND LARVAE OF BIBIONIDS IN TRANSFORMATION OF PLANT LITTER

V. Šustr & J.Frouz, Academy of Sciences of the Czech Republic, Inst. of Soil Biology, Na sádkách 7, České Budějovice, 370 05, Czech Republic, E-mall: sust@upb.cas.cz

Dipteran larvae play an important rule in soil of some deciduous forests. They may consume an important part of annual litter fall and produce large amount of faecal pellets, which may form an important part of fermentation horizon of some moder forest soils. The changes of leaf litter during the passage through the gut are important for consequent changes of faecal pellets. The quality of produced faecal pellets influence litter micro-flora and soil forming processes in the forest. We measured the changes of pH, direct counts of bacteria and pH optimum of enzymatic activity in digestive tract of larvae of Bibio marci and Penthetria holosericea (Bibionidae). The pH of the litter offered as a food was about 5. The gut content became highly alkaline (pH about 10) in anterior part of the midgut. pH decreased in the posterior part of the midgut and in the hindgut and excrements had neutral or slightly alkaline pH (about 7.5-8). The direct counts of bacteria decreased strongly in the midgut content in comparison with litter and midgut caeca. Their numbers increased again in freshly produced excrements. Similar pattern appeared when the excrements are re-consumed, but the absolute numbers of bacteria were higher. The pH optimum of amylase was about 10. Similar results were obtained in both species. In Penthetria holosericea, pH optima of other carbohydrases were 7 (trehalase and cellobiase) or 8 (maltase and saccharase). Bacteria killed in the anterior part of the midgut may be important food source for larvae and the utilization of bacterial assemblage growing in excrement can be one from the reasons for coprophagy. The pH optimum of amylolytic activity indicated, that maximum of amylase activity may be expected in alkaline anterior midgut where the bacteria were suppressed. This supported the idea that amylase is of animal origin. Recently, similar method is applied to receive some indication about the role of micro-flora and gut wall cells in production of other enzymes including enzymes of cellulase complex.

Index terms: Diptera, Bibionidae, digestion, bacteria, amylase.

[1182] RESPONSE OF APHYTIS MELINUS TO AN EXPERIMENTALLY-INDUCED OUTBREAK OF CALIFORNIA RED SCALE

<u>S. L. Swarbrick</u>¹ & W. W. Murdoch², ^{1, 2} Dept. of Ecology, Evolution & Marine Biology, Univ. of California, Santa Barbara, CA, 93106-9610, USA

Control of California red scale, Aonidiella aurantii, by the parasitic wasp, Aphytis melinus, is an outstanding example of successful biological. Scale populations are kept at very low densities and the abundance of both scale and parasitoid is remarkably constant over many The ecological processes underlying the success have not yet been generations. established. In these, as many other insect populations, it has been difficult to detect density-dependence. Nevertheless, our previous experiments suggest that regulation occurs on the local spatial scale.We are conducting a large-scale field experiment in a lemon grove in Fillmore, California, aimed at demonstrating the role of A. melinus in controlling red scale and at discovering the mechanisms producing the stable interaction between the host and parasitoid. We created scale outbreaks in individually-caged lemon trees by adding scale crawlers over a single generation (3 months). Controls are caged trees with no scale added and uncaged trees in the grove. We then measured abundance of red scale and A. melinus, and parasitism, as scale converged to ambient control density. The results show the parasitoid controlling and regulating the scale population with astonishing speed. Scale populations converged to ambient density within a year. There is a clear density-dependent response in parasitism by *A. melinus*. This suggests that failure to detect density dependence in previous studies may be due to the tightness of the regulation. Control occurred on individual trees, confirming previous suggestions that regulation of pest abundance occurs locally. Control may occur on an even smaller spatial scale. A previous experiment showed apparent convergence of scale to ambient density following an outbreak created on a single, large, caged branch of a grapefruit tree. Experiments to explore the detailed mechanisms are now in progress.

[1183] DYNAMICS OF OCCURRENCE OF CRIOCERIS ASPARAGI (COL., CHRYSOMELIDAE) AS OBSERVED AT AN ASPARAGUS PLANTATION WITHIN A 15 YEARS' LASTING TIME LAPSE

<u>J. Szweida</u>, Research Institute of Vegetable Crops, ul. Konstytucji 3 Maja 1/3, 96-100 Skierniewice, Poland, E-mail jszwejda@inwarz.skierniewice.pl

Asparagus beetle (*Crioceris asparagi*) occurring at the same asparagus plantation in 1983, 1984 and 1999 was subjected to observations on its biology and intra-seasonal occurrence dynamics. In 1983 and 1999 - egg, larval and adult developmental stages were less numerous within the first than in the second generation of asparagus beetle, the situation in 1984, however, being reversed. Weather conditions have been found the most important factor affecting the occurrence of *C. asparagi*. Adult beetles were always observed at the end of April during the emergence of plants. Observations on location of eggs laid by females on asparagus in the three cited years have revealed that the most attractive plant part, comprising from 50 to 80 % of eggs laid were the "needles" and then flowers, lateral branches and main stems with shares reaching up to 25, 10 and 5 %, respectively. Studies on harmfulness of larvae have shown that five individuals can completely destroy the upper part of the stem causing a precocious yellowing and drying up of the asparagus plant. No significant differences in the time of adult occurring, egg laying and larvae developing have been stated between the study years compared.

[1184] THE INFLUENCE OF INCREASED ATMOSPHERIC CO2 AND TEMPERATURE ON NEPHOTETTIX CINCTICEPS LIFE CYCLES ANDECOSYSTEMS

O. Takahashi, 1, M. Okada 2, K. Kobayashi 3 & S. Kawabe3, 1 Dept.of Entomology, Iwate Univ. 3-18-8, Ueda. Morioka. Iwate 020-8550, Japan.; 2 Tohoku National Agricultural Experiment Station. 4 Akahira. Shimo-kuriyagawa. Morioka. 020-0123, Japan. 3 National Institute of Agro-Environmental Sciences. 3-1-1, Taukuba, Ibaraki 305-8604, Japan.

It is predicted that atmospheric CO2 concentration will increase up to about 560ppm by the middle of 21th century. Because CO2 is a "greenhouse" gas, the increase in atmospheric CO2 is also predicted to affect the Earth's temperature with expected increases of about 20 by the year 2050. This will affect the ecosystems and life cycles of insects. The increase in atmospheric CO2 will also have a large influence on the growth of host plants, mainly by increasing the rates of photosynthesis and growth. The nutrient content of plants grown under elevated CO2 has been shown to be different from that of plants grown under ambient CO2. Most importantly, protein content usually decreased. Lower plant protein content has been shown to decrease the survival rate and weight of larvae of some insect species. For rice at least, it has been shown that the plants derived from seed harvested from crops grown under elevated CO2 are more vigorous and have greater biomass than plants grown from seed from seed obtained from ambient crops. The reason for this is not known, however it is possible that this paternal effect also influences plant nutrient status. If this is the case, it is likely that insect growth and activity is different when feeding on these plants. It is aim of this study to test the combined effects of elevated CO2, temperature and seed source on the developmental and reproduction activity of the green rice leafhopper, Nephotettix cncticeps , on the rice. Here we report on the first results from this study and discuss its implications. Index terms: CO2, temperature, Nephotettix cncticeps

[1185] ECOLOGICAL AND EVOLUTINARY CORRELATIONS AMONG ACCEPTABILITY, OVIPOSITION PREFERENCE AND PERFORMANCE IN ZABROTES SUBFASCIATUS (COLEOPTERA, BRUCHIDAE)

I.R.V. Teixeira & F.S. Zucoloto, Depto. Biologia FFCLRP-USP. Av. Bandeirantes, 3900, 14040-900, Ribeirão Preto, SP, Brazil. E-mail: isabelfe@usp.br

Phaseolus vulgaris is considered the usual host to the Zabrotes subfasciatus eggs. The immature are limited to oviposition place, eating only this host. As Z subfasciatus, most insects have restricted diet. The ecological and economic importance of these species is unquestionable and there have been many discussions about the ecological and evolutionary aspects that influenced this condition. This work has as objective to study several factors related with the oviposition behavior and performance in different hosts and to understand how these behavior and performance develop and change throughout generations. Five hosts were used: 2 varieties of the usual host (A1 e A2) and 3 unusual hosts: Cicer arietinum (B), Glicine max (C) and Lens culinaris (D). For each host were done tests to measure acceptability (egg average), oviposition preference (egg % in each host, 1x1) and performance (adults emergency, number of offspring eggs and their emerging adults). The directional experiments to performance were done by observing each generation, when a newborn couple was placed to oviposit on same host that it developed (10 generations). The artificial selection was done to increase the oviposition on the less chosen host. In each generation newborn females from this host were placed to oviposit between the two hosts used. The experiments were developed between A1 and A2 and between A2 and B. The acceptability results showed the followed rank: the biggest was on A1, followed by A2, C, D and B. One preference hierarchy was revealed: 1-A1, 2-A2, 3-C, 4-D and 5-B. The performance was better in A1, followed by A2 and relatively good in B; in C and D there were no adult emergencies. The artificial selection of performance showed a notable increase in A1, A2 and B in only 7 generations. In only 5 generations, 70% of eggs already oviposited in A2 (initially, the less oviposited variety). However, between A2 and B there was any increase in B. These results suggest that descendent performance didn't influence directly the acceptability and preference. In this case, behavioral as physiological factors contributed to diet restriction. The performance showed a fast fitness increase in each host tested throughout generatons. The selection of preference showed that when 2 usual hosts varieties were used, this behavior had enough variability to permit a positive answer to selection that resulted in a preference inversion, which didn't occur when the host was the unusual, showing the behavior importance in size diet determination.

Index terms: Artificial selection, Fitness, hosts, behavior variation, hierarchy

[1186] POPULATIONAL FLUCTUATION OF *PANTHERODES PARDALARIA* (LEPIDOPTERA: GEOMETRIDAE) IN RIO GRANDE DO SUL STATE, BRAZIL

J. A. Teston^{1,3}, A. Specht^{1,2} & E. Corseuil^{1,4}, ¹ PPG-Biociências PUCRS, Av. Ipiranga, 6681, Caixa Postal 1429, CEP 90619-900, Porto Alegre, RS, Brasil; ² Curso de Agronomia, UNISUL, Av. José Acácio Moreira, 787, CEP 88704-900, Tubarão, SC, Brasil, E-mail: spechta@pucrs.br; ³E-mail: jateston@pucrs.br; ⁴E-mail: corseuil@pucrs.br.

Geometrid moths are characterized by their relatively small and fragile body with quite developed wings. These characteristics do makes them with that, among the macrolepidopterans, the ones with smaller dispersion capacity, what turns them particularly adapted for relationships with the environmental conditions of small areas. Pantherodes pardalaria is a common species in Rio Grande do Sul State and of easy identification due so its predominant yellow coloration with grayish circular stains which external borders and central areas darker. Its larvae feeds on plants of the genus Tecoma (Bignoniaceae), Urera and Boehmeria (Urticaceae), being considerate plagues of the ramie crop (Boehmeria nivea). Objectifying to verify the influence of different places and times, monthly collections were accomplished in 10 places (districts) of the State, from January to December 1998, with two black-light traps model "Pennsylvania", with lamps F15 T12 LN, in each place. In Iraí there were 1,860 sampled specimens; in São Pedro da Serra 824; in Lagoa Vermelha 195; in Camaqua 94; in Cachoeira do Sul 77; in Santana do Livramento 23; in Vila Maria 21; in Pelotas 5; in Piratini 5 and Mostardas 3. The multivariate analysis of variance indicate significant differences between the places and months. This significance, according to the places, highlighted Iraí, followed by São Pedro da Serra. In relationship to the months, it indicated differences with peak populational in August in the three places with larger abundance. In Iraí the peak was repeated in October, but the population stayed quite elevated during the three months. In relation to the presence in the samplings, this was constant in São Pedro da Serra (87.5%), Iraí (83.3%) and Camaqua (54.2%), accessory in Vila Maria (45.8%), Cachoeira do Sul (25.0%) and accidental in the other places, varying from 4.2% to 16.7%. In the areas where the collections were accomplished, it was observed the presence of Urera spp., which development begins in the end of the winter, being vulnerable to the conditions of extreme heat. The distribution and phenology of these plants determinate the abundance and constancy values of this moth on different places, being that some representatives can be found during the whole year in forests.

[1188] INSECTS ASSOCIATED TO THE LONG PEPPER IN THE STATE OF ACRE, BRAZIL

M.J. Thomazini¹, ¹Embrapa Acre, P. O. Box 392, Rio Branco, AC 69908-970, Brazil, Email marcilio@epafac.embrapa.br.

The long pepper (Piper hispidinervum) is an arbustive plant, that occur naturally in fallow areas in the State of Acre, Brazil, mainly in Acre River Valley. This plant has being studied for obtaining essential oils that contain substances used in the production of biodegradable insecticides and fragrances. However, the process of domestication of this species, with the cultivation in commercial scale, can be a factor that leads to the appearance of pests. This research had the objective to determinate the main insects associated to the long pepper. The insects were collected, fortnightly, from May/98 to May/99, with an entomological net in 150 plants of an 0.5 ha experimental area at Embrapa Acre. Insects present in the inflorescence were observed in 20 plants of the germoplasm bank, during the rain season (October/98 to February/99), by walking around each plant during 4-5 minutes. This insects were collected using a mouth aspirator. After one year of insects sampling, using entomological net, 190 species were collected, but only 10 of them were collected frequently. The diversity and the amount of insects increased with the development of the plants. However, during the months of July, August and September (dry season) the population of insects was low, turning to increase in October (beginning of the rains). In the end of January the plants were cut for oil extraction, so the samplings started again only in March. The main insects collected were natural enemies such as lacewings (Chrysopidae), ladybugs (Coccinelidae) and wasps (Vespidae). The main phytopagous insects collected were crysomelids and cicadellids. The insects collected with entomological net and identified, at least, until genera were: Cerotoma tingomarianus, Diabrotica speciosa, Mormidea maculata, Cycloneda sanguinea, Homophoeta aeguinoetialis, Zulia entreriana, Doru lineare, Molomea sp., Polybia sp., Lebia sp., Maecolaspis sp. In the inflorescence of long pepper were collected mainly hymenopterous belonging to families Apidae (subfamily Meliponinae) and Halictidae. It was not detected any insect species that could be considered a pest of this crop and, probably, most of these insects come from crops surrounding the long pepper and use this plant as a shelter or alimentary suplementation.

[1189] POPULATION FLUCTUATION AND INFESTATION LEVELS OF THE CUPUAÇU FRUIT BORER, CONOTRACHELUS HUMEROPICTUS, IN AGROFORESTRY SYSTEMS IN STATE OF RONDONIA, BRAZIL

M. J. Thomazini¹, ¹Embrapa Acre, P. O. Box 392, 69908-970, Rio Branco, AC., Brazil, E-mail marcilio@cpafac.embrapa.br.

The cupuaçu fruit is one of the most promising crop to be explored commercially in the agroforestry systems at Brazilian North Region. Among the pests related to this crop, the fruit borer, insect belonging to the Conotrachelus genera, is the most important one due to its damages and for being disseminated in several states of the North Region. The C. humeropictus population was evaluated weekly during the period from March/98 to January/00 in 20 cupuaçu plants in two areas of the RECA Project, Nova California, RO, Brazil. In one of the areas, ten plants were chosen near to the forest to verify the influence of it in the intensity and in the beginning of the borer infestation. The insects were collected in a nylon screen (with four squared meters) placed under the cupuaçu treetop. The branches of the tree were shaked for five seconds approximately and the adults of the borer were counted on the nylon screen. For determination of fruit infestation the number of infested (with a hole of larval exit) and non infested fruits were recorded. The adult of C. humeropictus was collected in almost all the samples, but occurred at lower levels during the vegetative period. The population of this insect pest is directly related with the plant phenology and with the climate. Thus, the pest population level was higher at the stages of flowering and fruit formation and at the end of the harvest period, and lower in the dry season. It is important to point out that the insect distribution is not homogeneous in the region, existing areas with large infestation, others with less or without the presence of the insect. Some factors as the insect dispersion, cultural treatments, age and density of cupuaçu plants in agroforestry systems can determinate those differences. The plants sampled near the forest presented, during the study period, a larger number of adults than those sampled inside the cultivation area. Such fact demonstrates that the forest around the cupuaçu plants can serve as source of alternative hosts or shelter for C. humeropictus. Losses greater than 50% in fruits production were found in one of the areas in 98/99 season, due to the insect, which emphasize the importance of this pest in this region.

Index terms: Theobroma grandiflorum, Curculionidae, insect-pest, Occidental Amazonia

[1191] MIMETIC ASSEMBLAGES OF LYCID BEETLES IN SOUTHERN BRAZIL

<u>R. F. Torres</u>¹ & K. Del-Claro², ¹Federal University of Paraná, Dept. of Zoology; Home address: R. Carlos Cavalcanti, 19, ap.1702, Curitiba, PR, Brazil, 80020-280, e-mail: rodrigo@bio.ufpr.br ²Federal University of Uberlândia, Dept. of Biosciences, C.P. 593, Uberlândia, MG, Brazil, 38400-902, E-mail: delclaro@ufu.br

Lycid beetles are traditionaly considered aposematic models due to their conspicuous coloration and unpalatability. We would like to know if they participate of any Batesian/Müllerian mimetic relationship at Mananciais da Serra, a subtropical Atlantic Rain Forest area in southern Brazil (Piraquara city, Paraná State). Some classical premises of the Batesian and Müllerian minicries were tested in the field: mimics must resemble models in their conspicuous appearance and behaviour; mimics must occur at the same place (habitat) and time as models; mimics must be less abundant than their models. Collections of about 6 h intervals (morning and afternoon), along a 6 km transect, were carried out weekly for one year. All the insects that resembled the local lycid pattern in habitat, morphology and coloration (black-yellow-black transversal bands in the elitra) were captured with a hand net. Definition of models and mimics was based at the literature on chemical defenses and palatability to predators of the groups of insects studied. Models, which exhibited Müllerian mimicry among themselves, were in the following taxa (number of species in parenthesis): Coleoptera - Lycidae (3), Meloidae (1), Oedmeridae (1), Catharidae (5) and Lampyridae (3); Hemiptera - Coreidae (1). The Batesian mimics (Coleoptera) were: Cerambycidae (2), Belidae (1), Elateridae (1) and Chrysomelidae (3). Two mimetic complexes were distinguished: one with large models and mimics, the other with small ones. Models and mimics occurred sincronously, abundance of models being greater than that of minics along the year. Results were placed in relation to the hypothesis of the existence of a palatability and resemblance spectrum between models and mimics, and to the presence of local potential vertebrate and invertebrate predators. The study presents field evidences that suggest Batesian/Müllerian minicry relations between lycids and other insects in the area, and points out the species involved in such mimicries.

Index terms: Lycidae, Coleoptera, mimicry, aposematism, rain forest.

[1190] BIONOMICS OF THE CITRUS YELLOW MITE, EOTETRANYCHUS CENDANAI (TETRANYCHIDAE)

T. Thongtab¹, <u>A. Chandrapatya¹</u> & G.T. Baker², ¹Dept. of Entomology, Kasetsart Univ., Bangkok 10900, Thailand, E-mail agramc@ku.ac.th; ² Dept. of Entomology and Plant Pathology, Box 9775 Mississippi Sta. Univ., Mississippi State, MS, USA 39762

Eotetranychus cendanai Rimando was found on six different citrus plants and two are new host records: Citrus hystrix DC., Citrus aurantifolia Swingle, Citrus reticulata Blanco, Citrus maxima (Burm. f.) Murr., x Citrofortunella microcarpa (Bunge) D.O. Wijnands (new record) and Murraya paniculata (Linn.) Jack (new record) in 34 provinces and completed its life cycle on the five edible host plants under the study. The egg, larva, protonymph and deutonymph stages lasted 4.8-5.8, 1.52, 1.1-1.8 and 1.24 days. Completion of the life cycle required 11.20-13.97 days. A fertilized female produced 6.30-26.38 eggs (0.96-2.43 eggs/days). Female longevity lasted 6.55-10.52 days. Fertilized females produced offspring with sex ratio of male: female 1:1.02-1:2. Life table study of *E. cendanai* indicated that net reproductive rate of increase (Ro) = 14.1 times, cohort generation time (Tc) = 17.37 days, intrinsic rate of increase (r_m) = 0.156

individual/day and finite rate of increase $(\lambda) = 1.165$. Major mortality occurred during larval stage followed by nymphal and egg stages. Index terms: *Eotetranychus cendanai*, citrus plants. [1192] MIMICRY DYNAMICS OF WASPS AND OTHER INSECTS IN SOUTHERN BRAZIL R. F. Torres¹ & K. Del-Claro², ¹Federal University of Paraná, Dept. of Zoology: Home

R. F. Torres¹ & K. Del-Claro², ¹Federal University of Paraná, Dept. of Zoology; Home address: R. Carlos Cavalcanti, 19, ap.1702, Curitiba, PR, Brazil, 80020-280, e-mail: rodrigo@bio.ufpr.br ²Federal University of Uberlândia, Dept. of Biosciences, C.P. 593, Uberlândia, MG, Brazil, 38400-902, E-mail: delclaro@ufu.br

Stinging wasps are traditionaly considered aposematic models due to their outstanding appearance and behaviour associated with unpalatability. We would like to know if they participate of any Batesian/Müllerian mimetic relationship at Mananciais da Serra, a subtropical Atlantic Rain Forest area in southern Brazil (Piraquara city, Paraná State). Some classical premises of the Batesian and Müllerian mimicries were tested in the field: mimics must resemble models in their conspicuous appearance and behaviour; mimics must occur at the same place (habitat) and time as models; mimics must be less abundant than their models. Collections of about 6 h intervals (morning and afternoon), along a 6 km transect, were carried out weekly for one year. All the median-sized black-bodied Vespidae and the other insects that resembled them in habitat, morphology, size, coloration and behaviour were captured with a hand net. Stinging wasp species, all with the same vespid pattern, were defined as models, and only their high fidelity mimics were studied. Models, which exhibited Müllerian minucry among themselves, were in the following taxa (number of species in parenthesis): female Hymenoptera - Vespidae (5), Sphecidae (1), Pompilidae (2) and Halictidae (1). The most numerous model was the vespid Polybia (Trichothorax) minarum. Batesian mimics were: Diptera - Syrphidae (3), Tabanidae (1) and Asilidae (1); Lepidoptera - Ctenuchidae (1); Hymenoptera Ichneumonidae (4), Formicidae (1) and male Pompilidae (2). Models and mimics occurred sincronously, abundance of models being greater than that of mimics along the year. Results were placed in relation to the hypothesis of the existence of a palatability and resemblance spectrum between models and mimics, to the central role played by aculeate Hymenoptera as models in many mimicry complexes, and to the presence of local potential vertebrate and invertebrate predators. The study presents field evidences that suggest a Batesian/Müllerian mimicry complex involving wasps and other insects in the area, and describes the mimetic aspects of such species.

Index terms: Hymenoptera, Diptera, Lepidoptera, aposematism, rain forest.

[1193] MIGRATION, METAPOPULATIONS, AND LANDSCAPES: RECENT DEVELOPMENTS

J.M.J. Travis, Climate Impacts Group, Department of Ecology, Plant Ecology, Lund University, SE-223 62 LUND, Sweden, E-mail justin.travis@planteco.lu.se.

Throughout the last decade we witnessed the development of an extensive literature investigating metapopulation processes. Much of the earlier work was theoretical in nature, but more recently an increasing number of field studies have been published demonstrating that many of the model predictions do occur in real populations. In this contribution, recent developments in metapopulation biology will be reviewed. Using entomological examples, the key roles that are played by dispersal and landscape structure will be emphasised. Dispersal is the process that holds the constituent subpopulations together, and as such is critical to the functioning of the metapopulation as a whole. Most metapopulation models assume a fixed, density-independent rate of dispersal between patches, and also make simplifying assumptions about the distance of dispersal. However, empirical results show that a rich variety of different forms of dispersal exist. Thus, there is an urgent need for models that incorporate more realistic dispersal functions. Dispersal is also likely to be under different selection pressures in a fragmented habitat than would act in a pristine landscape, and this too may have important consequences for metapopulation processes. Landscape structure is a second key determinant of the form of metapopulation dynamics that will be observed. Recently progress has been made linking more realistic landscape patterns with traditional metapopulation models. There is a continuing need to bring the disciplines of Landscape Ecology and Population Ecology closer together.

[1195] ANALYSIS OF SPECIFIC ADAPTATION TO A DOMICILE HABITAT: A COMPARATIVE STUDY OF TWO CLOSELY RELATED COCKROACH SPECIES

C. W. Tsai & H. J. Lee, Dept. of Entomology, National Taiwan University. No. 1 Roosevelt Rd., Sec. 4, Taipei 106, Taiwan. E-mail: m480@ccms.ntu.edu.tw

The German cockroach, Blattella germanica and the double-striped cockroach, B. bisignata are closely related species. Both of them are belonging to the germanica species-group and have similar appearances, life history characters, reproductive cycles, and courtship behaviors. One of their significant differences is their living habitat: B. germanica is a domicile species, but B. bisignata lives in field. When we kept 20 pairs of B. germanica and B. bisignata together in a small space (2 litters) for 3 months, B. germanica out competed B. bisignata and drove the latter to extinction. It decreased its newly emerged adult body weight and increased its mortality, when B. bisignata was reared in group. We found no evidence of aggregation pheromone and gregarious behavior existing in B. bisignata. From the results of mate preference experiment, females B. germanica only accepted conspecific males as mates, but females B. bisignata could equally accept both species as mates when the long distance calling was bypassed. Based on an unique characteristic of domicile habitat, limited space, *B. germanica* strives with the help of aggregation pheromone and gregarious behavior. Its keen discrimination for conspecific mates at close range certainly helps maintain species integrity in the limited crowd environment. In addition, its high reproductive potential keeps the leading edge in the competition with B. bisignata.

Index terms: Blattella germanica, Blattella bisignata, competition, aggregation pheromone, mate preference.

[1194] CLIMATE CHANGE, DISPERSAL AND INSECT BIODIVERSITY

J.M.J. Travis, Climate Impacts Group, Department of Ecology, Plant Ecology, Lund University, SE-223 62 LUND, Sweden, E-mail justin.travis@planteco.lu.se.

Climate change poses a major potential threat to insect biodiversity. This poster briefly reviews current knowledge of the various effects of changing climatic conditions on insect species, and highlights some less considered problems that may affect many insect species. It has been suggested previously that species with good dispersal characteristics are more likely to be able to shift their ranges in response to climate change than more sedentary species. This makes intuitive sense, and for plant species may be the single most important factor determining whether a species will persist. However, for many insect species the problem is more complex. For example, there is likely to be a difference between the response of specialists and generalists. A generalist species with good dispersal capabilities is best suited to tracking changing climatic conditions, as it can migrate with the climate and feed on a species it finds in the new part of its range. This is not necessarily true for a specialist species, even a highly dispersive one, as the species it feeds on may not yet be present in the new region. There are many other ways in which the interaction between species characteristics (such as dispersal) can determine the nature and extent of the problems faced by a particular species during climatic change. Dispersal is likely to be under strong selection during range shifting events, and the selection pressures may be very different to those exerted when the climate (and ranges) are stable. Model results illustrate the way in which dispersal is likely to evolve during range shifting events.

Index terms: migration, dispersal, range shifting, biodiversity, climate change, evolution

[1196] THE ROLE OF FRASS-COVER ON INSECT EGGS: FROM THE VIEWPOINT OF PARASITIZATION REDUCTION

M. Tsukada, Entomology Laboratory, Faculty of Bioresources, Mie University, Tsu, Mie 514-8507, JAPAN, E-mail: tsukada@bio.mie-u.ac.jp

Frass-covering on eggs is known from many insect species. However, its ecological significance has not been explicitly documented. I examined the effects of frass covering the overwintering eggs of andromeda lace bug, Stephanitis takeyai (Heteroptera: Tingidae), on egg parasitization rate by the wasp, Anagrus takeyanus (Mymaridae). S. takeyai is trivoltine in central Japan, and usually alternates its host plants seasonally. In such a habitat, most wasp individuals in the overwintering eggs of the bug, which are inserted into living leaves of an evergreen shrub, enter summer diapause immediately after winter diapause. The parasitization rate in this generation is ca. 80 %. When the wasp was experimentally excluded by fine meshed gauze during ovipositional period of the bug, the hatchability of eggs was nearly 1.0. Therefore, if the frass cover reduces parasitization rate, it would directly increases the fitness of the mother. The estimated rate was significantly lower in egg masses covered by frass (0.72) than in uncovered egg masses (0.82). Although the difference in parasitization was only 10 % between them, the hatchability was 50 % higher in egg masses with the cover than without, due to the high parasitization rate. Though the egg-mass size was significantly larger in the masses with cover (48.6) than that without cover (27.8), there was no positive or negative relationship between egg-mass size and parasitization rate. Therefore, at least in the winter season, parasitization by the wasp is the main mortality factor of the eggs, and frass cover on the egg mass functions as a parasitization avoidance mechanism.

Index terms: Stephanitis takeyai, Anagrus takeyanus, egg parasitoid, oviposition, maternal care.

[1197] A TRITROPHIC ANALYSIS OF HOST PREFERENCE AND PERFORMANCE IN THE POLYPHAGOUS LEAFMINER LIRIOMYZA HUIDOBRENSIS

<u>G. Valladares</u>^I, A. Salvo^I & M. Videla^I, ¹ Centro de Investigaciones Entomológicas, F.C.E.F.Y.N., Univ. Nac. Córdoba, Av. Vélez Sársfield 299, (5000)-Córdoba, Argentina, E-mail: grv@onenet.com.ar.

Most species in Agromyzidae (Diptera) show close association to a species or genus of plant host. Liriomyza huidobrensis (Blanchard) is one of the rare polyphagous species as well as one of the most important pests in the family. Oviposition preferences of this leafminer within its local host range in Central Argentina were analysed, considering consequences for larval development and translation of such plant-insect relationships into the third trophic level (parasitoids). Infestation levels, suggesting apparent preferences, were estimated from field samples taken fortnightly in various crops at Córdoba (Argentina) along 2 years. Larvae were reared to assess percentage parasitism, and to measure adult body size of leafminer and parasitoids. In laboratory tests, host preferences and larval performance (as development time, survival, pupal weight and adult size) were further assessed, on three selected plant species (Vicia faba, Phaseolus vulgaris, Cucurbita maxima). L. huidobrensis was recorded on 24 crop species, its density noticeably varying among them. Adult leafminers were significantly bigger on plants where the species was more abundant. Parasitoid assemblages on the leafminer differed among host plants, regarding number of species (2 - 12 Hymenoptera species, their richness being associated to sample size), parasitism rate (between 2% and 77%, being independent of host abundance or number of species involved), and relative representation of the main parasitic species. Average body size of particular parasitoid species significantly increased on plants where leaf mining larvae were also bigger. In the laboratory, L. huidobrensis females consistently preferred V. faba for feeding and ovipositing. Larval development time was significantly shorter, while survival was 2.5 times higher and adults reached bigger size on the former plant than on the other hosts. In almost every aspect considered, a pattern of decreasing preference and performance on V. faba - P. vulgaris - C. maxima was observed, in coincidence with the tendency for infestation levels observed in the field. From these observations, Liriomyza huidobrensis appears as a very efficient generalist, being able to select the most adequate plant hosts from among its wide range, and developing greater populations on such hosts. Plant host suitability did not seem to be obviously altered by parasitoids, although some parasitoids benefited from the higher performance of the leafminers, attaining bigger body size on plants where their hosts were bigger.

Index terms: host selection, insect-plant interactions, parasitoids, Agromyzidae

[1198] EFFECT OF HABITAT TYPE ON AQUATIC INSECTS IN FOUR STREAMS OF PATAGONIA (ARGENTINA)

S.M. Velasquez¹ & <u>M.L. Miserendino¹</u>, ¹Laboratorio de Ecología Acuática. Universidad Nacional de la Patagonia, Sede Esquel, Sarmiento 849, 9200 Esquel, Chubut, Argentina, E-mail Jauram@teletel.com.ar

Streams and rivers contain a variety of habitats with different physical and chemical conditions. The availability of habitats, as well as the benthic resources and the nature of their faunal assemblages, have been focus of several researchs. The benthic community pattern in relation to the habitat type is an unknown aspect in Patagonian rivers. In this study, we examined the distribution of aquatic insect communities among habitat types in four Patagonian streams. The studied streams were located in the Patagonian Andes (41° 26' S, 71º 26' W). The main differences among rivers were in stream order, discharge and species of the riparian vegetation. The streams studied were Blanco, Baguilt, Rifleros and Nant y Fall; in each stream one representative reach was sampled twice in both low and high water period. Stream habitat composition was defined as: sand (S), cobble (C). boulder (B), leaf-pack (LP) and aquatic plants (AP). Three random benthic insect samples were collected from each habitat type, at each stream, on each sampling date. Samples were obtained using a Surber net (250 µm mesh). All organisms captured were fixed with formalin (4 %), and in the laboratory were preserved with ethanol (70 %). Communities were dominated by insects of the orders Ephemeroptera (Meridialaris chiloeensis, M. laminata), Trichoptera (Brachisetodes major, Smicridea sp., Parasericostoma ovale), Diptera (Paratrichocladius sp) and Plecoptera (Aubertoperla illiesi, Klapopteryx kuscheli). A few species were able to live in unstable substrates such as sandy bottoms. Specific richness was higher in leaf-packs and aquatic plants than in boulders and cobbles. Our results suggest that habitat types in riffles support more abundance and biomass than habitat pools.

Index terms: riffle habitats, leaf pack habitats, aquatic plants, abundance, specific richness.

[1199] INTRAGUILD INTERACTIONS IN AN ARTHROPOD FOOD WEB ON PLANTS

M. Venzon¹, A. Janssen² & M. W. Sabelis², ¹Agriculture and Livestock Research Enterprise of Minas Gerais (EPAMIG), 38001-970, Uberaba, MG, Brazil. E-mail venzon@bio.uva.nl; ²Section Population Biology, University of Amsterdam, Kruislaan 320, 1098 SM, Amsterdam, The Netherlands, E-mail janssen@bio.uva.nl.

In theory, intraguild predation can affect dynamics of herbivores and their natural enemies and this may cascade down to effect on plants. Although several empirical studies reported on effects of intraguild predation on predator-herbivore dynamics, only few have considered effects on plants. Including effects on plants is important because intraguild predation modifies the effectiveness of plant defence through its interaction with the herbivore's enemies. We studied the effects of a generalist (intraguild) predator (Orius laevigatus) on population dynamics of the specialist predatory mite Phytoseiulus persimilis and the herbivorous mite Tetranychus urticae, and on the performance of cucumber plants in a greenhouse. Behavioural studies showed that the generalist predator and the specialist mite predator were both attracted to plants infested by herbivorous mites and that each of the two predators did not avoid plants occupied by the other predator. Observations on foraging behaviour of the generalist predator further showed that it attacks and kills large numbers of specialist predators and herbivores, suggesting a possible role for intraguild predation on herbivore densities and plant performance. However, addition of the generalist predator to populations of herbivorous and predatory mites on cucumber plants had small effects on herbivore numbers and no effect on predator numbers, plant weight and fruit weight. We discuss possible biological mechanisms causing the absence of effects. Moreover, we argue why this absence is important for biological control as well as for understanding of the evolution of indirect plant defense.

Index terms: Orius laevigatus, Phytoseiulus persimilis, Tetranychus urticae, behaviour, olant performance

[1200] BIOLOGICAL AND NUTRITIONAL ASPECTS OF ANTICARSIA GEMMATALIS (LEPIDOPTERA: NOCTUIDAE), RAISED ON SOYBEAN, PEANUT AND ARTIFICIAL DIET

H. V. Vescove¹, A. T. Murata² & S. A. De Bortoli³, ¹Depto. de Fitossanidade, Univ. Estadual Paulista, CEP. 14870.000, Jaboticabal, SP, Brasil, E-mail: vescove@bol.com.br (bolsista CNPq/PIBIC). ²Depto. de Biologia, Univ. de São Paulo, CEP 14040.901, Ribeirão Preto, SP, Brasil (Fapesp fellowship). ³Depto. de Fitossanidade, Univ. Estadual Paulista, CEP 14870.000, Jaboticabal, SP, Brasil.

The work was carried out to study biological and nutritional aspects of Anticarsia gemmatalis raised on soybean (varietis Foscarin and IAC17), peanut and artificial diet, under lab conditions ($T = 27\pm2^{\circ}C$, $UR = 70\pm10\%$, and 14 hours of photophase). The experimental design used 4 treatments and 10 replications, being evaluated the folowing parameters: length of each larvae instar, length of larvae period, final larvae weight, weight of each larvae instar and pupae, larvae mortality, and sexual rate. Also, the nutritional indexes were obtained to the fourth larvae instar. According to the results, larvae raised on peanut showed the longest larvae period (15 days), being 13.2 and 13.1 days to the Foscarin and artificial diet, respectively. The sexual rates to the larvae raised on Foscarin, IAC17, peanut and artificial diet were 0.55, 0.60, 0.65 and 0.65, respectively. The greatest consumption was observed to the artificial diet (520.06 mg) and the greatest digestibility (44.25%).

BAHIA, NORTHEAST BRAZIL

B. F. Viana¹ & A. M. P. Kleinert², ¹Dept. de Zoologia, Inst. de Biologia, Univ. Federal da Bahia/UFBA, Salvador, BA, Brazil, ZIP 40.170-290, E-mail: blande@ufba.br; ²Dept. de Ecologia, Inst. de Biociências, Univ. de São Paulo/USP, São Paulo, SP, Brazil, ZIP 05.508-900.

Aspects of the community structure of Apoidea of a restricted area of dunes with "restinga" vegetation in Salvador (12°56'S; 38°21'W) Bahia State of Brazil were analysed. Samplings, with standardised methodology, were accomplished for 1 year, 3 times a month of the 6:00 a.m. at the 6:00 p.m. A total of 3983 individuals (3770 females and 213 males) of 49 species, belonging to 5 families were collected on the flowers. The fauna of Abaeté is composed, in its majority for solitary bees of big load, whose larger representative, so much in species as in individuals, it is of Anthophoridae (26 and 2373, respectively) proceeded by Apidae (10; 1321); Halictidae (6; 159); Megachilidae (5; 105) and Colletidae (2; 25). The bees were active during the whole year, presenting picks in the period of low rainfall. The daily activity was larger between 8:00 a.m. and 2:00 p.m., coinciding to the period in that the relative humidity decreased and the temperature increased. The abundance pattern and the richness were plenty similar to the other studies accomplished in similar habitats in the Brazilian Northeast. 49% of the species sampled were represented for less than 8 individuals and 6 species were abundant representing 84% of the total individuals collected. The rainfall associated with the availability of resources seems to be the main factors regulators of the bees' flight activity in Abaeté, along the year. The foraging activity was related positively with the intensity of flowers in the field (r=0.68; p <0.05).

Index terms: Community structure, Apoidea, Hymenoptera, Coastal sand dune.

[1202] GROUND BEETLE COMMUNITY STRUCTURE AS A BIOINDICATOR OF FOREST HEALTH IN TWO PINE-BUNCHGRASS ECOSYSTEMS SUBJECTED TO DIFFERENT DISTURBANCE EVENTS

J. Villa-Castillo & M. R. Wagner, School of Forestry, Northern Arizona University, P. O. Box 15018, Flagstaff AZ 86011, USA, E-mail jvc@dana.ucc.nau.edu.

Forest health in northern Arizona Pinus ponderosa forest has declined since European settlement. Reintroduction of fire and thinning are the main practices suggested to regain forest health. We designed a landscape-level experiment to evaluate forest stand treatment impact on ground-beetle (Coleoptera: Carabidae) community structure and evaluate its potential use an indicator of forest health. A gradient from low-to-high disturbance was established. The treatments across the gradient were: unmanaged stands, thinned-only stands, thinned plus prescribed burned stands, and wildfire burned stands. A thorough screening of 100 stands was carried out to select 4 homogeneous replicates per treatment. During the summer of 1998 and 1999 we recorded ground-beetle species caught in pitfall traps. Ten traps were located in a circular fashion in the center of each 20-40 ha stands. We addressed the influence of time after disturbance on forest health by sampling ground beetles in Pinus hartwegii stands in Nevado de Colima National Park, Mexico. We located stands where salvage logging after bark beetle attack was undertaken 2, 5, 11 and 15 years previously. The control treatment was established on currently infested stands without salvage logging. In northern Arizona, we collected as many as 20 species of ground beetles in thinned plus prescribed burning and wildfire sites, and as few as 2 species in unmanaged and thinned-only stands. Lower diversity was also found in Nevado de Colima, Mexico stands being both recently bark-beetle attacked and logged. Older disturbed sites had greater diversity, than recently disturbed sites but diversity was still low. Results in Nevado de Colima are strikingly similar to those in Northern Arizona treatments where fire was not a treatment factor. We concluded that ground beetle community structure has great potential as a bioindicator of forest health in relatively simple pine-bunchgrass ecosystem types.

Index terms: Carabidae, diversity, Pinus ponderosa, Pinus hartwegii, forest health

[1203] ADAPTIVE POTENTIAL OF THE SWEET-POTATO WHITEFLY BEMISIA ARGENTIFOLII TO SEVERAL HOST PLANTS

G. L. Villas Bóas¹, F. H. França¹ & N. Macedo², ¹Embrapa Hortaliças, Caixa Postal 218, 70.359-970. Brazilia-DF. Brazil. E-mail: geni@cnph.embrapa.br; ² CCA/UFSCar, Caixa Postal 153, 13600-000. Araras-SP.

The sweet-potato whitefly *Bemisia argentifolii* (Homoptera: Aleyrodidae) is potentially damaging for several crops and ornamentals. The objective of this research was to determine the adaptation of the pest to poinsettia, cabbage, beans, zucchini, cassava, tomato and corn by the determination of life table parameters important to support the establishment of IPM strategies. The experiments were carried out at the Experimental Station of Embrapa Hortaliças, located in Brasilia from November 1998 to September 1999 in BOD chambers and greenhouse. The biological development of the sweet-potato whitefly was studied from a population base generated from poinsettia cuttings obtained in Cassava (2.7 \pm 0.4 eggs) and corn (1.9 \pm 0.3 eggs). Pre-imaginal development was lowest in cabbage and beans (20.5 \pm 0.3 and 21.9 \pm 0.7 days, respectively). Highest pre-imaginal mortality was found in cassava (98 \pm 1.3 %) and corn (94 \pm 2.8 %) suggesting that the pest has not adapted to the hosts. Sexual ratio female: male usually favored females in crom (3:1), tomato (2:1), zucchini (1.5:1); ratio was similar on cabbage (1:1) and poinsettia (1:1), and for cassava it was 1:2.

Index terms: biology, host plant, poinsettia, tomato, cabbage.

[1204] CLIMATE DETERMINED PATTERNS IN THE OUTBREAKS OF THE AUTUMNAL MOTH (*EPIRRITA AUTUMNATA*, LEP.: GEOMETRIDAE)

T. Virtanen¹ & S. Neuvonen², ¹Section of Ecology, Dept. of Biology, Univ. of Turku, Finland. Present address: Finnish Forest Research Institute, Rovaniemi Research Station, P.O. Box 16, 96300 Rovaniemi, Finland. E-mail tarmo.virtanen@metla.fi, ²Kevo Subarctic Research Institute, Univ. of Turku, 20014 Turku, Finland

Outbreaks of E. autumnata occur in northern and mountainous parts of Fennoscandia. Occasionally mountain birches (*Betula pubescens* ssp. czerepanovi) are killed over large areas. Earlier it has been found that the driving factors behind the population cycles of E. autumnata consist of delayed negative feedbacks caused by parasitoids and delayed induced resistance of host trees, but the areal distribution and intensity of outbreaks is affected by climate. We have studied (1) how the distribution of the outbreak areas of E. autumnata can be explained and modelled on the basis of altitude-related egg-killing winter minimum temperatures, (2) how summer temperatures (directly and via lower and higher trophic levels) affect the populations of E. autumnata, (3) how predicted climate warming could affect to these relations. Utilizing a digital elevation map with a GIS, we developed models for egg survival and minimum temperature, taking into account altitude and local topography. In our study area from 1961 to 1991 more than 33% of the years had eggkilling winters in the mixed birch-pine forests zone, and 15% of years in the healthy birch forest zone. So, during that time outbreak possibilities were noticeably restricted by winter minimum temperatures. During the larval period of E. autunnata, we found differences in both food plant quality and parasitism between sites in an altitudinal gradient. Differences in the performance of *E. autumnata* were related to temperature conditions: at higher temperatures survival and the egg production index were lower, and larval parasitism was higher than at lower temperatures. The higher parasitism at higher temperatures was probably due to greater parasitoid activity during warmer days. In a comparison of different sources of spatial and annual variation in the performance of E. autumnata, the most important factor appeared to be winter time egg mortality, followed by parasitism, and finally the variation in food plant quality. If climate warms as predicted, the birch-growing areas in our study area protected by low temperatures from outbreaks will be only one third as great as that of today by the middle of the next century. On the other hand, the effects of warmer summers on the outbreaks suggest decrease in outbreak intensity. It seems that more quantitative data would still be needed, if we want precisely evaluate the net outcome of a warmer climate for the population dynamics of E. autumnata.

[1205] ASSESSING THE HISTORICAL AFFINITIES OF NEOTROPICAL BEETLE FAUNAS AT A JOINT UK-BELIZEAN FIELD SITE

<u>A. P. Vogler^{1,2}</u>, D. J. G. Inward^{1,2} & T. G. Barrraclough², ¹Department of Entomology, The Natural History Museum, Cromwell Road, London, SW7 5BD, and ²Department of Biology, Imperial College at Silwood Park, Ascot, Berks SL5 7PY, UK

The Natural History Museum (London) is operating a field station in the Cayo District of the Maya Mountains south western Belize, jointly with the Belizean Ministry of Forestry. Before the establishment of this research facility some five years ago, very little faunistic and taxonomic work had been done in this area in the centre of the largest contiguous tropical forest in Central America stretching across the border with Guatemala's Peten region. Only very limited resources for survey work on insects was available, but it was desirable to have basic information on the kind of taxa present in the area. To establish a rough categorisation of the insect fauna at this site we pursued a strategy whereby the local fauna is put in the context of existing information from literature and the collection of the NHM, focussing on three taxonomically narrow groups of insects that had been readily collected during a short field trip to the site. These included Scarabaeidae, Cerambycidae (both Coleoptera), and Sphingidae (Lepidoptera). We first established the geographic ranges of the species encountered, based on literature and collection records. Similarly, geographic ranges for closely related species (species in the same genus) were recorded, and the presence of each species in five major geographic regions of Central America was established. Comparisons of geographic ranges were then made for the focal species and their close relatives. This crude measure of distribution revealed strong geographic patterns and is informative with regard to the evolutionary affinities of these taxa. Broadleaf tropical forest harboured mostly species with highest diversity in the Neotropics, whereas a nearby pine-oak forest had a major Nearctic element, indicating that plant communities and insect assemblages share common geographic origins. In dung beetles, a mostly tropical group, however, the assemblage of the pine-oak forest essentially constitutes a subset of the species found in the broadleaf forest, but there were several cases where each forest type harboured a different, but closely related species. This type of analysis can provide valuable information on historical processes of species movements and lineage splitting. A more detailed analysis carried out on dung beetles is now underway, based on information on phylogenetic relationships from molecular data. Because of the need for recently collected material in DNA studies, the Maya Mountain and many other Neotropical sites are an extremely important resource for molecular work. Index: biodiversity survey; faunal affinities; dung beetles; Belize

[1206] FACTORS LIMITING THE RED IMPORTED FIRE ANT (SOLENOPSIS WAGNERI) IN ITS NATIVE RANGE IN BRAZIL

K.M. Wackford¹ & D. H. Feener, Jr.², ^{1,2} Dept. of Biology, Univ. of Utah, 257 South 1400 East, SLC, UT, 84112-0840, USA, ¹ E-mail: wackford@biology.utah.edu, ² E-mail: feener@biology.utah.edu

Invasive species which assume dominant, destructive roles in their new communities are often much less dominant in their native ranges. In many cases, invasive species are successful in new locales because they have left behind key competitors, predators, pathogens, or parasites. Although the Red Imported Fire Ant (Solenopsis wagneri) has been a major pest invader in the US for over fifty years, to date no studies have comprehensively examined its ecological interactions in its native range in Brazil. In Brazil, the fire ant is a dominant competitor, and may be the most dominant ant in its preferred habitat of short grass. However, is does not achieve the levels of monodominance that it does in the U.S. Instead, it shares both short and tall grass habitats with at least twenty other species of directly competing ants. In a four-year study, wc examined three interacting factors that limit the fire ant in its native range: competition, flooding, and parasitoids. The ants Camponotus rufipes and Paratrechina fulva are superior competitors to the fire ant, but prefer less-flooded locations in taller grass. Seasonal flooding forces the movement of fire ant nests and intensifies competition between fire ants and superior ants by forcing them to occupy the same tall grass habitats for part of the year. Flooding may also favor competitively inferior ants that can colonize short grass areas after floods more rapidly than fire ants. The presence of multiple species of species-specific phorid parasitoids restricts the foraging of fire ants and decreases their competitive ability. Here we evaluate of the importance of several factors; competitive superiors, flooding, and parasitoids, to the limitation of the fire ant in its native range.

Index terms: Solenopsis invicta, Camponotus rufipes, Paratrechina fulva, flooding, Pantanal

[1207] COMPETITION BETWEEN TWO ARMORED SCALES FOR CITRUS LEAVES COLONIZATION

M. A. Watanabe¹, F. J. Tambasco¹, E. A. B. De Nardo¹, R. I. Viana¹ & G. D. Pereira¹, ¹Laboratório de Quarentena Costa Lima, Embrapa Meio Ambiente, P. O. Box 69, 13820-000 Jaguariúna, SP, Brazil. E-mail watanabe@enpma.embrapa.br.

Seven citrus orchards located in São Paulo State citrus region were monthly monitored for armored scale population dynamics studies. The most abundant species are the rufous scale Selenaspidus articulatus and the black scale Parlatoria ziziphi, where the first one is the dominat species. The P. ziziphi population only increases in the absence or drastic reduction of the former. A random sample of 100 leaves were collected from each orchard and each leaf was examined under stereomicroscope for species identification and counting. The population dynamices data were plotted against time and the pairs of graphics for these species compared for examination of alternance in the incidence, what is an indication of alternate ecological niche occupation. Correlation with mean monthly temperature and precipitation was also examined. S. articulatus scale occurred in high densities during the wet and hot season from October to March. During the dry and cold season from April to September, its incidence was low. No correlation with temperature and precipitation was found for P. ziziphi which incidence is poorly affected by climatic factors. Each female of S. articulatus lays an average of 150 eggs, whereas P. ziziphi female an average of 34,3 eggs. Thus under favourable conditions - wet and hot season the former species population -+6 --* builds up rapidly, winning the competition. During the dry and cold season, after S. articulatus death, P. ziziphi succeeds establishing in the vaccant ecological niche, its number even surmountign that of the former species.

Index terms: Selenaspidus articulatus, Parlatoria ziziphi, population dynamics, competition

[1208] INVESTIGATIONS INTO CARABIDES AT TYPICAL HABITATS OF THE NATURE RESERVE AND WINE GROWING REGION "SÜBER SEE", SACHSEN-ANHALT, GERMANY

C. Weinhold & K. Epperlein, Inst. of plant breeding and plant protection, Martin-Luther-Univ. Halle-Witten-berg, 06108 Halle/Saale, E.-Abderhalden-Str. 27, Germany

The investigation area is a nature reserve. The whole area is characterized by an especially warm and dry climate which allows to grow wine at this latitude. Investigations into the carabid fauna were carried out from spring 1998 until spring 2000. Nine plots with different types of cultivation and stages of intensity were chosen as typical habitats. So investigation plots were established at arable land, wine- and fruit-growing land, an uncultivated meadow on a north slope and a relatively moist forest habitat around a spring. In each investigation area 6 pitfall traps were installed and emptied regularly around the year. After 2 vegetation periods the results show that this highly parcelled out area is habitat for a high number of carabides. 89 different species were be registered of which 17 species are listed in different categories in the Red Data List of Sachsen-Anhalt. The occurrence of Acupalpus interstitialis (Reitter) and Ophonus sabulicola (Panzer) is especially remarkable. This nature reserve is the only known habitat in Sachsen-Anhalt of this species. Great differences in number of individuals and number of species could be observed between the different plots. The results show that the influence of the stages of intensity of cultivation seems to have greater influence on both facts than the type of cultivation. Altogether it is obvious that the many different forms of landuse in this relatively small area cause the great variety of carabides. Therefore the preservation of the site should be extended to the surrounding areas with their special structure and different types of use.

[1209] WHY DO DROSOPHILIDS PRODUCE AGGREGATION PHEROMONES WHEN IT GUIDES PARASITOIDS TO THEIR OFFSPRING?

B. Wertheim, L. E. M. Vet & M. Dicke, Laboratory of Entomology, Wageningen University, P.O. Box 8031, 6700 EH Wageningen, The Netherlands, E-mail Bregje.Wertheim@users.ento.wag-ur.nl

Chemical communication plays a central role in the biology of almost all insects. The effects of chemical communication are manifold and can be found on both the individual level (behaviour, evolution) and on population or higher ecological levels (e.g. the interaction between insects and their natural enemies, or interspecific competition). So far, most studies on pheromones (i.e. the chemical signals) have been focussing on mechanisms, chemical identity or on applied questions. Yet, the fascinating ecology of chemical communication has hardly been studied. In this project, we study the role of a class of chemical signals, the aggregation pheromones, in an evolutionary, behavioural and population ecology context. These volatiles are emitted by an individual and induce aggregative behaviour in members of the same species. They are widespread among insects and have been reported in over 175 species, belonging to 35 families and 10 orders. Yet here again, the whole complex network of ecological interactions and evolutionary processes involving aggregation pheromones is largely unexplored: Why do some insects use aggregation pheromones? What are the advantages for both emitter and responder? And what consequences do aggregation pheromones have on higher ecological levels, such as population dynamics and community ecology? Drosophilids also use aggregation pheromones, and mechanisms are well described in a number of Drosophila species. We chose these fruit flies as a model system and our aim is to study the ecological costs and benefits of the use of aggregation pheromones in this system and the role of the aggregation pheromones in interspecific interactions. So far, we have been testing several hypotheses for benefits. The results of different laboratory and field experiments have quantified the impact of the pheromones both in intra- and interspecific interactions. And it has become evident that evolution might be strongly directed to multi-functionality of single pheromones. On the other hand, several costs have also been identified. One especially intriguing cost involves the interaction with natural enemies: The volatile aggregation pheromone is exploited by parasitoids foraging for drosophilid larvae. The use of aggregation pheromones by the adult flies increases the conspicuousness of the larval hosts to their natural enemies. This espionage by parasitoids of communication between fruit flies was investigated in laboratory set-ups and subsequently it was shown to have significant consequences for the risk of being parasitized in the field. The results of the studies in this model system could contribute to a more general understanding of the ecology of chemical communication in insects.

Index terms: Drosophila, Leptopilina, chemical communication, ecology, fruit flies.

[1210] GALL MIDGE - PARASITOID DYNAMICS AT THE LANDSCAPE SCALE - EFFECTS OF DISTURBANCE AND PROLONGED DIAPAUSE

O. Widenfalk & C. Solbreck, Dept. of Entomology, Swedish Univ. Of Agricultural Sciences, P.O. Box 7044, SE-750 07 Uppsala, Sweden, E-mail: olof.widenfalk@entom.slu.se.

The gall midge Contarinia vincetoxici induces flower galls on the perennial herb Vincetoxicum hirundinaria, a plant that occurs in small and isolated patches in the landscape. Although the gall midge is a poor colonizer and subjected to high mortality, imposed by frequent drought and parasitism, most patches are continuously occupied by the midge with only minor density fluctuations over time. This persistence is explained by a prolonged larval diapause, a strategy to îspread the risk? over time. An experiment, where complete gall removal for four years only marginally affected gall densities compared with control plots, shows the strong buffering effect of prolonged diapause. However, in the same experiment the rate of parasitism was affected by gall removal. One parasitoid - with a low frequency of prolonged diapause - decreased markedly whereas another ñ with a higher frequency - was only marginally reduced. This result is consistent with the observed distribution of parasitism in the landscape, where the most sensitive parasitoid species is restricted to larger patches with a low frequency of disturbance.

Index terms: Contarinia vincetoxici, Omphale salicis, Synopeas accuminatus, population dynamics, prolonged diapause.

[1211] PLANT QUALITY AND THE ORGANIZATION OF CYNIPID GALL WASP COMMUNITIES

M. A. Williams & J. T. Cronin, Dept. of Biology, Univ. of North Dakota, P.O. Box 9019, Grand Forks, ND 58202 -9019, USA, E-mail mwilliam@badlands.nodak.edu.

Two of the most influential hypotheses used to explain variation in herbivore loads among plants are the plant vigor and plant stress hypotheses. The plant vigor hypothesis predicts that insects will preferentially feed or lay eggs upon the most vigorous, healthy, or fast growing plants (e.g., those high in nitrogen). In contrast, the plant stress hypothesis predicts that stressed plants will incur greater infestation levels (often thought to be a consequence of decreased production of defensive chemicals when stressed). There are a growing number of studies that have tested these hypotheses with a single herbivore species. However, very few studies have subjected a whole assemblage of insects and their natural enemies to experimental tests of these hypotheses. Because members of the herbivore assemblage may respond differently to changes in plant quality, and these effects may in turn affect higher trophic levels, the composition of the insect community is likely to vary depending on the condition of the plant's environment (i.e., a donorcontrolled system). We experimentally tested the plant stress/vigor hypotheses using five species of cynipid gall wasp and their natural enemies associated with prairie rose, Rosa species of cympic gain wasp and the matter matter arkansana. In the Spring of 1999, we established 180 1-m² plots each containing a minimum of 10 roses. Each plot was assigned to 1 of 3 salt and nitrogen addition treatments (none, low and high levels), where elevated levels of salt were intended to stress the plants and elevated levels of nitrogen were intended to increase plant vigor. At monthly intervals throughout the summer we recorded plant morphological changes and xylem water potential of sub-sampled plants (indicative of plant stress), collected leaf samples for later chemical analysis, and recorded abundances of cynipid galls on each rose plant. Preliminary results indicate the following. First, both salt and nitrogen additions stressed the rose plants, as indicated by changes in plant physical condition, reduced growth rates and altered chemistry (C:N ratios, amino acid profiles, etc.). Second, densitydependent relationships among roses and insect associates were rare: rose density per plot had no effect on cynipid abundance, nor did cynipid densities have much effect on parasitism rates. Third, the assemblage of cynipids tended to be most abundant in plots with low salt and nitrogen additions, but there were exceptions. Currently, we are conducting a more detailed analysis of the effects of our treatments on rose-plant chemistry, analyzing the effects of treatments on the inquilines and natural enemies of these cynipids, and assessing whether nitrogen and salt treatments had interactive effects on cynipid and natural enemy abundances among plots.

[1212] SPATIO-TEMPORAL DYNAMICS OF AERIAL INSECT POPULATIONS EXAMINED WITH VERTICAL-LOOKING RADAR

I. P. Woiwod¹, J. W. Chapman⁴, A.M. Dewar², D. R. Reynolds³, A. D. Smith³ & J. R. Riley³, ¹IACR Rothamsted, Harpenden, Herts., AL5 2JQ, UK, E-mail Ian.Woiwod@bbsrc.ac.uk; ²IACR Brooms Barn, Higham, Bury St Edmunds, Suffolk, I228 6NP, UK; ³ NRI Radar Unit, Great Malvern, Worcs., WR14 1LL, UK.

Routine monitoring of high-flying insects is now possible due to the development of an inexpensive vertical-looking radar (VLR). Such a system has operated on the roof of the Entomology & Nematology Department at Rothamsted, south-east England, since May 1999. The aerial insect fauna has now been monitored continuously over an extended period and has provided some unique information on the dynamics of the aerial distribution system of insects. Data have been collected for targets passing through the radar beam at altitudes ranging between 150 to 1200 m above roof level; the radar records for a 5 minute sample period every 15 minutes, 24 hours a day. The novel signal analysis capability of the VLR allows the calculation of the averial density, body mass, speed and direction of movement, body alignment and altitude of the over-flying insects. Analyses of the day-to-day variation in insect aerial density, diurnal patterns of flight activity and density-height profiles, will be presented and related to meteorological factors. Spatial analysis of the VLR data with insect samples routinely collected by the Rothamsted Insect Survey's suction and light-trap networks, and aerial netting at Cardington, Bedfordshire, some preliminary identifications of the larger insects recorded by the VLR have been made.

Index terms: VLR, monitoring, aerial density, aerial netting, Rothamsted Insect Survey

[1213] GRAIN APHID PERFORMANCE ON TRITICALE

A. Wojcicka, <u>B. Leszczynski</u>, R. Krzyzanowski & R. Lipinska, Dept. of Biochemistry, Univ. of Podlasie, Prusa 12, PL-08110 Siedlee, Poland, E-mail leszczb@ap.siedlee.pl

Grain aphid, Sitobion avenae Fabr. is recognised as a serious pest of cereals across Europe. During last decades, a lot of efforts were put through to determine natural resistance factors to cereal aphids. Hitherto, role of such cereal allelochemicals as: hydroxamic acids, phenolic compounds and indole alkaloids in the resistance mechanisms were established. Present paper reports on surface waxes of triticale as resistance factors to the grain aphid. Commercial triticale cultivars slightly and heavy covered by the epicuticular waxes were used in the experiments and laboratory resistance tests were performed. Triticale heavy covered with the surface waxes negatively influenced the grain aphid growth and development. Aphids fed on such cultivars showed longer prereproductive period (time from birth do maturity), reduced fecundity and survival and lower values of intrinsic rate of natural increase rm. EPG (electrical penetration graphs) recordings showed some differences in the aphid feeding behaviour on the triticale. Aphids seen on the cultivars with heavy wax layer spent more time without probing of such plants or penetrating only peripheral tissues: epidermis and mesophyll. While on the wax-less cultivars, the aphid activity was mostly concentrated on salivation into sieve elements and phloem sap ingestion. The possible role of surface waxes as triticale resistant factors to the grain aphid is discussed.

Index terms: Sitobion avenae, fecundity, survival, surface waxes, EPG

[1215] THE CAAS ENTOMOLOGICAL RADAR

K. Wu, D. Cheng & Y. Guo, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing, 100094, China, E-mail wukm@mail.east.net.cn.

The CAAS entomological radar is equipped with a marine radar (RA722UA) manufactured in Japan by Anritsu Corporation and an antenna system of Chinese meteorological radar. The radar has a microcomputer, image-processing LSI, and a custom-LSI for processing and storing the echo signal, displaying the radar image with high brightness, and for providing various high-level functions. It possessed a peak power of 10kW and an operating frequency of 9.4GHz (X band, 3.2cm wavelength). The radar antenna consists of a double feed and a 1.5 m parabolic. The picture of the radar observations is recorded by a computer and a special camera which can take multiple-exposure photographs. Simulation observations indicate that the insect radar can display clearly single insect target from 2000 to 3000m.

[1214] PRELIMINARY STUDIES ON FORENSIC ENTOMOLOGY IN MEDELLIN-COLOMBIA

M. Wolff & A. Uribe, Dept. Biology, Univ .of Antioquia. AA 1226 Medellín-Colombia. E-mail Errot Indicador não definido.

This is the first report of an ongoing study of insect succession in carrion carried out in Medellfn - Colombia using pigs (*Sus scrofa*) as a model to determine the insect sequence over 225 days. During this period 2131 insects were collected in the following families; Calliphoridae, Muscidae, Sarcophagidae, Syrphidae, Vespidae, Apidae, Formicidae, Hailicitiae, Staphylinidae, Histeridae, Carabidae, Scarabaeidae, Silphidae, Tenebrionidae, Dermestidae, Cleridae, Nitidulidae, Forficulidae, Gelastocoridae, Coreidae and Hesperidae. Five decomposition stages were observed (fresh, bloated, active decay, advanced decay, and dry remains) and four ecological categories (necrophagous, predators, omnivorous and adventive). During the fresh stage the first insects that appeared were flies of the families Sarcophagidae and Muscidae and specimens of Formicidae (Hymenoptera). During the bloated period Calliphoridae (Diptera) was predominant being the first in oviposition. During the third and fourth stages (active decay and advanced decay) the most abundant family was Muscidae, although Silphidae (Coleoptera) also stood out. During the last stage (dry remains) the dominant family was Formicidae (Hymenoptera) followed by Dermestidae (Coleoptera) with a large number of inmature insects.

Index terms: carrion entomofauna, forensic entomology, insect succession

[1216] THE APPLICATION OF CECIDOMYIDS GALLS ON THE SYSTEMATICS OF THE GENUS MACHILUS (LAURACEAE) IN TAIWAN

<u>S. Y. Yang</u>¹, M. Y. Chen¹ & J. T. Yang², ¹ Dept. of Botany, National Chung-Hsing Univ., Taichung, Taiwan 402, E-mail syyang@dragon.nchu.edu.tw; ² Dept. of Entomology, National Chung-Hsing Univ., Taichung, Taiwan 402

The plants of the genus Machilus (Lauraceae) in Taiwan have high diversity of cecidomyiids galls induced by the genus Dpahnephila (Cecidomyiidae). Using amplified fragment length polymorphism (AFLP) to analyze the 38 trees of four Machilus taxa in Taiwan including Machilus kusanoi, M. thunbergii, M. zuihoensis var. zuihoensis and M. zuihoensis var. mushaensis. UPGMA of the AFLP data revealed three distinct clusters. M. zuihoensis var. zuihoensis and M. zuihoensis var. mushaensis were indistinguishable with three primer combinations and they are suggested to be the same taxon. PCR and DNA sequencing methods were used to analyze the nucleotide sequences of the mitochondrial 16S rDNA gene of the 29 gall midges from three gall types of four Machilus taxa. The phylogenetic tree inferred from the partial 16S rDNA sequence by Neighbor-Joining method of proportion distance, revealed that the analyzed gall midges can be divided into three groups according to the gall types. The phylogenetic tree within each group can't separate the two varieties of M. zuihoensis. The systematic relationships of four Machilus taxa from the data of host plants are congruent with the data gathered from gall makers. Based on AFLP and DNA sequencing methods, M. zuihoensis var. zuihoensis and M. zuihoensis var. mushaensis can't be distinguished, and they are more closely related to M. thunbergii than to M. kusanoi. Our studies suggest the gall makers of genus Daphnephila provide insights into the plant systematic relationships. Index terms: Dpahnephila, AFLP, 16S rDNA.

[1217] HOST UTILIZATION, OVIPOSITION PATTERNS AND POPULATION DYNAMICS OF A DIPTERAN MINER OF BIRCH STEMS

T. Ylioja, Punkaharju Research Station, Finnish Forest Research Institute, Finlandiantie 18, FIN-58450 Punkaharju, Finland, E-mail tiina.ylioja@metla.fi.

Larvae of Phytobia betulae (Diptera: Agromyzidae) mine several meters downward through the differentiating xylem in stems of birch (Betula pendula and Betula pubescens). The long larval tunnels become filled with brown parenchyma tissue and leave a historical record of Phytobia abundance within the annual rings of birch trees. We collected stem disks and measured the number of larval tunnels that were created each year within individual host tree. Samples were collected from three even-aged birch stands (30, 47 and 65 years). General linear models fitted to the data explained a majority (about 60-80%) of the variation in Phytobia abundance, and indicated a strong contribution from exogenous, bottom-up effects from host trees. Phytobia abundance increased and then decreased in a consistent pattern that followed the development of even-aged birch stands. We tested for contributions from density-dependent processes by fitting response surface models to residuals from the general linear models (mean population growth rate); the best densitydependent model explained about 10% of the total variation in Phytobia abundance, most of which was attributable to immediate negative density-dependence, but some of which was attributable to delayed negative density-dependence. Apparently, changes in the condition of host trees, which changed with stand age, determined the level around which negative density-dependence was tending to regulate population abundance. Intraspecific competition might be important in regulating Phytobia abundance. Phytobia females lay their eggs singly into the soft tissue of current year shoots in birch canopies. Superficially, neither the shoot resource nor the differentiating xyleni are obviously limiting for Phytobia, but behavioral mechanisms associated with oviposition could nonetheless lead to intraspecific competition. Oviposition patterns from 48 5-year old birch trees were determined by tracing the larval tunnels backwards to the oviposition shoots. Successful ovipositions were more frequent in the upper parts of tree crowns and fast growing long shoots were preferred. Ovipositions tended to be aggregated in that there was more than one oviposition per shoot more frequently than expected if the eggs were laid in random. The number of ovipositions per shoot was correlated with the length of the oviposition shoot. This pattern suggests that high quality shoots are limited and that young larvae may compete for space and food within these preferred shoots. It still seems unlikely that intraspecific competition is the only factor that regulates population density and we suspect that there are other unknown effects from e.g. predation and inducible host plant defenses.

Index terms: Phytobia betulae, Diptera, Agromyzidae, Betula, density-dependence.

[1218] NATURAL HYBRIDIZATION AND EVOLUTION IN PARNASSIUS (LEPIDOPTERA: PAPILIONIDAE) IN SIBERIA AND RUSSIAN FAR EAST

E. V. Zakharov, Lab. of Entomology, Inst. of Biology and Soil Science, 159 Vladivostok's Century Ave, Vladivostok, 690022, Russia, E-mail entomol@mail.primorye.ru.

Natural hybridization events are of considerable interest because they provide evidence for the occurrence of interspecific gene exchange or introgression. In animals, it seems to be a rule that the nuclear gene pool is protected from contamination by genes of other species by very strong mechanisms of reproductive isolation. Most obvious of them are the sterility of hybrids and the physiological disharmonies between the genes of the hybrids. However, numerous observations of natural hybrids suggest more genetic exchange between animal species than formerly thought. Existence of phenotypically presumed hybrids between some Parnassius species was described from different locations in Siberia and Russian Far East as long ago as the beginning of the century. However, those publications did not present any obvious facts corroborating hybrid origin of the specimens, which had phenotype slightly distinguishing them from parent species. Our objectives were to prove hybrid origin of such the specimens and to evaluate evolutionary significance of natural hybridization. Using PRC-based technology, we tested some Parnassius (sensu lata) species to reveal species-specific molecular markers. We have discovered that these butterflies have a high level of intragenomic heterogeneity and a high degree of genetic polymorphism. Nevertheless, we found some conservative sequences that were treated as species-specific markers. Using these markers, we estimated origin of presumed hybrid specimens. In some cases, we had a complete additive pattern of RAPD-markers of parent species as if we had F1-hybrids. Sometimes we had evidences of introgression between different Parnassius species that testified to hybrid origin of several subspecies. Data obtained in our research allowed us to carry on phylogenetic analysis and to reconstruct possible ways of evolution in Parnassius. The results received and the numerous observations provided by amateur entomologists let us to conclude that in Parnassius butterflies natural hybridization is not just an occasional phenomenon. Mostly it occurs fairly often and causes appearance of F1-hybrids and sometimes it played a role of the evolutionary mechanism that led to formation of new forms, subspecies or species.

Index terms: Parnassius nomion, Parnassius bremeri, Parnassius phoebus, Parnassius eversmanni, RAPD-PCR

[1220] UNUSUAL NEST SUBSTRATE OF AN AUGOCHLORINE BEE WITH DESCRIPTION OF NEST STRUCTURE AND POLLEN RESOURCES

<u>A. Zillikens¹</u>, Z. Mihalkó^{1,2} & J. Steiner², ¹Zool. Inst., Univ. of Tübingen, Auf der Morgenstelle 28, 72076 Tübingen, Germany, E-mail anne.zillikens@uni-tuebingen.de; ²Univ. Fed. de Santa Catarina, CP 476, 88010-970 Florianópolis, SC, Brazil.

Sweat bees (Halictidae) have been studied intensively because they exhibit a wide spectrum of life histories ranging from solitary breeding to reproductive division of labour. Within the tribe Augochlorini such eusocial organization has been reported for species of the genera Augochlorella, Pereirapis and the subgenus Oxystoglossella. Nests of halictid bees are also of special interest under aspects of comparative studies of behaviour and the evolution of social organization. Halictid bees typically nest in the soil but Augochlora sensu stricto is known to nest in rotten wood. Two nests of Augochlora (Oxystoglossella) sp. have been detected in the rosettes of bromeliads in a secondary forest belonging to the Atlantic rain forest biom, Santa Catarina. Details on substrate and cell arrangement are provided and nest structure is discussed in relation to data reported for related species. Nests were opened to collect brood and pollen. Nest 1 contained all stages from egg to pupae as well as a newly emerged female whereas the second contained only three larvae at the end of the feeding stage. Obviously, larvae were developing without diapause suggesting a bi or even multivoltine life cycle. This is also supported by the prolonged activity period of adult females which were observed foraging on flowers at least till mid February. Analysis of foraged polien from the female scopae, pollen balls and faeces found in the nests revealed an origin from plants of at least 18 species. These belonged to various families such as Aquifoliaceae, Melastomataceae, Myrtaceae, Rubiaceae but pollen of Asteraceae dominated in number. Thus Augochlora (Oxystoglossella) sp. can be characterized as a polylectic forager.

Index terms: Augochlora (Oxystoglossella) sp., Augochlorini, nest structure, polien sources, eusociality, annual cycle.

[1221] PROPOSAL OF MODIFICATION IN LIFE TABLES TO STUDY THE EFFECT OF PROPORTIONAL MORTALITY DIFFERENCES ON LIFE EXPECTANCIES

<u>C. J. Von Zuben¹</u> & R. H. C. Fonseca¹, ¹Dept. of Zoology, UNESP, Ave. 24A, 1515, P.O. Box 199, Rio Claro, SP 13506-900, Brazil, E-mail vonzuben@rc.unesp.br

In situations where male and female life expectancies differ, for the same species, one question that arises is "how much do the mortality rates differ that ultimately determine the life expectancy differences?" (Carey, 1993). This author addressed this question by

letting \hat{e}_0^m denote a new male expectation of life at age 0 computed using a modified

age-specific mortality schedule \hat{q}_x^m where $\hat{q}_x^m = (1+\delta)q_x^m$ and q_x^m is the original

male age-specific mortality rate at age x. The same procedure can be made for \hat{q}_x^f in females. The utilization of different δ values to alter age-specific mortality yields hypothetical modified life tables. The magnitude of δ values will determine the factor that modifies uniformly across all age classes the age-specific mortality schedule. The importance of this analysis is to obtain the δ value that allow the male \hat{e}_0 to approximate to that of the female and vice versa. In this sense, the objective of the present work is to propose a way to permit this kind of modification in life tables, from \hat{q}_x values. The following steps are suggested: (1) from the \hat{q}_x value, it is possible to calculate $\hat{p}_x = 1 - \hat{q}_x$; (2) to evaluate $\hat{l}_x = \prod_{y=0}^{x-1} \hat{p}_x$; (3) to obtain $\hat{d}_x = \hat{q}_x \hat{l}_x$; (4) to evaluate \hat{L}_x from the expression $\hat{L}_x = \hat{l}_x - \hat{d}_x/2$; (5) to calculate $\hat{T}_x = \sum_{y=x}^{w} \hat{L}_y$, where W represents the last day of possible life and finally (6) to estimate the hypothetical new life expectancy through. In considering the expression $\hat{e}_0 = \sum_{x=0}^{w} \hat{l}_x - (1/2)\hat{d}_x \Big| \hat{l}_0$ to calculate the new value of life expectancy, the

estimate the hypothetical new file expectancy integral. In constanting the expectancy, the $\hat{e}_0 = \sum_{x=0}^{w} \left[\hat{l}_x - (1/2) \hat{d}_x \right] / \hat{l}_0$ to calculate the new value of life expectancy, the parameters \hat{L}_x and \hat{T}_x (steps 4 and 5 respectively) remain implicit in the calculation of \hat{e}_0 .

[1221] ROLE OF HOST PLANT QUALITY IN HERBIVORE POPULATION DYNAMICS IN HABITATS DISTURBED BY POLLUTION

E. L. Zvereva, Sect. of Ecology, Univ. of Turku, Turku FIN-20014, Finland, E-mail elezve@utu.fi.

Population density of the leaf beetle, Melasoma lapponica, its mortality due to natural enemies, and quality of its primary host plant, Salix borealis, were monitored in 10 sites around the nickel-copper smelter at Monchegorsk (Kola Peninsula, NW Russia) during 1991-1999. In clean localities, density of M. lapponica was low during all study years (due to high mortality from generalist predators) and demonstrated no among-year variation. In polluted localities, where abundance of predators was very low, densities of the leaf beetle were higher than in clean sites and demonstrated significant annual fluctuations, reaching outbreak levels asynchronously in different sites. Although mortality due to parasitoids was high (up to 60%), it was density independent and thus did not contribute to leaf beetle density fluctuations. In contrast, host-plant quality (assessed in bioassays with M. lapponica by preimaginal mortality and female fecundity) was a good predictor of next year changes in leaf beetle density. Outbreaks were preceded by an increase in S. borealis quality compared to low-density sites. In the year of peak density willow quality decreased, significantly reducing preimaginal survival, adult survival during hibernation and fecundity, which resulted in 2-3-fold decrease in density in the next year. However, densities did not decrease any more during the following five years, consistently with an improvement of willow quality after one-year drop. Amelioration of willow quality in polluted habitats may result from (i) high spring temperatures, (ii) SO2 impact, (iii) winter and spring damage of apical buds by herbivores, gaseous pollutants and frost (due to lower temperatures, stronger wind and thin snow cover in forest death areas). The decrease in plant quality was caused by severe defoliation by the leaf beetle during an outbreak - the effect known as delayed inducible resistance (DIR). However, experiments showed that DIR in boreal willow might be weakened by pollution, keeping herbivore density at high levels for several years. I conclude, that while in undisturbed habitats natural enemies play the leading role in regulation of populations of *M. lapponica*, in deteriorated habitats, where relationships with natural enemies are disturbed, host plant quality becomes the main factor driving population dynamics of this herbivore. Pollution induced or mediated changes in host plant quality and plant responses to herbivory in enemy-free space explain frequent and long-lasting herbivore outbreaks in disturbed habitats.

Index terms: *Melasoma lapponica*, *Salix borealis*, regulation, induced amelioration, induced resistance

[1222] MODE OF ACTION OF INDOXACARB IN PEST INSECTS AND IMPLICATIONS FOR CONTROL

K. D. Wing, M. E. Schnee, M. Sacher & M. Connair¹, E. I. DuPont and Co., Inc.Crop Protection Products, Stine-Haskell Research Labs, P.O. Box 30, Elkton Rd. Newark, DE. 19714, USA, Email:keith.d.wing@usa.dupont.com

Indoxacarb is a new insecticide from E.I. DuPont which has broad spectrum and agronomic utility, a new mode of action, and high levels of environmental and non-target safety. The oxadiazines DPX-MP062 (Indoxacarb; 75%S;25%R) or DPX-JW062 (racemic) are bioactivated to their N-decarbomethoxyllated metabolites (DCMP/DCJW) via esterase/amidases in the gut and fat body of Lepidoptera. The bioactivation is nearly quantitative within 5 hrs. post-ingestion in several Lepidoptera, but slower after topical application of either technical materials or SC formulated material. Pest representatives of Hemiptera, Homoptera and other insect orders perform this bioactivation much more slowly than the Lepidoptera, either by oral or topical application. Temporal progression of neurotoxic symptoms and ensuing toxicity correspond well with appearance of the active metabolite in all insects; results of a comparative study are presented. After bioactivation, the toxic metabolite blocks sodium channels in a voltage-dependent and nearly irreversible manner. When sodium -dependent compound action potentials (CAPs) in a Manduca sexta larval motoneuron preparation are monitored, they show a rapid, dose-dependent block after treatment with 0.01- 1 um DCJW. However they are only weakly responsive to even 1uM JW062. Other data presented strongly support the bioactivation hypothesis. Voltage-clamp experiments in embryonic *Periplaneta americana* cells reaffirm the voltage-dependent sodium channel block, and show that DCJW or DCMP are qualitatively similar to dihydropyrazoles and other related compound classes, and certain local anesthetics. These compounds may share a common binding domain in the sodium channel distinct from the pyrethroid/DDT site, making Indoxacarb highly active on insects resistant to other insecticides and an excellent Integrated Pest Management tool. Thus the key factors for Indoxacarb insect pest toxicity in the field are 1.Maximizing insect ingestion bioavailability on crop plants with optimized formulations and application 2. Rate of compound penetration, bioactivation and sodium channel sensitivity in the particular insect, which are inherent to the pest. Lepidopteran larvae are extremely sensitive to Indoxacarb, because of this combination of factors. [1224] MODE OF ACTION OF THIAMETHOXAM, A NOVEL LIGAND OF NICOTINIC ACETYLCHOLINE RECEPTORS – A COMPARATIVE STUDY OF NEONICOTINOIDS AND INSECTS

P. Wiesner, L. Kaufmann, F. Schuermann & <u>H. Kayser</u>, Novartis Crop Protection AG, Research Biochemistry, WRO-1060.4.04, CH-4058 Basel, Switzerland. E-mail: hartmut.kayser@cp.novartis.com.

Neonicotinoids represent a novel chemical class of insecticides which are structurally and functionally related to nicotine. Due to their systemic activity and high performance in the field, neonicotinoids are becoming increasingly used for the control of sucking insects and some other pests, also those showing resistance to organophosphates and pyrethroids. This is obviously due to the fact that neonicotinoids, as is well documented for imidacloprid, act by binding to nicotinic acetylcholine receptors, which thus became a validated novel insecticidal target site. Thiamethoxam, which is currently marketed as a second generation neonicotinoid, represents an example of the thianicotinyl subclass, which is distinguished by a thiazolyl group from the other pyridyl-based compounds. The mode of action of thiamethoxam has been studied in aphids (Myzus persicae, Aphis craccivora) as target insects, and in the locust (Locusta migratoria) as a lab model insect. Competition binding studies with membrane preparations of nicotinic acetylcholine receptors, performed with [^tH]-imidacloprid, revealed significant species differences in IC50 values for thiamethoxam which were in the range of nicotine in the aphids, but 100-fold higher than nicotine in the locust. In all insects, the best competitor of imidacloprid was thiacloprid, the weakest one was nithiazin in the aphids and thiamethoxam in the locust. Furthermore, the inhibition curve for *M. persicae* receptors suggested a heterogeneous population of binding sites in this insect. Minor structural variations at the heterocycle carrying the niro binding sites in this insect. Minor structural variations at the neterocycle carrying the hirro group were shown to have a large impact on the affinity to the binding site of imidacloprid. In electrophysiological studies, which were limited to *Locusta migratoria* for technical reasons, thiamethoxam, like other neonicotinoids, acted on nicotinic acetylcholine receptors by reducing the action potentials elicited by acetylcholine pulse-applied to isolated neuronal somata from the metathoracie ganglion. The IC50 value from the fourth of the source of the sou this functional assay compared fairly well to that obtained in the competition binding assay (µM range). Imidacloprid was active at a lower level (nM range) in both locust assays. On the isolated locust foregut, imidacloprid produced a tonic contraction, whereas assays. On the isolated locust foregut, initiation in posticed a tone contraction, infectors thiamethoxam was inactive. Overall, the results suggested that differences may exist in the modes of action between these two compounds, and possibly among neonicotinoids in general, though they all presumably act on nicotinic acetylcholine receptors. Index terms: Aphis craccivora; Myzus persicae; Locusta migratoria

[1223] CHARACTERISATION OF NEONICOTINOID MODE OF ACTION AT INSECT NICOTINIC ACETYLCHLOINE RECEPTORS

R. J. Lind, Zeneca Agrochemicals, Jealott's Hill Research Station, Berkshire, RG42 6ET, UK.

The introduction of neonicotinoid insecticides such as imidacloprid (IMI) has led to increased interest in insect nicotinic receptor pharmacology. The specific binding of a number of labelled cholinergic ligands to membranes of the aphid Myzus persicae was investigated. Saturation and kinetic data for [⁴H]-IMI; [⁴H]- and [²³I]- σ -bungarotoxin (α BgTx); and [²H]-epibatidine (EPI) all demonstrated more than one class of binding site. In each case the number of high affinity sites was about 25% of the total. By contrast, [⁴H]-methyllycaconitine (MLA) had only a single high affinity binding component, apparently corresponding to all of the other ligand sites, and therefore appears to be a "universal" ligand for insect nAChR. This is unlike mammalian brain, where MLA is a highly specific probe for some receptor subtypes. Unlabelled nicotinics were used to displace labelled probes from high affinity sites. Although the pharmacology, there were differences in the order of potency of the displacing ligands, again indicating heterogeneity of the aphid nAChR. The differing binding characteristics of the different subunits. Others have shown that genes for multiple nicotinic receptor subunits are expressed in *M. persicae*. However, apparent heterogeneity could also arise through co-operative interactions within the same receptor. Dissociation experiments show that such interactions occur in *M. persicae*.

Index terms: nicotinic acetylcholine receptor, Myzus persicae, imidacloprid, α bungarotoxin, epibatidine, methyllycaconitine, radioligand binding. [1225] SPINOSAD: PROPERTIES OF A SUCCESSFUL REDUCED RISK INSECT CONTROL PRODUCT

G.D. Thompson, T.C. Sparks & F.K. Dietz, Dow AgroSciences, Indianapolis, IN, USA

During the 1990's the U.S. Environmental Protection Agency (EPA) established a Reduced Risk category for new products and gave them priority in the registration process. Registrants applying for the category were required to demonstrate that their new product had improved properties when compared to current products in one or more of the following categories in a descending order of priority. The factors were: human health effects, non-target organism effects, groundwater risks, reduced application rates or frequency, low pest resistance potential, highly compatible with Integrated Pest Management, and improved efficacy. Spinosad is a fermentation metabolite of the actinomycete *Saccharopolyspora spinosa* Mertz and Yao. Spinosad was one of the first products accepted into the EPA reduced risk category. It has received rapid registrations and is currently registered on over 100 crops in over 20 countries as Tracer*, Success* or SpinTor* Naturalyte* Insect Control. The toxicology, environmental fate, and mode of action properties that qualified spinosad as a reduced risk product are reviewed. Additionally, an overview of the insecticidal properties that re equally responsible for the rapid adoption of the new active are provided. A vertebrate selectivity ratio (mammalian toxicity divided by insect toxicity), suggests that spinosad is a very selective insect control agent.
[1226] PYMETROZINE, A SELECTIVE FEEDING INHIBITOR FOR SUCKING INSECTS, ACTS THROUGH A NOVEL MECHANISM

L. Kaufmann, B. Popp, F. Schuermann & <u>H. Kayser</u>, Novartis Crop Protection AG, Research Biochemistry, WRO-1060.4.04, CH-4058 Basel, Switzerland. E-mail: hartmut.kayser@cp.novartis.com.

Pymetrozine is a new insecticide, highly selective for sucking insects, which is primarily used for the control of aphids; it is further active against whiteflies and rice hoppers. This unique selectivity of pymetrozine corresponds to its unique chemistry. However, bearing an essential 3-pyridyl group it is also reminiscent to the neonicotinoid class of insecticides. By directly recording feeding behaviour in several aphids it was previously shown that pymetrozine immediately (and selectively) blocks sucking by acting on the pumping mechanism thus finally resulting in death by starvation. To decipher this novel mode of action, studies on the locust (Locusta migratoria) were initiated since (repeated) application of pymetrozine to this non-target insect similarly resulted in feeding inhibition. As specific symptoms of intoxication by pymetrozine, locusts stretched and raised their hind legs without being paralyzed. This effect is unique to pymetrozine among the insecticide classes on the market suggesting a novel action mechanism. Overall, these symptoms and the effect on behaviour point to a neuro(-muscular) mode of action. In agreement with its unique symptoms, pymetrozine was not active in all tests on established target mechanisms of insecticides. A neuronal mode of action, obviously a novel one, became evident from the immediate increase of spontaneous spiking activity of locust ganglia, as recorded in situ, and from a similar activation of peristalsis of the isolated foregut when perifused with pymetrozine; it was active down to the nM range in both assays. In further experiments with the gut preparation the target site of pymetrozine could be clearly localized to the ingluvial ganglion; the gut muscle per se did not respond to the insecticide, but it remained sensitive to 5-HT. Isolated neuronal somala from the metathoracic ganglion (which, when intact, could be activated by pymetrozine) did not show either agonistic or antagonistic effects of pymetrozine on any neurotransmitter receptor. Using a radiolabeled close analog of pymetrozine, the presence of specific binding sites in the locust nervous system could be demonstrated down to the nM range. Remarkably, binding of pymetrozine was not inhibited by imidacloprid and thiamethoxam. respectively; however, nicotine was an effective displacer of pymetrozine. Hence, as a tentative conclusion, the binding site of pymetrozine may represent a novel neuronal receptor, though it might belong to the nicotinic acetylcholine receptor family. Index terms: aphids; neuronal receptor; Locusta migratoria

Symposium and Poster Session

[1228] MOLECULAR STUDIES OF INSECT ACETYLCHOLINESTERASE: IS THERE NEW LIFE IN AN OLD TARGET?

M. S. Williamson¹, S. B. Walsh¹, G D Moores¹, A. L. Devonshire¹, A. Taylor³, R. Viner³, C. Personeni² & T. Lewis², ¹Biological & Ecological Chemistry Department, IACR-Rothamsted, Harpenden, AL5 2JQ, UK. E-mail martin.williamson@bbsrc.ac.uk; ²Zeneca Agrochemicals, Jealott's Hill Research Station, Bracknell, Berks, RG42 6ET, UK.

Acetylcholinesterase (AChE) is the target enzyme for two major classes of insecticides, the organophosphates (OPs) and carbamates. The widespread use of these compounds over many years has, however, led to the development of resistance in a range of insect pests. This, together with ongoing safety concerns over their vertebrate toxicity, has resulted in a general decline in their use and effectiveness over recent years. Nevertheless, these compounds still constitute over 50% of the world insecticide market (\$4.5 billion in 1998). A major drawback in the mode of action of these compounds is that they are irreversible inhibitors of AChE that can also bind and modify other serine hydrolases within the nervous system. To investigate the mode of action and mechanism of resistance of these insecticides in more detail, we have cloned the AChE gene from the housefly (Musca domestica) and compared its sequence across a panel of resistant strains with altered (insensitive) AChEs. A number of base mutations were identified in the resistant strains, including five that result in changes in the encoded AChE protein sequence; V180L (Torpedo residue V150), G262A & G262V (G227), F327Y (F290) and G365A (G328). In vitro expression of these mutant AChEs using the baculovirus system have confirmed that all except the V180L mutation contribute to the varying levels of resistance observed in the original strains, and this is consistent with structure-based modelling studies that show these mutations are located at the base of the active site pocket where they appear to affect the access and/or binding of insecticides. In order to exploit recent advances in our understanding of the structure and catalytic mechanism of AChE, we are using a combination of computer modelling, molecular biology and biochemistry to investigate the activity of reversible inhibitors that show large differences in their selectivity for either insect or vertebrate AChEs. Our results suggest that key differences within the active site pocket of the enzyme between vertebrates and invertebrates can be exploited for the design of potent new inhibitors with novel modes of binding that are highly selective for insect AChEs. Moreover, such inhibitors are unlikely to be predisposed to the existing resistance mutations that occur within insect populations. Index terms: Musca domestica, inhibitors, mutation, resistance, expression, baculovirus

[1227] THE MOLECULAR BASIS OF TARGET SITE RESISTANCE: HOW MANY MUTATIONS?

R.H. ffrench-Constant, Dept. of Biology, Univ. of Bath, BAth, BA2 7AY UK, E-mail bssrfc@bath.ac.uk

Field isolates of target site resistance are often associated with single major genes. Over the last five years we have been studying the number of resistance associated mutations found in these target sites: the *Rdl* encoded GABA receptor, the *para* encoded sodium channel and the *Ace* encoded insect acetylcholinesterase. The central question examined in each case is: How many mutations can cause resistance and why? We have examined this question using several different approaches. 1) Surveys of resistance associated mutations present in nature. 2) Detailed biophysical analyses of the effects of these mutations on the associated receptor/enzymes. 3) Chemical mutagenesis of *Drosophila* to examine how many different combinations of mutations can give resistance in the laboratory. In this talk we will examine each of the three targets and discuss the applicability of each of these three approaches in trying to understand how many mutations have been found in each receptor or enzyme and why.

Index terms: Drosophila melanogaster, para encoded Sodium channel, Rdl encoded GABA receptor, Ace encoded acetylcholinesterase

[1229] SODIUM CHANNEL MUTATIONS AND PYRETHROID RESISTANCE

K. Dong¹, Z. Liu¹, J. Tan¹, J. Ren¹, S.M. Valles² & A.L. Goldin³, ¹Department of Entomology and Neuroscience Program, Michigan State University, East Lansing, MI 48824, USA, E-mail dongk@pilot.msc.edu; ¹USDA-ARS, Center for Medical, Agricultural and Veterinary Entomology, 1600 SW23rd Dr., Gainesville, FL 32608; ¹Department of Microbiology and Molecular Genetics, 240 Medical Science Building B, Irvine, CA 92697.

For decades, pyrethroid insecticides have been used widely to control many insect pests. Due to intensive use, however, many insect pest populations developed resistance to these compounds. One class of resistance mechanism is knockdown resistance (kdr). A single amino acid substitution, from leucine to phenylalanine, in the Para sodium channel protein has been found to be responsible for kdr in several insect species, including German cockroaches. Recently, we identified two more mutations in the para gene of five fieldcollected German cockroach strains that exhibit high levels of kdr. The two mutations, from glutamic acid (E434) to lysine (K434) and from cysteine (C764) to arginine (R764), respectively, are located in the first intracellular linker connecting domains I and II. Two additional mutations from aspartice acid (D57) to glycine (G57), and from proline (P1888) at leave to leave in (L1888), respectively, were found in one of the resistant strains. The four mutations co-exist with the previously identified L993F kdr mutation and are present only in the highly resistant individuals of a given strain. These findings suggest that the four novel mutations might be responsible for high levels of knockdown resistance to pyrethroid insecticides in the German cockroach. A full-length *para* cDNA has been isolated from a pyrethroid-sensitive German cockroach strain, CSMA, and *kdr*-associated mutations have been introduced into this cDNA. We have succeeded in functional expression of cockroach para cDNAs in Xenopus oocytes. We are currently examining the effects of the kdr-associated mutations on Para channel properties and channel sensitivities to deltamethrin, a pyrethroid insecticide.

[1230] INVESTIGATIONS ON NEONICOTINOID RESISTANCE IN BEMISIA TABACI FROM ALMERIA, SPAIN

R. Nauen & A. Albert Bayer AG, Agrochemicals Division, Research Insecticides, D-51368 Leverkusen, Germany, E-mail: RALF.NAUEN.RN@bayer-ag.de

The first neonicotinoid insecticide to be commercialized in 1991 was imidacloprid. Meanwhile several other compounds belonging to this chemical class and which are structurally related to imidacloprid have also been launched or are under development. All these compounds are active as agonists of the insect nicotinic acetylcholine receptor (nAChR). Neonicotinoids are especially active against homopteran pest species, such as aphids, leaf- and planthoppers and whiteflies. Whereas in aphids and leafhoppers numerous monitoring programs revealed no signs of developing resistance, several field derived strains of the tobacco whitefly, *Bemisia tabaci*, especially from southern Spain, showed considerable loss of susceptibility towards neonicotinoid insecticides such as acetamiprid, imidacloprid and thiamethoxam. Furthermore, our laboratory bioassays revealed high levels of resistance to a broad range of chemically diverse active ingredients in different types of laboratory bioassays. In order to elucidate the possible mechanisms conferring resistance to neonicotinoid insecticides in *B. tabaci* from Almeria/Spain, biochemical and biological investigations were undertake. We studied the affinity of imidacloprid to nicotinic acetylcholine receptors (nAChR) in whitefly homogenates using tritium labelled imidacloprid, the effect of synergists in different bioassay types, possible behavioural components associated with neonicotinoid resistance as well as possible fitness costs. Options for resistance management strategies will be discussed in the light of our results.

Index terms: whiteflies, imidacloprid, nAChR

[1231] ROLE OF ESTERASES IN RESISTANCE TO PYRETIIROIDS IN LEPIDOPTERA

<u>R.V. Gunning</u>¹, G.D. Moores² & A.L. Devonshire³ ¹NSW Agriculture, Tamworth Cent. Crop Improvement, RMB 944, Calala Lane, Tamworth, NSW, Australia, 2340; ^{2,3} IACR-Rothamsted, Harpenden, Herts., AL5 2JQ, UK.

Some Lepidoptera and in particular the Noctuidae, are major pests of crops, such as cotton, throughout the world and chemical insecticides are considered necessary for control. These insects are routinely exposed to pyrethroid insecticides and it is therefore not surprising that a number of economically important species have developed resistance to these insecticides. Esterase- mediated hydrolysis and sequestration of pyrethroids has been shown to be important as a mechanism of resistance in many insect species and the presence of elevated enzyme activity has become increasingly monitored as a biochemical marker for resistance in many insect pests. Esterase-moderated resistance to pyrethroids has been found to be important in a number of Lepidopteran species, with increasing evidence that esterases play a major role in Helicoverpa armigera (Hübner) Helicoverpa punctigera (Wallengren), Heliothis virescens (F.) Spodoptera exigua (Hübner) Spodoptera littoralis (Boisd.) and Wiseana cervinta. Most studies have shown increased hydrolytic activity in the resistant strains, however, pyrethroid sequestration appears also to be important. The best documented case implicating esterases in pyrethroid resistance is in Australian H. armigera. Pyrethroids were first introduced for control of Helicoverpa spp. in the late 1970's and resistance was first diagnosed in H. armigera, in late 1983. The spin the task of the state of t could be partially suppressed by piperonyl butoxide (PBO). Pyrethroid synergism by PBO, led to a widely held assumption, that pyrethroids were metabolised by monooxygenases. However, it has become clear, that an overproduction of esterase isoenzymes is responsible for pyrethroid resistance in *H. armigera*. The esterases both sequester and metabolise pyrethroids. Biochemical studies showed that PBO was in fact an esterase inhibitor in H. armigera and recent studies with H. virescens concur with these findings. Some organophosphates are effective esterase inhibitors in *H. armigera* and can restore pyrethroid susceptibility. Pyrethroid/esterase binding studies revealed that pyrethroids which contain a halogenated benzyl group bound more readily to *H. armigera* esterases and were more resisted, in comparison to pyrethroids where the benzyl ring was replaced by a dihalogenated aliphatic entity. Pyrethroid resistance in H. punctigera was

also shown to be the result of an esterase mediated resistance mechanism. Index terms: Helicoverpa armigera, Helicoverpa punctigera, Heliothis virescens, Spodoptera exigua, Spodoptera littoralis, Wiseana cervinta [1232] RESISTANCE AND SYNERGISM TO ORGANOSPHOSPHATE INSECTICIDES IN POPULATIONS OF LEUCOPTERA COFFEELLA (LEPIDOPTERA: LYONETIIDAE)

D. B. Fragoso', <u>R. N. C. Guedes'</u>, M. Picanço' & W. C. Antunes', 'Dept. of Biology Animal, Federal Univ. of Viçosa, Viçosa, MG 36571-000, Brazil, E-mail: guedes@mail.ufv.br..

Insecticide resistance is an increasingly wordwide problem. In this context, the objective of this study was to detect resistance of *Leucoptera coffeella* to the insecticides chlorpyrifos, disulfoton, ethion and methyl-parathion and to preliminarly identify the probable resistance mechanisms involved. The biological material used encopassed ten populations of L. coffeella from important coffee producing counties of the State of Minas Gerais, which were field-collected and reared in cages within a greenhouse. An additional population from an area adjacent to the coffee nursery of the Federal University of Viçosa was used as susceptibility standard. At first, preliminary biossays were carried out using 3rd instar larvae of the susceptible population to obtain the range of concentrations to be used in the concentration-response bioassays aiming the determination of the LC, The data obtained from the concentration-response biossays were subjected to probit analysis to estimate the CL₂₉ for each insecticide, which were used as discriminatory concentrations to recognize the resistant populations. Significant differences in mortality between the field-populations and the susceptibility standard were recognized by the Z test with correction for continuity. The results showed resistance in the majority the insect populations studied. Eight of them showed resistance to disulfoot, five to etholon, four to methyl-parathiom, and just one showed resistance to chlorpyrifos. Correlation and multiple regression analysis, were used to evidence the association between the frequency of resistant individuals and the insecticide use. The results obtained suggested patterns of cross-selection between the insecticides and the existance of cross-resistance in the populations under investigation. In the study of the the probable resistance mechanisms of L. coffeella to these insecticides, bioassays with insecticide plus sinergyst were carried out for the susceptible population using the same metodology referred above with the goal of obtaining the LC_y to be used to identify the probable main detoxification enzymes involved in the resistance. Detoxification by cytochrome P450-dependent monooxygenases and glutathion-S-transferases seem to be the main resistance mechanisms to organophosphates insecticide in L. coffeella. Detoxification by esterases seem to play a minor role on organophosphate resistance in this insect-pest, suggesting a possible case of multiple resistance.

[1234] DIFFERENTIAL SUSCEPTIBILITY AMONG LIFE STAGES TO TOXICANTS: IMPLICATIONS FOR EFFECTS ON NON-TARGET INVERTEBRATES

I. D. Stark¹ & J. E. Banks⁷, ¹Ecotoxicology Program, Dept. of Entomology, Washington State Univ. Puyallup, Washington 98371 USA, E-mail stark@puyallup.wsu.edu; ²Univ. of Washington – Tacoma, 1900 Commerce St., Tacoma WA, 98402 USA E-mail: banksj@u.washington.edu.

A great deal of work has been conducted to determine the impact that pesticides and other toxicants have on nontarget organisms both by ipm practitioners and those concerned with conservation biology, although most studies are designed to estimate toxicological effects on one life stage, some have focused on the susceptibility of different life stages to pesticides and other toxicants. however, little attention has been paid to the population-level significance of differential susceptibility among life stages. if for example one life stage of an insect is much more susceptible to a pesticide than another, how does this translate to overall population growth? Furthermore, populations in nature often exist as mixtures of ages and stages that change over time. the role that population structure plays in susceptibility has also not been explored thoroughly. Our work in demographic ecotoxicology has indicted that differential susceptibility among life stages and differences in initial population structure can have major consequences at the population-level. As such, this should be explored further if we want to develop realistic measures of toxicant impacts on ecosystems, we will present a series of mathematical simulations based on life table data for the seven-spot lady beetle, coccinella septempunctata l. And its prey, the pea aphid, acyrthosiphon pisum harris that indicate that differential susceptibility to toxicants among life stages may have serious implications for both populations and even communities in both natural and managed ecosystems. [1235] CAPTURING POPULATION, COMMUNITY AND LANDSCAPE PROCESSES IN PESTICIDE ECOTOXICOLOGY

P.C. Jepson, Dept. of Entomology, Oregon State University, Cordley Hall, Corvallis, OR 97331, USA.

Carabid beetles and linyphiid spiders fall at the extremes of the dispersal spectrum for predatory arthropods colonizing temperate agricultural crops. Models have been developed that explore the ways in which the contrasting life histories of carabids and linyphiids affect the impact of pesticide sprays on population density and local persistence. Although such models may be of value in improving our understanding of the mechanisms that underlie the loss of natural enemies in some sprayed systems, they are of limited value in the management of pesticide use, or in prediction of potential impacts on the wide range of beneficial taxa that contribute to important ecological functions in agricultural crops. The development of indices of tolerance to pesticides at the community level, provides an opportunity to build new ways of predicting pesticide risks. Estimates of the so-called 95% protection level (or HC5), the maximum dose that in theory, will be non-toxic to 95% of the species present within a habitat, will be presented for invertebrates that inhabit forest streams and riparian zones in Oregon. The potential value of this statistic for pesticide management at the watershed level will be reviewed. Databases may provide an effective tool for the analysis of possible impacts to highly diverse assemblages. The web-based modeling and database system Pond-Fx (http://www.ent3.orst.edu/PondFX/), will be summarized and explored, to demonstrate one approach to the integration of chemical, toxicological and ecological data, in the prediction of pesticide risks to non-target invertebrates in pond systems.

[1238] NOVEL INSECTICIDAL TOXINS FROM *PHOTORHABDUS*: ALTERNATIVES TO BT?

R.H. ffrench-Constant, Department of Biology, University of Bath, BAth, BA2 7AY UK.

With widespread concerns over resistance to Bt transgenic crops the need for alternatives is paramount. We have cloned four insecticidal toxin complex (tc) encoding loci from the bacterium *Photorhabdus luminescens*. This bacterium lives in the gut of nematodes that invade insects where it is released to help overcome the insect host. Each of the four loci encodes a high molecular weight protein toxin and Tca together with Tcd have been shown to constitute the majority of the oral toxicity to lepidoptera via genetic knock-out. The LC₁₀ of Tca is similar to some of the less active Bt toxins but feeding is inhibited at much lower doses. The histopathology of Tca action on the insect midgut is shown and potential implications for possible modes of action are discussed.

[1239] EXPRESSION OF *BACILLUS THURINGIENSIS* CRY2A PROTEINS IN PLANT CHLOROPLASTS: INCREASING TOXICITY TO SUSCEPTIBLE AND *BACILLUS THURINGIENSIS* RESISTANT INSECTS

W. I. Moar '& H. Daniell', 'Dept. of Entomology and Plant Pathology, Auburn Univ., 301 Funchess Hall, Auburn, AL 36849, USA, E-mail <u>wmoar@accessg.auburn.cdu</u>. ² Dept. of Molecular Biology and Microbiology, University of Central Florida, Orlando, FL 32816 USA

The use of commercial, nuclear transgenic crops expressing Bacillus thuringiensis (Bt) toxins has escalated in recent years due to their advantages over traditional chemical insecticides. However, in crops with several target pests with varying degrees of susceptibility to Bt (e.g. cotton), there is concern regarding the suboptimal production of toxin, resulting in reduced efficacy and increased risk of Bt resistance. Additionally, relance on a single (or similar) Bt protein(s) for insect control, increases the likelihood of Bt resistance development. Expression of economically important genes via the chloroplast has been reported for insect and herbicide resistance with much higher expression levels than nuclear transgenic plants. Besides extremely high protein levels (potential "high dose"), chloroplast gene expression also results in tissue specificity. The maternal inheritance of the chloroplast genome in most crops also reduces the potential for outcrossing of foreign genes to other plants (especially weedy species). We report here, the overexpression of the Cry2Aa2 protoxin in tobacco chloroplasts, and a possible approach to delay the evolution of Bt resistance in the field. Cry2Aa2 was chosen because of its high toxicity against many insect pests, limited homology to Cry1A proteins, small size of the protoxin, and increased stability. When transgenic tobacco leaves expressing Cry2Aa2 protoxin in chloroplasts were fed to susceptible, Cry1A resistant and Cry2Aa2 resistant tobacco budworm, *Heliothis virescens*, cotton bollworm, Helicoverpa zea, and the beet armyworm, Spodoptera exigua, 100% mortality was observed against all insect species and strains. Southern blot analysis confirmed stable integration of cry2Aa2 into all of the chloroplast genomes of transgenic plants. Transformed tobacco leaves expressed Cry2Aa2 protoxin at levels between 2 and 3% of total soluble protein, 20-30 fold higher levels than current commercial nuclear transgenic plants. These results suggest that plants expressing high levels of a non-homologous Bt protein should be able to overcome or at the very least, significantly delay, broad spectrum Bt resistance development in the field.

[1241] ECOLOGICAL IMPLICATIONS OF THE LARGE-SCALE PRODUCTION OF INSECTICIDAL, TRANSGENIC PLANTS

A. Hilbeck, Swiss Federal Institute of Technology, Geobotanical Institute, Zurichbergstr. 38. CH-8044 Zurich, Switzerland, E-mail: hilbeck@geobot.umnw.ethz.ch

The adoption of genetically engineered crop plants proceeds very fast. Currently, several In a adoption of genetically engineered crop plants proceeds very fast. Currently, several cultivars of 8 major crop plants are commercially available including soybcan, corn, cotton, canola, potato, tomato, tobacco, sugar beet but many more plants with new and combined, multiple traits are close to registration. While currently agronomic traits (herbicide resistance, insect resistance) dominate, traits conferring 'quality' traits (altered oil compositions, protein and starch contents) will begin to dominate within the next years. However, acompany the advectory for the sector accompositions of the sector accomposition of the sector accom However, economically the most promising future lies in the development and marketing of crop plants expressing pharmaceutical or nutraceuticals ('functional foods') and plants that express a number of different genes. From this, it is clear that future agricultural and, ultimately, also natural ecosystems will be challenged by the large-scale introduction of entirely novel genes and gene products in entirely novel combinations at high frequencies all of which will have unknown impacts on their associated complex of nontarget organisms, i.e. all organisms that are not targetted by the insecticidal protein. In a multiple year research project, we investigated tritrophic and bitrophic effects of transgenic Btexpressing corn on the natural enemy species, *Chrysoperla carnea* (the green lacewing), and a number of other predator species. In these laboratory trials, we found prey-mediated effects of transgenic corn, expressing the gene from Bacillus thuringiensis (BI-corn) that codes for the expression of an insecticidal toxin (Cry1Ab), causing significantly higher mortality of an important insect natural enemy, the Green Lacewing (Chrysoperla carnea, order: Neuroptera). This was the first report on the susceptibility of a third trophic level insect (i.e. natural enemy) to a Bt-toxin which was believed to only affect herbivores in the order of Lepidoptera. In further laboratory trials, we confirmed that the route of exposure (fed directly or via herbivorous prey) and the origin of the Bt (from transgenic plants or incorporated into artificial diet) strongly influenced the degree of mortality. In further molecular studies, we confirmed direct toxicity of Cry1Ab by finding receptor binding in C. carnea midgut epithelium. Field implications could be multifold but will be difficult to assess because they interfere in very intricate ways with complex ecosystem processes that we still know only very little about. However, there is a number of lessons that can be learned from the past that could help anticipating potential implications and designing long-term, area-wide monitoring programs to detect possible adverse effects on ecosystem functioning and biodiversity at a stage where early intervention might still help to avert undesired developments.

[1242] NON-TARGET EFFECTS OF TRANSGENIC INSECTICIDAL CORN -THE MONARCH AND BEYOND

L. C. Hansen & J. J. Obrycki, Dept. of Entomology, Iowa State University, Ames, IA 50011, USA, E-mail: lrahnsen@iastate.edu

During the past 5 years, transgenic crops expressing a insecticidal protein from Bacillus thuringiensis (Bt) have been widely planted in the United States. The speed with which this new technology has become commercially available has caused controversy over how to assess and manage the risk of transgenic plants. Previous examinations of non-target ecological effects of transgenic insecticidal crops have focused on species that are representative of crop-based food webs, for example, natural enemies, phytophagous species, or plant pathogens. However, unintended effects on species beyond field borders have not been fully addressed. Consumption of transgenic insecticidal pollen on non-crop plants outside crop fields is one probable mechanism since insecticidal toxins may be expressed in wind-dispersed pollen. Recently, experimentally applied relatively high concentrations of transgenic Bt corn pollen on milkwed leaves in the laboratory were shown to cause significant mortality of monarch larvae (Losey, et al. (1999) Nature 399, 214). This laboratory study raises questions about the effects on monarch populations of naturally deposited Bt corn pollen on milkweeds. Field deposition of pollen was assessed by placing potted milkweed plants within and around a transgenic corn field. The cumulative deposition of transgenic pollen in 1998 was highest within the corn field (74 to 217 pollen grains/cm²) and decreased to between 6 and 20 pollen grains/cm² at 3 m from the edge. Similarly in 1999, deposition within the field was highest within the corn field (80-115 pollen grains/cm²) and decreased to 5 to 7 pollen gains/cm² at 3 m and 1 pollen grain/cm² at 10 m. Monarch larvae were exposed for 48 hrs. to three densities (14, 135, and 1300 pollen grains/cm²) of two types of transgenic (MAX 454, 7333Bt) and nontransgenic (4494) pollen. Exposure to 135 pollen grains/cm² leaf surface, of transgenic event 176 caused 50% larval mortality within 5 days and 62% mortality prior to pupation. Exposure to similar amounts of pollen from a transgenic event Bt11 hybrid caused 38% mortality within 5 days and 46% mortality prior to pupation. At both 1,300 and 135 pollen grains/cm² leaf area, 5-day survival of monarch larvae following a 48 hr exposure was lower on transgenic pollen. The two higher concentrations of transgenic pollen from event 176 significantly reduced survival to the pupal stage. At 14 pollen grains/cm², survival was similar for the three pollen types. Based upon the expression of toxin in transgenic pollen, and wind dispersal of this pollen beyond the edges of agricultural fields, we predict that the effects of transgenic pollen on monarchs may be observed at least 10 meters from transgenic field borders. However, the highest larval mortality will likely occur within 3 meters from the edge of a transgenic field.

[1243] INTERACTIONS BETWEEN TRANSGENIC OILSEED RAPE AND PARASITOIDS

T. H. Schuler, R. P. J. Potting, I. Denholm & G. M. Poppy, Dept. of Entomology & Nematology, IACR-Rothamsted, Harpenden, AL5 2JQ, UK, E-mail Tanja.Schuler@bbsrc.ac.uk..

The behaviour of non-target insects is likely to play a role in determining how their populations will be affected by transgenic plants expressing toxin genes of Bacillus thuringiensis (Bt). We have investigated this for a model system involving Bt oilseed rape expressing the CrylAc toxin (highly active against many lepidopteran pests), the diamondback moth (Plutella xylostella) and the braconid parasitoid Cotesia plutellae. The latter, a solitary endoparasitoid, is an important enemy of P. xylostella, itself notorious as the first insect pest to evolve resistance to microbial Bt sprays in the field. We present evidence that although parasitoid larvae forced to develop in Bt-treated susceptible hosts inevitably died with their hosts, behavioural factors are likely to limit the scale of this effect under field conditions. Furthermore, the performance of parasitoids attacking Btresistant hosts on transgenic plants demonstrated no measurable adverse effects of Bt toxins on the behaviour of adult C. plutellae or the survival of parasitoid larvae. Any tactic aimed at suppressing pest populations risks disrupting the dynamics of natural enemies, due to a reduction in host or prey densities. These effects will be most pronounced for species, such as hymenopteran parasitoids, that tend towards greater ecological specialism and may even be specific to particular pest organisms. The apparent lack of effects on survival or host-seeking ability of the parasitoid implies a considerable environmental advantage over broad-spectrum insecticides used for pest management at present. It is also possible that the continued ability of C. plutellae to locate and parasitise Bt-resistant hosts on transgenic crops could assist with constraining the build-up of Bt-resistant pest populations. More generally, these results highlight the need to consider behavioural as well as toxicological aspects when investigating possible side-effects of transgenic crops on non-target organisms.

Index terms: Bacillus thuringiensis, Plutella xylostella, Cotesia plutellae, behaviour, diamondback moth

[1244] NON-TARGET EFFECTS OF BT-COTTON: A CASE STUDY FROM AUSTRALIA

L. J. Wilson & G. P. Fitt, CSIRO Cotton Research Unit and Australian Cotton Cooperative Research Centre, Locked Bag 59, Narrabri, Australia, 2390, E-mail lewisw@mv.pi.csiro.au

The advent of transgenic cotton containing the CrylAc gene offers the potential to significantly reduce pesticide use on Australian cotton, where the primary pests are the larvae of Helicoverpa armigera and H. punctigera. However, there is the potential for non-target effects of this technology, including effects on species dependent in some way on lepidoperan larvae for food, unforeseen effects on other components of the cotton fauna that use the plant, or its residues, as food or indirect effects due to reduced spraying. We undertook a series of large scale experiments to address some of these issues, with a particular emphasis on comparison of the overall fauna complex present in conventional and transgenic crops. Experiments had three treatments, unsprayed conventional cotton, unsprayed Bt-cotton and sprayed conventional cotton. Five experiments were completed over four years. The sprayed treatment was not replicated due to the risk of insecticed drift. Regular samples were collected using suction samples, pitfall traps and visual assements were also made. In general across all experiments there was significant reduction in most taxa in the sprayed treatment compared with both unsprayed treatments. Comparing the unsprayed Bt-cotton and conventional cotton there were no significant differences between treatments in any taxa, except for the abundance of lepidopteran parasitoids which were less abundant in Bt-cotton due to the reduced abundance of hosts. Outbreaks of spider mites tended to be more prevalent in the commercially sprayed cotton, while outbreaks of aphids occurred earlier in the unsprayed conventional and Bt-cotton. We did not investigate the response of specific non-target species to Bi-cotton, nevertheless the results suggest that Bi-cotton had little detrimental effect on the overall abundance or diversity of insects, compared with unsprayed conventional cotton. Index terms: Helicoverpa, Bt-cotton, pest management

[1245] UK FIELD-SCALE TRIALS OF GM HERBICIDE TOLERANT CROPS TO DETECT THE ENVIRONMENTAL EFFECTS ON INVERTEBRATE ABUNDANCE AND BIODIVERSITY

L. P. Woiwod', A. M. Dewar², A. Haughton⁴, C. Hawes³ & M. Heard⁴, ¹IACR Rothamsted, Harpenden, Herts., AL5 2JQ, UK, E-mail: Ian.Woiwod@bbsrc.ac.uk; ²IACR Brooms Barn, Higham, Bury St Ednuunds, Suffolk, IP28 6NP, UK; ³Scottish Crops Research Institute, Invergowrie, Dundee DD2 5DA UK; ⁴ITE Monks Wood, Abbots Ripton, Huntingdon, Cams. PE17 2LS, UK.

At present no genetically-modified (GM) crops are grown commercially in the United Kingdom. The first four awaiting introduction are GM herbicide tolerant maize, spring and winter oilseed rape (canola) and beet. As these crops are intended to allow more efficient weed control, concern has been expressed that their widespread introduction will reduce further the food resources available to wildlife associated with conventional arable agriculture in the UK, particularly birds, many of which have recently shown alarming population declines on farmland (Firbank et al. 1999). In response to these concerns the British Government has introduced the concept of 'managed development' of GM crops which involves a voluntary delay in their commercial introduction whilst research is carried out to investigate likely effects on the abundance and biodiversity of wildlife at the field scale (Firbank et al. 2000). The field-scale trials described here will form the major part of these investigate likely effects on the abundance field scale and introduction of these four crops into the UK. Sampling will be targeted on weed and invertebrate populations as these are likely to be the most rapidly affected by any change in crop husbandry and herbicide regime and hiey also have important functional roles in the food chain supporting mammals and birds. Indicator invertebrate groups selected for detailed study are Collembola, carabid beetles, Heteroptera, adult butterflies, bees, Lepidoptera and sawfly larvae, and gastropods. The background to this study, the choice of indicators, and the reason that this ecological research programme has become so controversial will be discussed.

[1246] EFFECTS OF TRANSGENIC PLANTS ALONG THE FOOD CHAIN: CAN THEORY HELP?

G. L. Lövei, Danish Institute of Agricultural Sciences, Department of Crop Protection, Research Centre Flakkebjerg, DK-4200 Slagelse, Denmark.

Transgenic plants grown in agricultural fields will become parts of natural ecological systems, such as parts of food webs. Ecological theory of food webs will be reviewed with a focus on the presence and significance of indirect interactions in ecological communities. Evidence will be presented which indicates that: 1. indirect interactions frequently occur in food webs; 2. such indirect interactions can be more significant than direct interactions; 3. there is no inevitable time delay between the manifestation of direct and indirect effects; indirect fects can appear quickly.

and indirect effects: indirect effects can appear quickly. Several genetic manipulations aim at changing the chemical composition of plants, while not necessarily making them toxic to insects. A review of literature on the occurrence of significant effects reverberating along the food chain as a result of modified base resource quality indicates that such effects are likely to occur with transgenic plants, too. Nontarget effects of transgenic plants can be significant, and we cannot ignore them in environmental impact evaluations.

Keywords: transgenic plants, non-target effects, tri-trophic links, food webs

[1248] INSECT RESISTANCE MANAGEMENT ON INSECT PROTECTED CROP IN LATIN AMERICA: PERSPECTIVES, CHALENGES AND EXPERIENCES

O. D. Fernandes¹ & G. W. Videla², ¹Monsanto Brazil, Av. Nações Unidas, 12.901, 70 andar. 04578-000. S. Paulo, SP. Brazil, E-mail odnei.d.fernandes@monsanto.com; ²Monsanto Argentina, Maipú 1210, Piso 6, Buenos Aires, Argentina, E-mail: guillermo.w.videla@monsanto.com

Lepidopteran pests are the major insect pests of soybean, corn and cotton in Argentina and Brazil. These countries have, respectively, the following crop areas: 8 milion ha and 12.5 milion ha of soybeans, 19 milion ha and 12.7 milion ha of corn, and 500,000 ha and 800,000 ha of cotton. Field studies utilizing genetically modified crops containing Btgenes are being conducted in these countries. Bt-Corn and Bt-Cotton have been commercially introduced in Argentina. In Brazil these technologies are under development. To date, control of lepidopterans pests in these crops is mainly done with the use of chemical insecticides. In this scenario, genetically modified plant, expressing the Bt proteins, may become an important pest control tool, if the principles of Integrated Pest Management (IPM) are considered. Insect Resistance Management (IRM) strategy is being addressed within the basis of the IPM philosophy, considering the scientific knowledge and the current agricultural practices for each crop. The basic principles of IRM (i.e., IPM, Refuge for susceptible pests, Monitoring target pests susceptibility, and Educational program) have been presented as important tools for the success of the program. In regards to the Refuge component, areas with specific sizes for each crop, in the different countries are being established, considering both local biological aspects and the international experience. Susceptibility baselines are being determined for different key pests. This information will be useful for resistance monitoring, which will be done in coordination with Research Institutes. To implement the IRM program, partnerships with research, education and extension institutes are being formed to provide information to growers and educate them on the importance, advantages and practicability of the program to assure a long-term viability of the technology. Key to a successful implementation of an IRM plan is the establishment of concerned efforts with seed companies. Technical recommendations based on a uniform IRM program will facilitate farmer understanding of the strategies to be implemented. Monsanto in Latin America, utilizing experiences gathered internationally, is working to set an effective IRM program, and is proactively seeking enrollment of seed companies in this effort.

Index terms: transgenic crop, resistance management, lepidopterans

[1247] SOME ASPECTS OF THE ENVIRONMENTAL RISK ASSESSMENT OF GENETICALLY MODIFIED PLANTS IN BRAZIL

D. M. F. Capalbo & V.L.S.S. Castro, Embrapa Environment, Caixa Postal 69, Jaguariúna, SP, 13820-000, Brazil, E-mail deise@cnpma.embrapa.br.

In the last decades, the anachronism between the need of new products to control agriculture pests and the offering of alternatives to them, has led to the development of new biological control tools. Among them are the genetic modified plants and microorganisms (GMOs) but their environmental risks are unknown because of the recent use of this technology. In the evaluation of environmental risks many aspects should be taken into account, specially when analyzing the GMOs: competitive displacement, alergenicity, toxicity, pathogenicity as well as the possibility of mutation of the new organisms. In Brazil any type of GMO has to get its authorization for use and commercialization from the National Technical Biosafety Committee (CTNBio) of the Ministry of Science and Technology. Although this Committee was established in 1995, only in 1997 an environment release of a GMO was applied. This caused an strong debate among environmentalists, official agencies, scientific and non scientific society, as well as among themselves. At that time, it came up the necessity for establishing a protocol for food safety and environment risk assessments of the GMOs and its establishment is being discussed. Many studies are under development for Brazilian agriculture utilization, and among them are those developed by Embrapa, envolving a multidisciplinary researchers group studying the environment risk assessment of some of Embrapa's GMOs. It is expected to generate enough knowledge to maintain the biodiversity and protect the environment, and also to reduce the public concern on the GMOs release. Embrapa Environment Unit, is responsible for establishing the main non target organisms to be studied and to develop, evaluate and validate such a protocol. As a conclusion it is expected to generate a better scientific knowledge and support for the risk analysis for the effective safe management of the GMOs used in the country. Index terms: biosafety, GMO, protocol

[1249] DEVELOPMENT AND IMPLEMENTATION OF RESISTANCE MANAGEMENT STRATEGIES FOR BT COTTON IN AUSTRALIA

G.P. Fitt & **R.T. Roush**², 1 - Australian Cotton Co-operative Research Centre, CSIRO Entomology, P.O. Box 59, Narrabri NSW 2390, Australia.Email: gary.fitt@ento.csiro.au. 2 - Centre for Weed Management Systems, University of Adelaide, Glen Osmond, SA 5064, Australia

Pesticide resistance is a challenge to many agricultural production systems. In Australia, cotton production has been dependent on the use of a range of pesticides for management of *Helicoverpa* spp., sucking pests and mites. *Helicoverpa* armigera has shown a propensity to readily evolve resistance to synthetic pesticides. With the introduction in 1996 of transgenic cotton varieties expressing the Cry1Ac gene from Bt, a pre-emptive resistance management strategy was implemented. While Bt resistance is not evident in field populations of *H. armigera*, the potential for resistance is high. The strategy has five components: (i) effective refuge crops to generate moths not exposed to Bt proteins (ii) cultivation of crop residues to destroy overwintering pupae of *H. armigera*, (iii) planting windows for Bt cotton to avoid wide divergence in phenology among transgenic crops, (iv) defined thresholds for late season management and (v) monitoring of Bt resistance levels. Considerable research has validated and refined elements of the strategy. It is critical to avoid resistance to the Cry1Ac protein until pyramided varieties can be introduced. For this reason the Australian industry has also restricted Bt cotton to 30% of the cotton area until two gene varieties become available. Deployment of Bt genes and resistance management must also be co-ordinated across the many crops throughout a cropping system.

Index Words: Bt Cotton, resistance_management, Helicoverpa.

[1250] NORTH AMERICAN CORN

R. L. Hellmich, USDA-ARS, Corn Insects and Crop Genetics Research Unit and Dept. of Entomology, 109 Genetics Laboratory, c/o Insectary, Iowa State University, Ames, IA 50011, USA, E-mail: rlhellmi@iastate.edu.

Growers in some regions of North America have rapidly adopted Bacillus thuringiensis (Bt) transgenic maize for controlling lepidopteran pests. Dramatic control of European corn borer, Ostrinia nubilalis, on these plants has many scientists concerned about high selection pressure to toxins in these plants and subsequent adaptation. In cotton-growing Tegions there are concerns about corn earworm, also called cotton bollworm, *Heliocoverpa* zea, resistance to these plants. There are many complexities with Bt corn insect resistance management (IRM) that are being considered by scientists, regulators, and growers. Within a few years IRM may become even more complex as transgenic maize for coleopteran pests become available. This talk will emphasize current IRM issues including refuge management, educating growers, monitoring for resistance, remedial plans, and alternatives to current practices.

Index terms: transgenic maize, Bacillus thuringiensis, resistance management.

[1252] BOTANICAL INSECTICIDES: ACCEPTABILITY OF ESTABLISHED PRACTICES AND CHALLENGES IN DEVELOPING NEW ONES

B. P. S. Khambay, Biological and Ecological Chemistry Department, IACR-Rothamsted, Harpenden, Hertfordshire, AL5 2JQ, UK, E-mail: bhupinder.khambay@bbsrc.ac.uk

The use of botanical insecticides remained the main method for controlling insect pests until the end of 19th century. Highly effective synthetic insecticides have now largely replaced them globally on medium to large-scale farms. Continued interest in botanicals within sections of the community in developing countries arises mainly from emotive rather than scientific considerations. Key factors include the perceived advantages (e.g. lower mammalian toxicity) associated with 'natural' materials. However several considerations, including limited photostability, production costs and patent protection, have deterred multinational companies from developing souch products. In contrast, their widespread use by small-scale farmers in many developing countries is primarily dictated by economic considerations where safety and efficacy are assumed on the basis of long traditional practices. Scientific studies have indicated that these can be dangerous assumptions. The international scientific community has till now concentrated mainly on issues surrounding the registration of botanical insecticides in developed countries. However, there is now clearly the need for greater effort in evaluating the efficacy and safety of the traditional practices used by resource-poor farmers so that they too can be confident of producing safe and healthy foods. The opportunity then arises for them to benefit from globalisation of markets through GATT. This introductory presentation to the session will highlight the broad issues surrounding

This introductory presentation to the session will highlight the broad issues surrounding the development and use of botanical insecticides and will include experiences from research at IACR-Rothamsted.

[1251] PINK BOLLWORM RESISTANCE TO BT COTTON

B.E. Tabashnik, T.J. Dennehy, Y. Carrière, Y.B. Liu, S.K. Meyer, A. Patin, & M.A. Sims, Department of Entomology, University of Arizona, Tucson, AZ 85721 USA, E-mail brucet@ag.arizona.edu.

Many insects have evolved resistance to *Bacillus thuringiensis* (Bt) toxins in the laboratory and diamondback moth has evolved resistance to sprays of Bt toxins in the field. The refuge strategy is the major tactic used for slowing evolution of insect resistance to crops that are genetically modified to produce Bt toxins. Refuges consist of host plants that do not produce Bt toxins and thus allow survival of susceptible insects. So far, Bt cotton has been extremely effective in controlling the pink bollworm (*Pectinophera gossypiella*), a global pest of cotton that is the key lepidopteran pest of cotton in Arizona. However, intense selection for pink bollworm resistance to Bt cotton is likely because of the high proportion of Bt cotton in Arizona and limited use of alternate host plants by this pest. The refuge strategy is expected to be most effective when three assumptions are valid: 1) random mating occurs between susceptible adults emerging from non-Bt cotton refuges and resistant adults emerging from Bt cotton, 2) inheritance of resistance is recessive, and 3) the frequency of alleles conferring resistance is less than 0.001. We are testing these assumptions for pink bollworm in Arizona with experiments in the field, greenhouse, and laboratory. Results to date suggest that violations of one or more of the assumptions are likely. Thus, pink bollworm is at high risk for rapid evolution of resistance to Bt cotton.

Index terms: Bacillus thuringiensis, Pectinophora gossypiella, transgenic cotton

[1253] OPPORTUNITIES AND PROBLEMS FOR DEVELOPMENT AND USE OF BOTANICAL INSECTICIDES IN INDUSTRIALIZED COUNTRIES

M.B. Isman, Faculty of Agricultural Sciences, Univ. of British Columbia Vancouver, BC, Canada V6T 1Z4, Email: murray.isman@ubc.ca

The Food Quality Protection Act (1996) in the United States will dramatically limit the uses of synthetic insecticides (e.g. organophosphates, carbamates and pyrethroids) in the years to come. As all fresh produce imported into the United States must meet US standards for pesticide residues, the impact of this legislation will be felt by many other countries who depend on the US as an export market. One positive result however, is the creation of a window of opportunity for alternative products and technologies for pest control, among which are botanical insecticides. Neem (Azadirachta indica, Meliaceae) control, among which are bolanical insecticutes, teem or analytic matter, means of the subject of intensive investigation worldwide for over 25 years, and subsequently, a voluminous literature. In spite of this, neem has yet to become well established as an important pest control product in the United States, where it has been approved for use on food crops since 1993. To this point, cost of production of reliably efficacious, standardized neem products has been a limiting factor, but competition among companies producing neem insecticides should make neem more cost-effective to growers. Although many people view neem as the modern paradigm for the development of botanical insecticides, neem has also suffered from a major problem common to modern botanicals – reluctance of regulatory agencies to approve it for use. While neem has been approved in the US, several other industrialized countries (e.g. Germany, Canada) have yet to give approval in spite of reviews spanning several years. Insecticides based on plant essential oils represent a completely different approach to the development of botanicals. Widely used as flavoring agents in the food and beverage industries, essential oils and their pure constituents (mostly monoterpenoids) are readily available in large quantities and can be relatively inexpensive. Some of these are exempt from registration in the US, even though they show considerable efficacy against insects. As such, it has been possible to get pest control products based on plant essential oils from the research laboratory to the market in less than two years. A number of other well investigated botanicals have yet to reach the marketplace, primarily because they fail to meet the criteria of (1) availability on a commercial scale, (2) chemical standardization, or (3) registration. Regulatory agencies could use modified criteria to review these types of products in a fair manner. Index terms: neem, plant essential oils, pesticide registration

[1254] CURENT DEVELOPMENTS WITH ETHNOBOTANICAL INSECTICIDES FROM GHANA: REVIVING AND MODERNISING AGE-OLD PRACTICE

S. R. Belmain⁴, H. F. Andan³, D.E. Neal³ & J.R. Cobbinah⁴, 'Natural Resources Institute, University of Greenwich, Central Avenue, Chatham Maritime, Kent ME4 4TB, UK, E-mail: <u>S.R.Belmain@gre.ac.uk;</u> ³Ministry of Food and Agriculture, P.O. Box 950, Tamale, Ghana; ³Medical Research Council, P.O. Box 138, Lancaster Road, Leicester LE1 9HN, UK; Forestry Research Institute, UST Box 63, Kumasi, Ghana

Insecticides of botanical origin are particularly relevant for small-scale subsistence farmers. In this context, botanicals have many advantages over synthetic pesticides because they are normally gathered locally by farmers and can provide an inexpensive method of pest control. For the majority of farmers in the world, commercial insecticides are often too costly or unavailable. Similarly, many uneducated farmers use synthetic pesticides inappropriately, leading to environmental and human safety hazards as well as promoting insecticide resistance. These factors have led to increased efforts to understand indigenous pest control strategies with a view to reviving and modernising age-old practices. However, previous studies assessing the insecticidal properties of plants have often failed to simultaneously assess their safety. Potential vertebrate toxicity associated with using insecticidal plants requires investigation before their institutional promotion at farm-level. The objectives of our research have been to identify plants from Ghana that are traditionally used by subsistence farmers as post-harvest protectants, screen them for bioactivity against target pests, develop optimal application protocols and assess their potential deleterious effects against vertebrates. Participatory rural appraisal surveys in Ghana identified hundreds of plant species with uses against a range of target pests. Laboratory screening of plants with known ethnobotanical uses as storage protectants showed that thirteen plant species were effective in controlling common storage pests. Laboratory bioassays showed that powdered admixed roots of Securidaca longipedunculata were the most effective material in controlling all the insects tested by dose-dependently reducing overall F, emergence and increasing adult mortality. The next most effective plants in controlling storage pests were *Ocimum americanum* and Chamaecrista kirkii. Farmer participatory research trials and field station trials in Ghana were used to develop optimum application protocols and showed similar results to laboratory bioassays. Rodent feeding trials with six of the plant species showed that none of the plants were toxic when incorporated into rat diet at 1%. However, a 5% concentration of *S. longipedunculata* and *C. kirkii* was found to affect rodent growth rate, reduce kidney size and increase liver cell hyperplasia. The implications of these findings are discussed in the context of increased promotion of botanical usage.

[1255] THE USE OF BOTANICAL INSECTICIDES IN BRAZIL

<u>S. S. Martinez</u>¹, 'Área de Proteção de Plantas, Instituto Agronômico do Paraná, C. Postal 481, 86.001-970, Londrina-PR, Brazil, E-mail: suemart@onda.com.br

The extraction, commercialisation and exportation of botanical insecticides, mainly rotenone and pyrethrum, were a regular practice in Brazil before 1940. The intensive use of synthetic insecticides during the following decades, in Brazil as in the world, promoted serious environmental problems and human and animal intoxication, thus indicating the need of natural alternatives for insect control. The research on botanical insecticides received special input with the development of equipments like the NMR and HPLC, which helped to identify and to quantify the chemical compounds responsible for the action on the insects. Brazil has a very wide range of plant species with properties against insects. Nonetheless the studies on the use of these plants on pest control during the last decades are not many and they are mostly restricted to laboratory conditions. Species rich in rotenoids have been tested on crop pests, like: Tephrosia toxicaria, T. tunicata and T. candida killed larvae of Empoaska kraemeri and adults of Diabrotica speciosa, besides showing antifeedant effects on D. speciosa. These extracts have totally suppressed populations of Zabrotes subfasciatus in stored dry beans. Pachyrhyzus tuberosus killed larvae of Ascia monuste and showed antifeedant effects. Derris spp. killed larvae of Musca domestica. Other studies include plants like Sesamum indicum and Ricinus communis to control Atta spp. However these studies still need to be continued so to have DL50 determined, the methods of extraction well established, the products standardised. During the last 15 years the interest of research on botanical insecticides in Brazil directed to Azadirachta indica, the neem tree, mainly due to the high effectiveness of the compounds, facility of extraction, low toxicity to vertebrates and to the great amount of steps already clarified. Biotypes from different origins were planted in different regions in Brazil in order to evaluate their adaptation. The content of azadirachtin is being determined in these plants and during the development of the plants and the storage of the seeds. Several introductions of neem seeds were made and commercial areas are now being established in Central, Southwest and Northern Regions of Brazil. Neem extracts are being tested on crop pests, to be used particularly in organic coffee. Results on coffee pests are promising. Other Meliaceae species native in Brazil, like Melia azedarach, Trichilia sp., Cedrela sp., Cabralea glaberrima, are being tested on insect pests with similar effects.

Index terms: Azadirachta indica, Melia azedarach, Tephrosia sp., rotenoids, Meliaceae

Symposium and Poster Session

[1256] USE AND PERSPECTIVES OF BOTANICAL PESTICIDES IN CUBA

M. Alfonso, R. Avilés, J. Estrada y N. González, Institute of Fundamental Research on Tropical Agriculture (INIFAT), Santiago De Las Vegas, La Habana, Cuba. E-mail: inifat@ceniai.inf.cu.

Agricultural situation in Cuba changed dramatically when the Law of Agricultural Reform was promulgated and big state enterprises were founded . Then, pesticides and fertilizers were increasingly used, leading to an external supply based development. In the middle 80' this scope started to be replaced when a system of Integrated Pest Management as a state policy and the Pesticide Central Register were established, as well as the Biopesticides Production Enterprises Network and new production structures were created. These measures enabled to face the globalization challenges. Effective management concerning natural resources, biofertilizers and biotechnologies in terms of sustainability was carried out, and food production in cities increased by means of Urban Agriculture an the application of Organic Agriculture that lead to a production of more than one million tons of vegetables annually. During this period, botanical species traditionnally used by farmers have been processed in different ways leading, for instance, to aqueous extracts from tobacco harvest residues and to Tabaquina, a formulation for the white fly (*Bemisia tabaci*) control in beans. More recently, making use of native and introduced flora as a source of biologically active compounds, neem tree (Azadirachta indica) cultivation has been increased and china berry tree (*Melia azedarach*) and other plant species as *Gliricidia sepium*, *Solanum globiferum* and *Tagetes* spp. have been used to prepare formulations against a wide variety of insects, mites, nematodes, snails and weeds being ennemies of important crops as tobacco, banana, vegetables, corn, beans and others.

[1257] THE UPTAKE OF BOTANICAL INSECTICIDES BY FARMERS: A CASE STUDY OF TOBACCO BASED PRODUCTS IN NIGERIA

S. Morse¹, N. Ward³, N. McNamara³ & <u>I. Denholm</u>⁴, ¹International Development Centre, University of Reading, Reading RG6 6AU UK, E-mail s.morse@reading.ac.uk; ³Natural Resources International, Chatham Maritime, Chatham, Kent UK, E-mail a.f.ward@gre.ac.uk; ³Diocesan Development Services, P. O. Box 114, Idah, Kogi State, Nigeria; ⁴Institute of Arable Crops Research, Rothamsted, Harpenden, Herts., ALS 2JQ, UK, E-mail ian.denholm@bbsrc.ac.uk.

This paper will present the results of extensive experience in the development and promotion of tobacco-based insecticides for the control of field crop pests in Kogi State, Nigeria. An NGO, the Diocesan Development Services began the development of tobacco-based insecticide formulations during the early 1990s in partnership with a major European development donor and a 'sister' NGO based in Kenya. Since the mid-1990s these have been tested under 'farmer managed' on-farm conditions for two crops that are particularly vulnerable to pest attack in Kogi State: cowpea (Vigna unguiculata) and maize (Zea mays). The results of this on-farm programme, and a number of associated surveys conducted in the late 1990s, suggest that farmers are aware of botanical insecticides and do make limited use of them. It was also clear that even crude tobacco formulations had a significant benefit on cowpea and maize yields relative to the absence of pest control, although commercial insecticides were more effective. However, while having advantages of cost and availability over commercial insecticides, tobacco based products appear to have serious disadvantages that limit their widespread use, and some of these are discussed in the paper. One example is that tobacco sprays were not effective on the pod sucking bug insects that have a major effect on cowpea seed quality, and this is a major determinant of market price. It is clear that the uptake of botanical insecticides is influenced by a wide range of factors both within and external to the broad and complex 'crop protection' decision-making environment, and technical efficacy is but one element amongst many that has to be considered. A better understanding of these factors and how context-specific they may be is required in order to maximise their adoption by farmers under 'resource poor' conditions.

Index terms: Nigeria, botanical insecticide, tobacco, cowpea, maize.

[1258] GENETIC PRINCIPLES AND THE EVOLUTION OF INSECTICIDE RESISTANCE

[1260] THE IMPACT OF POLYPHAGOUS INSECT DISPERSAL ON DEPLOYMENT DECISIONS FOR TRANSGENIC CROPS

J. A. McKenzie, Department of Genetics, Faculty of Science, The University of Melbourne, Victoria 3010, Australia.

Insecticide resistance has developed to a range of different insecticides in a number of different species. the phenomenon has been investigated by specialists from many distinct discipline areas. the most effective studies have frequently used, or combined, the expertise of these specific disciplines within an evolutionary framework to inform strategies of resistance management. resistance systems, in turn, lend themselves to the investigation of more general evolutionary phenomena because the selective agent is known, the biochemical/molecular/physiological basis of selection is defined and relative fitness differences between susceptible and resistant phenotypes are sufficiently large to enable experimentation on a manageable time scale. Underpinning an evolutionary approach to resistance management is a foundation of the genetic theory of adaptive change. Applied to insecticide resistance, this theory predicts that if selection acts within the phenotypic distribution of susceptibles, that is at insecticide concentrations lower than that required to kill all susceptibles, the lc₉₉₉₉ of susceptibles rare resistant mutations are favoured and a monogenic response is more likely. Experiments in the australian sheep blowfly, lucilia cuprina (diptera: calliphoridae) confirm these general expectations and demonstrate that if a monogenic resistant variant is present in a susceptible population exposed to concentrations less than the $l_{\alpha_{mn}}$ of susceptibles the likelihood of establishment of the resistant allele is a function of the frequency of the allele in the population, the pleiotropic effect of the resistant allele and the concentration of exposure. The consequences of these results to the general general denote the order of the derivation of resistance management strategies will be discussed to provide an introduction to the other papers of the symposium.

Index Terms Lucilia cuprina, monogenic/polygenic response

[1259] EXPLAINING THE NON-COFFEE DRINKERS: DO WE KNOW WHY SOME ORCHARD PESTS EVOLVE RESISTANCE AND SOME DON'T?

D.M. Suckling, HortResearch, PO Box 51, Lincoln, Canterbury, New Zealand.

Orchards are highly modified environments, which are largely monocultures of high-value perennial crops. They provide a stable habitat of high quality food for herbivores, often of much higher nutritional and moisture content than the surrounding landscape. They are usually large areas, readily colonised by generalist or specialist arthopods in the local vicinity, and the complex trunk and canopy architecture offers a multitude of micro-habitats for establishment. For several decades in the second half of the 20° Century, many orchard pests were managed with a pesticide-intensive approach reliant on a single mortality factor to achieve the economic threshold. Differences in the rate of appearance, level, spread of pesticide resistance can be considered from our knowledge of the process of evolution. We have some understanding of predisposing factors towards insecticide resistance, involving attributes related to crop colonisation by pests (polyphagy, generation time on that crop, dispersal, patch size and ratio of treated to untreated habitat), as well as crop management factors (pesticide application frequency and persistence, previous pesticide use), and the interaction between the target pest and pesticide (life stages and target site affected, etc.). Despite this, some surprises still energe.

Keywords: Mutation, phenotypic expression, selection, gene flow

M. A. Caprio¹ & D. M. Suckling³, ¹Dept. of Entomology and Plant Pathology, Box 9775, Mississippi State, MS 39762, USA, E-mail mcaprio@entomology.msstate.edu; ¹HortResearch, PO Box 51, Lincoln, Canterbury, New Zealand.

In most cases, resistance management options, if considered for a product at all, only consider these options from the perspective of a single crop. However, many insects are polyphagous and move among multiple crops and agroecosystems. As a result of this movement, each of these systems interconnects to utilize a common and limited natural resource, susceptibility to one or more toxins. We have utilized a two-locus spatially explicit stochastic simulation model to explore the interactions resulting from insect movement among different habitats and the resistance management choices made in each system. These interactions are important to understand when developing deployment strategies for transgenic crops. Resistance management in one crop, particularly a crop with a high value and high conventional pesticide inputs, could be compromised by the use of the same or similar toxins in crops where the transgene is less likely to provide as much benefit. Simulations of an apple-clover system in New Zealand and the corn-cotton agroecosystem in the South Eastern U.S.A. suggest that the population dynamics of the entire system may be at least as important as the level of cross-resistance between toxins utilized in different crops attacked by the same pest species. Deployment decisions for transgenic crops in agroecosystems where insects move among multiple crops should consider the role of the individual crops as refuges for other crops and the economics trade-offs between the relative roles of crops as refuges for the maintenance of susceptibility and the benefits of transgenic technology to that crop.

[1261] NATURE'S SELECTION: GENETICS AND EVOLUTION OF RESISTANCE IN *HELICOVERPA ARMIGERA*

J.C. Daly, K.P. Olsen & R. Akhurst. CSIRO Entomology, GPO Box 1700, Canberra, ACT, Australia, 2601, E-mail: J.Daly@ento.csiro.au.

Resistance to a number of insecticides has evolved independently in field populations of *H. armigera*. In the two cases studied in detail, resistance is partially dominant. In contrast, resistance management strategies (RMS) for transgenic cotton, containing the Cry1Ac toxin from *Bacillus thuringiensis* (Bt) have assumed that any likely resistance genes will be inherited as a recessive trait. Recently, we have selected strains of *H. armigera* in the laboratory that are resistant to the Cry1Ac toxin. This strain can develop successfully on transgenic Bt cotton. We have begun crosses to determine the mode of inheritance. Preliminary results suggest that the resistance is consistent with a major gene that is incompletely dominant. We propose that such a gene is likely to shorten the period during the growing season in which the Bt cotton is effective at killing larvae. RMS will need to include the possibility of such a gene evolving in the field. Index: *Bacillus thuringiensis*, resistance, management strategies

[1262] RESISTANCE IN DIAMONDBACK MOTH: LESSONS FROM THE HELIOTHINES

D. G. Heckel, L. J. Gahan & B. E. Tabashnik, Dept. of Genetics, Univ. of Melbourne, Parkville 3052, Victoria, Australia, Email d.heckel@ genetics.unimelb.edu.au; ²Dept. of Biological Sciences, Clemson Univ., Clemson, SC 29634, USA; Dept. of Entomology, Univ. of Arizona, Tucson, AZ 85721, USA.

Over the past several years we have developed a genetic linkage map for the heliothine genera *Heliothis* and *Helicoverpa*, and used it to map and characterize genes conferring resistance to chemical and biological insecticides. To test whether this approach is useful in other lepidopteran pests, we have begun mapping diamondback moth (*Plutella xylostella*, DBM) resistance to insecticidal toxins of *Bacillus thuringiensis* (Bt). DBM is a worldwide pest of vegetables and is still the only insect to evolve resistance to at least four Bt toxins (including Cry1Ac) and enables DBM larval survival on transgenic plants. We utilized a similar experimental design as in the heliothine mapping studies to map Bt. Cry1Ac resistance gene we previously mapped in a laboratory-selected strain of *Heliothis virescens*. If these two species have independently developed the same resistance risk in other lepidopteran species that are targets of Bt-transgenic crops, such as *Helicoverpa amigera* and *Ostrinia nubilalis*.

Index terms: Bacillus thuringiensis, Plutella xylostella, resistance, Heliothis virescens, Helicoverpa [1264] HOW OFTEN DOES RESISTANCE ARISE IN NATURAL POPULATIONS: CYCLODIENE RESISTANCE AS A CASE STUDY

R.II. ffrench-Constant, Department of Biology, University of Bath, BAth, BA2 7AY UK.

Cyclodiene resistance is associated with a single amino acid substitution in the *Rdl* encoded GABA receptor subunit. Replacements of this same amino acid have been found in all target site resistant insects studied to date. This raises the important question: Does the mutation arise once and spread, or do novel mutations occur repeatedly at the same site? We have examined this question by looking at the global population genetics of several very different insects: 1) The *Drosophila melanogaster/simulans* group. 2) Whiteflies of the genus *Bemisia.* 3) The coffee berry borer *Hypothenemus hampei.* 4) The red flour beetle *Tribolium castaneum.* In this talk we will examine how the number of associated lifestyle of the insect. For example, in the strictly inbreeding coffee berry borer, resistance appears to have arisen only once in one inbreeding ine in one South Pacific island. Whereas in the outbreeding beetle *Tribolium* we can detect clear evidence several repeated global origins of the same resistance associated mutation.

[1263] A HITCH-HIKER'S GUIDE TO RESISTANCE IN THE SHEEP BLOWFLY

R. D. Newcomb¹, D. M. Gleeson², J. R. Stevens³, R. J. Russell⁴, J. G. Oakeshott⁴, ¹HortResearch, Private Bag 92169, Auckland, New Zealand, E-mail rnewcomb@hort.cri.nz; ²Landcare Research, Private Bag 92170, Auckland, New Zealand; ²School of Biological Sciences, Univ. of Exeter, Prince of Wales Rd, Exeter EX4 4PS, UK; ⁴CSIRO, Div. of Entomology, GPO Box 1700, Canberra, ACT 2601, Australia.

In the sheep blowfly Lucilia cuprina resistance to organophosphorus insecticides (OPs) is encoded at the Rop-1 locus. Increased levels of resistance to diethyl over dimethyl OPs is caused by a Gly137Asp substitution in the E3 protein encoded by Rop-1. This single substitution transforms the carboxylesterase into an OP hydrolase. A second type of OP resistance is encoded by another substitution in the same enzyme, Trp251Leu/Ser, which confers increased levels of resistance to dimethyl over diethyl OPs. We have studied Rop-I sequence variation in two sets of samples of sheep blowfly. In the first set of 40 isogenic lines of L, cupring from Australasia there was a absolute correlation between resistance to diethyl and dimethyl OPs, reduction in carboxylesterase activity, gain of OP hydrolase activity and the presence of the two Rop-1 substitutions described above. Sequence variation in a 1.2 kb region including these two substitutions and three introns surrounding them revealed that each of these mutations has occurred at least twice. Only three lines were susceptible to OP insecticides and each was of a different haplotype. In the second set of wild caught L. cuprina from around the world four new haplotypes were observed with all but one carrying resistance substitutions. In a similar global sample of the sibling species, *L. sericata*, 15 haplotypes were observed, including one containing the Gly137Asp substitution in New Zealand and four containing the Trp251Leu/Ser substitution. We have used these data to assess the predictions of the hitch-hiking model of molecular evolution. In particular; i) whether the original advantageous mutational events were rare and modern alleles are derived from a small number of these events, ii) whether levels of neutral variation at the locus under positive selection and linked loci have been reduced and iii) whether levels of neutral variation within L. cuprina are reduced in this region relative to levels observed in susceptible haplotypes in sibling species.

Index terms: Lucilia cuprina, organophosphorus resistance, carboxylesterase

[1265] ESTIMATING FITNESS IN COLORADO POTATO BEETLE

P. A. Follett, USDA-ARS, U. S. Pacific Basin Agricultural Research Center, PO Box 4459, Hilo, Hawaii 96720

Experiments were conducted to examine age, space, and time components of selection for resistance in Colorado potato beetle under field conditions. Fitness components were measured for permethrin-resistant, susceptible, and hybrid strains of this insect on permethrin-treated and untreated potato. Results indicated that there is significant selection against susceptible genotypes during all larval stages and in the adult stage at the time of permethrin application. Therefore, targeting a particular life stage to avoid selection is not an option. After insecticide application to potato plants, relative fitness of 1-d-old larvae of the three strains changed through time as permethrin residues decayed and plants grew. Selection against susceptible individuals persisted for the duration of the experiment (14 d), but the selection differential diminished with time. Selection against susceptibles was more intense on old foliage than new foliage treated with permethrin, probably due mainly to greater leaf expansion of new foliage. Tactics for slowing the rate of resistance development should emphasize reducing the proportion of the population subjected to insecticide selection and the frequency of selection.

Index terms: Leptinotarsa decemlineata, permethrin, insecticide resistance, ecological genetics, adaptation

[1266] ATTEMPTS TO MEET THE THREAT OF PYRETHROID RESISTANCE TO THE CONTINUED SUCCESS OF INSECTICIDE TREATED BEDNETS AGAINST MALARIA VECTORS

C.F.Curtis & <u>J Kolaczinski</u>, London School of Hygiene & Tropical Medicine, London WC1E 7HT, UK

Insecticide treated bednets appear to be the most promising method for malaria vector control, but only pyrethroids are currently used for net treatment and already there are reports of broad spectrum pyrethroid resistance in the main malaria vector, Anopheles gambiae, in three West African countries (Chandre et al 1999, Bull WHO 77: 230-4). Insecticide treatment of nets acts by improving the personal protection provided by the net to the individual net user and also, when nets are used by a whole community, by mass killing of mosquitoes attracted to the nets by the odour of the occupants. We have repeatedly found in Tanzanian trials that this mass killing effect greatly reduces the numbers of mosquitoes in a village population living long enough for malaria parasites to have matured inside them. Effective protection of the net user will probably require a net treatment with excito-repellent action on mosquitoes, but mass killing of mosquitoes attracted to nets presumably requires only a rapid insecticidal effect. In areas where the An.gambiae population is either pyrethroid susceptible or resistant we have tested various pyrethroids, as well as the non-pyrethroids pirimiphos methyl and carbosulfan, in experimental huts which allow evaluation of both the protection of sleepers under nets from biting, as well as of mosquito killing. Comparison of our data with that of Darriet et al (WHO/Mal/99.1088) suggests that some pyrethroids, but not others, may still perform satisfactorily against the existing form of resistance, but we are working to clarify this. Pirimiphos methyl was ineffective in prevention of biting but highly effective at mosquito killing. Carbosulfan was encouragingly effective at both functions against a pyrethroid resistant population (Fanello et al, 1999, Parassitologia 41: 323-6). We propose to investigate carbosulfan-pyrethroid mixtures for resistance management.

[1267] INSECTICIDE RESISTANCE GENES IN CULEX PIPIENS COMPLEX MOSQUITOES FROM CHINA

C. L. Qiao, X. Li, J. M. Xing & K. Zhang, The State Key laboratory of Integrated Management of Pest Insects and Rodents, Inst. of Zoology, Academia Sinica, Beijing, China, 100080, E-mail: qiaocl@panda.ioz.ac.cn

Insecticide resistance to organophosphorus chemicals has been studied at the gene and the population levels in the *Culex pipiens* complex in various geographic areas of China. In this species, overproduction of nonspecific esterases is a common mechanism of resistance to (OP) organophosphorus insecticides. The overproduction of all esterases B is due to the gene amplification of the same DNA haplotype which has been found in mosquitoes with an esterase B1 protein, independently of their geographical origin: Xishan and Beijiao in Beijing, Gaomi in Shandong province, Shashi and Wuhan in Hubei province, Guangzhou in Guangdong province and Kunming in Jiangsu province. It was observed that there were large variations in gene amplification levels. This situation is supported by the B1 amplification that has a unique origin, and has subsequently spread by migration and selection by OP insecticides. Esterase B1 has spread without limitation compared with that of A2B2 esterases in China, as B1 is observed in South, North and Central China, whereas the A2B2 distribution is found only in the South of China, Shanghai, the Kunming in Yunnan province, and Hangzhou in Zhejiang province. That variations exist in the esterases of several resistant populations indicates polymorphism in the mosquito enzymes. This finding supports the hypothesis of insecticide resistance occurring multiple times involving different resistance-conferring esterases. Index terms: organophosphorus, esterases, amplification

[1268] BIFENAZATE (D2341), A NOVEL AGENT TO CONTROL SPIDER MITES

<u>R. C. Moore</u>¹, M. A. Dekeyser³, P. T. McDonald³ & G. W. Angle Jr.³, ¹Uniroyal Chemical Co., World Headquarters, Middlebury, CT, USA; ²Uniroyal Chemical Co., Research Laboratories, 120 Huron Street, Guelph, Ontario, Canada; ³Uniroyal Chemical Co., New Product Research, 74 Amity Road, Bethany, CT, USA

Bifenazate (N'-(4-Methoxy-biphenyl-3-yl)-hydrazinecarboxylic acid isopropyl ester) is an novel carbazate acaricide discovered by Uniroyal Chemical for mite control in a range of agricultural and ornamental crops. The compound has a very good toxicological and environmental profile. Bifenazate shows no cross-resistance with currently available acaricides and provides preliminary results indicate it has a novel mode of action for mites. Bifenazate provides excellent control at low rates against all stages of tetranychid mites. Bifenazate shows minimal impact on beneficial insects and mites and is recommended for use in integrated pest management (IPM) programs. Bifenazate has shown no crop injury at rates well in excess of proposed field rates. Index terms: Panonychus species, tetranycid mites, new acaricides.

[1269] THIAMETHOXAM: NEW INNOVATIVE APPLICATION OPPORTUNITIES FOR A SYSTEMIC PRODUCT

R. Senn', W. Fischer¹, P.Wyss² & A. Morcos³, Novartis Crop Protection AG, 'Werk Rosental, CH-4058 Basel, Switzerland, 'Biology Research Insect Control, CH-4332 Stein, 'Agrochemical Research Station, Kaha, Qalubiya, Egypt

Thiamethoxam is a second-generation neonicotinoid belonging to the subclass of the Thianicotinyl compounds. Its physicochemical properties are favourable for an efficient transport in water. Studies with C⁴ radiolabelled material applied as a soil drench to tomato plants were done. Results show that thiamethoxam after uptake by the root hairs is transported via cell walls (apoplast) and cytoplasm (symplast) to the xylem in which it is transmitted in acropetal direction within the plant. Clear differences between three selected neonicotinoids, acetamiprid, imidacloprid and thiamethoxam were observed at 6 hours, 3 and 14 days after application. Acetamiprid was taken up by the roots very fast but did not and 14 mays after application. Acctainipita was taken up by the foots (p) has but not last for a long time in the plant, whereas thiamethoxam was slower in uptake into the tomato roots, but clearly for a longer time present in the plant. Imidaeloprid was in between the two other compounds. Due to the high water solubility of 4100 mg/ and the negative log P value of -0.13, thiamethoxam is neither adsorbed to the organic matter nor negative log F value of -0.13, thiamemoxam is neutrer adsorbed to the organic matter for affected by normal soil pH values. In greenhouse tests neither pH values of 5.5 to 8.1 nor organic matter content of 2-20% did affect the efficacy of thiamethoxam against *Aphis* gossypii on cotton. In addition it is available for uptake even under relatively dry soil conditions. This fact could be confirmed in a field trial done in Egypt, where tomato crops grown under wet conditions (normal irrigation) and under dry conditions (minimal irrigation) were compared. Soil application methods such as into drip irrigation system injection, in furrow spray, drench after transplanting, side dress or seedling dip, are suitable methods to control Homoptera, Coleoptera, Hemiptera and other insect pests over an extended period. The best placement of thiamethoxam is in the root zone, which means 2-4 cm below the sowing line at planting. In order to reach the root zone, thiamethoxam should be incorporated. After soil surface application, the product has to be washed in with enough irrigation water to move the active ingredient to the root zone. Product placement and irrigation have to be combined in a way that the water will lead the compound to the root zone. Over or under-irrigation may influence the efficacy level. Main advantages of any soil application method are the long time protection, the protection of the whole plant including the new growth and its convenient application.

Index terms: Thiamethoxam, soil application, chemodynamics.

[1270] INDOXACARB: ATTRIBUTES THAT IMPACT FIELD PERFORMANCE AND CONTRIBUTE TO CONSERVATION OF BENEFICIALS

J. T. Andaloro, K. D. Wing, L. J. Flexner, R. A. Cameron, J. P. Saienni, & C. J. Williams, DuPont Agricultural Products, Stine Research Center, Elkton Road, Newark, DE, 19711, USA.

Indoxacarb is a new oxadiazine insecticide from DuPont globally available in SC and WG formulations for fruits, vegetables, and cotton. Indoxacarb is very safe to workers and consumers with minimal re-entry time, post-harvest intervals, and personal protective equipment. Indoxacarb has a novel mode of action and is extremely potent at its biochemical target, blocking the sodium channel. Indoxacarb is a broad spectrum lepidopteran insecticide with activity against selected sucking insects at 25 to 125 grams AI/ha. The primary route of entry is mainly through ingestion and secondarily by contact resulting in irreversible paralysis and quick feeding cessation causing death within 48 hours. Indoxacarb has low water solubility and is not systemic. However, due to its lipophilicity it partitions in the leaf's waxy cuticle optimizing control of certain sucking insects and providing rainfastness and good residual activity. Indoxacarb formulations are very stable in the tank at extreme temperatures over a three day period. Compatibility with various insecticide, fungicide, and foliar nutrient tank mix partners to date has been excellent, assuming the proper product mixing sequence is followed. The behavior of indoxacarb in the application process and interactions with target crops are being

investigated; particularly as they apply to droplet flight, evaporation, droplet impact, leaf spreading, initial retention, leaf penetration, and residual. Indoxacarb exhibits selective safety to many beneficial arthropods due to differences in toxicity, differences in feeding behavior of herbivorous vs insectivorous insects, and different modes of entry resulting in the conservation of beneficials in commercial agricultural ecosystems. In addition, Indoxacarb's safety to workers and the environment, consistent and reliable efficacy, low use rate, and unique mode of action make it an excellent fit in Integrated Pest Management and Resistant Management programs and a prudent choice to alternate, replace, or complement existing insecticide chemistries.

Index terms: indoxacarb,oxadiazine,insecticide, biological efficacy, beneficial safety.

[1271] BIORATIONAL AGENTS – MECHANISM AND IMPORTANCE IN INTEGRATED PEST MANAGEMENT (IPM) AND INSECTICIDE RESISTANCE MANAGEMENT (IRM) PROGRAMS

L. Ishaaya & A. R. Horowitz, Dept. of Entomology, Agricultural Research Organization, The Volcani Center, Bet Dagan 50250, Israel, Fax: +972-3-968 3835, E-mail: vpisha@netvision.net.il,

In recent years, insect control by broad-spectrum insecticides has come under assault and scrutiny because of their undesirable effects on human health and the environment. Furthermore the rapidly developing resistance to conventional insecticides provides the impetus to study new alternatives and more ecologically acceptable methods as part of IPM and IRM programs. One of these approaches is the development of novel compounds affecting developmental processes in insects, such as chitin synthesis inhibitors, juvenile hormone mimics, and ecdysone agonists. In addition extensive efforts have been made to develop compounds acting selectively on some groups of insects by inhibiting or enhancing biochemical sites such as respiration (diafenthiuron), the nicotinyl acetyl choline receptors (imidacloprid and acetamiprid), and salivary glands of sucking pests (pymetrozine). Among the most recent novel insecticides with selective properties are the novaluron, thiamethoxam and spinosad. Novaluron (Rimon) is a novel benzoylphenyl urea that acts by both ingestion and contact. As such it is a powerful suppressor of lepidopteran larvae such as Spodoptera littoralis and Helicoverpa armigera (by ingestion) and of whiteflies such as *Bemisia tabaci* and *Trialeurodes vaporariorum* (by contact). Thiamethoxam (Actara) is a novel neonicotinoid acts specifically on aphids and whiteflies and spinosad (Tracer) acts on diversity of insect species and is considered an important agent for controlling the western flower thrips. The above compounds will be discussed in relation to their modes of action and their importance in IPM and IRM programs in various agricultural systems.

Key words: selective insecticides, benzoylphenyl ureas, juvenile hormone mimics, ecdysone agonists, biocontrol agents.

[1272] A GLOBAL PERSPECTIVE ON THE BIOLOGY AND FIELD PERFORMANCE OF SPINOSAD

P. Downard, G. Thompson, L. Pavan, R. Dutton, K. Kaneshi, A. Samsudin & P. Vergolas, Dow AgroSciences, Australia, USA, Brazil, England, Japan, Malyasia, and France.

Spinosad is a fermentation metabolite of the actinomycete Saccharopolyspora spinosa Mertz and Yao. Spinosad provides highly effective control of many Lepidoptera, Thysanoptera and Diptera insect pests while exhibiting large margins of selectivity for many beneficial insects, non-target organisms and applicators. Spinosad was one of the first products accepted into the U.S. Environmental Protection Agency reduced risk category. It has received rapid registrations and is currently registered on over 100 crops in over 20 countries as Tracer*, Success* and SpinTor* Naturalyte* Insect Control. This paper will focus on the field development program that enabled the rapid registration and adoption by agriculture. Special emphasis will be place on crops, pests, and use patterns in Australia, Japan, Southeast Asia, Latin America, USA and Europe. An overview of the philosophy and methods of the field development program as well as the biological response of Naturalyte Insect Control products in different environments will be provided.

[1273] BIOLOGICAL ACTIVITY AND FIELD PERFORMANCE OF METHOXYFENOZIDE: A CORNERSTONE FOR CONTROL OF LEPIDOPTEROUS PESTS

R. K. Jausson, Rohm and Haas Research Laboratories, 727 Norristown Road, Spring House, PA 19477-0904, USA, E-mail rahrkj@rohmhaas.com

Methoxyfenozide is a second-generation molt accelerating compound (MAC) in the diacylhydrazine family of chemistry discovered and developed by Rohm and Haas Co. This family also includes tebufenozide and halofenozide. Methoxyfenozide was discovered in 1990 and achieved its first commercial sales in 1999. Methoxyfenozide is binds to the receptor site for ecdysone and induces a premature and lethal molt. Like tebufenozide, methoxyfenozide is highly selective for lepidopterous pests, and is 3- to 10-fold more potent than tebufenozide against most lepidopterous pests. Methoxyfenozide is effective against a broader spectrum of pests than tebufenozide, it is safe to workers, loaders, applicators, consumers, birds, bees, natural enemies, and aquatic organisms. Because of its physiological selectivity for lepidopterous pests and its concomitant safety to beneficial arthropods, methoxyfenozide is well suited for integrated pest management programs. A pro-active resistance management platform was developed by Rohm and Haas Co. to prolong the longevity of methoxyfenozide and other MAC insecticide products in the marketplace.

Index terms: Methoxyfenozide, tebufenozide, ecdysone agonist

[1274] PERFORMANCE OF THIACLOPRID, A NEW FOLIAR APPLIED INSECTICIDE IN THE USA

R. Steffens & H. Lin, Research & Development, Agriculture Division, Bayer Corporation, 8400 Hawthorn Road, P.O. Box 4913, Kansas City, MO 64120, USA.

Thiacloprid, a new neo-nicotinoid (chloronicotinyl) insecticide, is being developed worldwide by Bayer for foliar application against a broad spectrum of sucking and biting insect Thiacloprid has excellent systemic activity and crop safety. It is effective at low nests. rates through contact and stomach activities. In the USA, Thiacloprid will be available in two products, CALYPSO® Flowable (4F) and CALYPSO® 70 WDG. The first registration application has been submitted to the US-EPA for use in apples, pears and cotton. The technical fit for use in additional crops is being investigated. Thiaeloprid has an excellent fit in pome fruits. In addition to post-bloom application, it can be applied prebloom because of its good safety to bees. On apples, it provides good to excellent control of leafminers, leafhoppers, mirid bugs, most aphids, codling moth and plum curculio. The control of other pests such apple maggot, scales, oriental fruit moth, glass wing moth, tuffed apple bud moth and others is under investigation. On pears, Thiacloprid offers excellent control of pear psylla in addition to leafminers, pear midge, aphids, and codling moth. Thiacloprid is soft on predatory mites, spiders and a number of beneficial insects. On cotton, Thiacloprid can be applied at low rates providing effective control of aphids, fleahoppers and other pests. It is particularly suitable for use before the start of pyrethroid sprays, due to its selectivity and IPM compatibility. For the control of whiteflies, including silverleaf whitefly, Thiacloprid offers an effective solution and an alternative to the frequently used tankmixes like Fenpropathrin plus Acephate. A favorable product profile and broad pest control spectrum make Thiacloprid an effective alternative for organophosphates and carbamates, and an attractive tool for resistance management in many situations.

Index Terms: Apples, Pears, Cotton, Codling moth, Pear psylla, Aphids

[1275] RECENT ADVANCES IN PESTICIDE RESISTANCE MANAGEMENT PROGRAMS IN BRAZIL

C. Omoto¹, R. N. C. Guedes² & L. A. Pavan³, ¹Depto, de Entomologia, Fitopatologia e Zoologia Agrícola, Escola Superior de Agricultura "Luiz de Queiroz", Av. Páduas Dias, 20010gia Agricola, Lecola, Sperior Soferior de Martine anticational activity and the second s AgroSciences, Caixa Postal 226, 13800-970 Mogi Mirim, SP, Brasil.

Almost 100 years have completed since the first detection of the resistance to a pesticide in a pest of economic importance and more than 500 cases of arthropod species resistant to the major classes of pesticides have already been documented around the world. However, researches on this subject gained importance in Brazil only in the last decade. The first Brazilian studies have focused on detection of the resistance after the documentation of frequent pest control failures with the use of a certain pesticide. Works have been done with some pests of stored products (Sitophilus zeamais and Rhyzopertha dominica), vegetables and ornamentals (Tetranychus urticae, Plutella xylosiella, Tuta absoluta and Bemisia tabaci), coffee (Leucoptera coffeellum), com (Spodoptera frugiperda), citrus (Brevipalpus phoenicis), among others. Researches on urban pests such as mosquitoes (Aedes aegypti and Culex spp.) and cockroaches (Blattella germanica) have also received attention. Besides detecting the resistance, some studies on genetics and mechanisms of the resistance have also been conducted. Not surprisingly, the most challenging step has been the implementation of the resistance management strategies in Brazil. A recent advance was the establishment of the Brazilian Insecticide Resistance Action Committee (IRAC-BR) in 1997 which is composed of professionals from 16 chemical companies, 2 consultants from universities and a representative from the Brazilian Ministry of Agriculture. The major activities of the IRAC-BR have been centered on research and educational programs. At moment, four research projects have been partially sponsored by IRAC-BR: Bemisia tabaci in vegetables, Spodoptera frugiperda in corn, Tuta absoluta in tomato and Alabama argillacea in cotton. After the implementation of this committee, studies on baseline susceptibility of the key pests to new chemical compounds that are launching in the market have also been emphasized for a proactive resistance management program. In this talk, progress on pesticide resistance management programs of Brevipalpus phoenicis in citrus and Spodoptera frugiperda in corn will be discussed.

Index terms: Brevipalpus phoenicis, Spodoptera frugiperda, chemical control.

[1276] SUCCESSES AND FUTURE CHALLENGES OF MANAGING WHITEFLY **RESISTANCE IN ARIZONA**

T. J. Dennehy & Y. S. Li, Extension Arthropod Resistance Management Laboratory, Dept. of Entomology, University of Arizona, Tucson, AZ 85721, USA, E-mail: tdennchy@ag.arizona.edu.

We will describe the successful management of whitefly resistance to synergized pyrethroid insecticides in Arizona cotton since 1995 and show how insecticide use against whiteflies has declined sharply since that time. Sustaining this success hinges on: 1) maintaining the effectiveness of buprofezin (Applaud®) and pyriproxyfen (Knack®), two insect growth regulators (IGRs) used in cotton; 2) averting more serious whitefly resistance to the insecticide imidacloprid (Admire®/Provado®) in winter vegetables and melons, and to two related neonicotinoid insecticides currently under development, acetamiprid and thiamethoxam; and 3) kceping highly resistant glasshouse whiteflies from spreading resistance to other commodities. While, imidacloprid continued to be used effectively against whiteflies on a very large proportion of Arizona melon and vegetable acreage, resistance levels have increased overall through time. The highest levels of resistance to imidacloprid were consistently detected in Arizona glasshouses and on poinsettias shipped to Arizona from other states. However, whiteflies from specific vegetable and melon fields displayed imidacaloprid resistance levels equal to those detected in glasshouses. Statewide levels of resistance to imidacloprid of whiteflies collected from cotton increased sharply from 1997 to 1998, but declined in 1999. The two newer neonicotinoid insecticides demonstrated significant but low order cross-resistance to imidaclprid. The IGRs, buprofezin and pyriproxyfen, provided the underpinning of the successful whitefly resistance management program implemented in cotton in 1996. Their use has been limited to a maximum of one treatment each in cotton. However, since 1996, less restrictive use of these insecticides has occured in glasshouses and on vegetables and melons. Both compounds continue to perform satisfactorily in cotton. However, the first evidence of reduced susceptibility to pyriproxyfen of whiteflies from Arizona cotton was obtained in 1999, and the populations least susceptible to pyriproxyfen or buprofezin were found in glasshouses and on melons. The future success of whitefly control in Arizona will be predicated on the degree to which use of neonicotinoid and IGR insecticides is limited and harmonized in these complex agricultural ecosystems.

Index terms: Bemisia argentifolii, imidacloprid, acetamiprid, thiamethoxam, resistance management.

1277] PROGRESSIVE INSECTICIDE RESISTANCE MANAGEMENT PROGRAMS IN THE ISRAELI AGRICULTURAL ECOSYSTEM

A. R. Horowitz¹, G. Forer², R. Ausher³, P. G. Weintraub³ & I. Ishaaya⁴, ¹Dept. of Entomology, ARO, Gilat Exp. Sta., M. P. Negev 85280, Israel, E-mail hrami@netvision.net.il; ²Cotton Production & Marketing Board, Herzliyya-B 46103, Israel; ³Dept. of Crop Prot., Ext. Service, Miniatry of Agric. & Rural Develop., P. O. Box 28, Bet Dagan 50250, Israel; ⁴Dept. of Entomology, ARO, The Volcani Center, Bet Dagan 50250, Israel Dagan, 50250, Israel.

Agriculture in the semi-arid Israeli climate has developed into intensive cropping systems including irrigated field crops, orchards and greenhouses. Israel has been plagued by many insect pest species that have seriously damaged yields, such as Bemisia tabaci, Spodoptera littoralis, Helicoverpa armigera, Pectinophora gossypiella and Frankliniella occidentalis, especially in cotton, vegetable and ornamental crops. Increasing failure to control B. tabaci with conventional insecticides led, in the late 1980s, to the introduction of a nationwide insecticide resistance management (IRM) strategy for cotton. One of its main objectives was to provide a means of exploiting and restricting newer chemicals, such as buprofezin, pyriproxyfen and other IGRs, to combat resistance along with other non-chemical measures. One of the achievements of this strategy is the reduction in insecticide use as well as in control costs. The Israeli strategy has since been adapted successfully to cotton in Arizona. Despite this success, however, outbreaks of resistance to newer insecticides have been observed in some cotton-growing areas of Israel. Recently, areawide pesticide management (APM) programs, covering most of the major agricultural crops has come under supervised control. Integrated pest management (IPM) and biological control practices have been introduced regionally. These programs have resulted in about a 30% reduction in the use of pesticides and, no doubt, have also improved the situation with regard to insecticide resistance. The progressing APM programs in such a diverse crop system will be discussed.

Index terms: Bemisia tabaci, Helicoverpa armigera, cotton, agricultural crops, IPM.

[1278] COMBATING INSECTICIDE RESISTANCE: ENMARIA AND THE EUROPEAN PERSPECTIVE

I. Denholm¹ & J. B. Jespersen², ¹Dept. of Entomology and Nematology, IACR-Rothamsted, Harpenden, Herts., AL5 2JQ, UK, E-mail ian.denholm@bbsrc.ac.uk; ²Danish Pest Infestation Laboratory, Skovbrynet 14, DK-2800 Lyngby, Denmark, E-mail j.b.jespersen@ssl.dk.

Insecticide resistance remains an important problem throughout Europe, reflecting a gradual accumulation of resistance mechanisms by some pests, and the greater diversity of species attacking valuable commodities, especially in the horticultural sector. Crop pests of particular concern include the aphids *Myzus persicae* and *Aphis gossypii*, the whiteflies *Trialeurodes vaporariorum* and *Bemisia tabaci*, the thrips *Frankliniella occidentalis*, the spider mites *Tetranychus urticae* and *Panonychus uni*, codling moth, *Cydia pomonella*, and the pear psylla, *Cacopsylla pyri*. In addition, resistance extends to coleopteran and mite pests of stored grain, and public health and livestock pests including mosquitoes, houseflies and occkroaches. ENMARIA (European Network for the Management of Arthropod Resistance to Insecticide and Acaricides) was launched four years ago as an EU-funded Concerted Action to promote the development and implementation of management strategies for insecticide and acaricide resistance throughout Europe. Patticipants in ENMARIA include scientists and advisors from 13 countries, as well as representatives of the agrochemical industry's Insecticide Resistance Action Committee (IRAC). The principal activities have been (i) compiling a database of known or suspected cases of resistance within Europe; (ii) convening workshops to promote the standardisation of techniques and the dissemination of management guidelines; (iii) sponsoring training visits between laboratories; and (iv) publicising the cause of resistance management at conferences, and through publications and a website. Some of these activities and their achievements will be presented and discussed.

Index terms: Insecticide resistance management, resistance monitoring, Europe.

[1279] PRO-ACTIVE RESISTANCE MANAGEMENT OF THIAMETHOXAM.

<u>P. Wyss</u>¹, **R. Senn**² & **M. Angsi**²Novartis Crop Protection AG, ¹Biology Research Insect Control, CH-4332 Stein, ²Werk Rosental, CH-4058 Basel, Switzerland. Email: peter.wyss@cp.novartis.com

Neonicotinoids are on the way to become the new leading class of insecticides. Among them, thiamethoxam is the first product of the second generation neonicotinoids. It has a broad spectrum combining high performance with low rates, thus contributes substantially to the economics of the farmers. this favourable cost /performance ratio will trigger an intensive use, as history has demonstrated, any type of over- or misuse of products results sooner or later in development of resistance. Learning from the past, a program is devised for thiamethoxam with the aim to assess the risk potential of developing resistance in target pests. Indeed, some of the target pests like whiteflies and colorado potato beetle are known and feared for their resistance genes. in some regions these pests are very hard to control and new active compounds have to be managed very carefully in order to maintain their efficacy. Therefore, resistance management does not start with the occurrence of resistance but much earlier and in several steps, as it is undertaken for thiamethoxam:

Experimental part:	Ativities/results with Thiamethoxam:
- Monitoring methodology:	Provokes a fast feeding stop. It takes a
	while until pests die. Mortality
- Cross-resistance tests:	Target pests resistant towards established insecticides are normal by
	sensitive to thiamethoxam.
	Field results indicate a X-resistance
	risk in whiteflies to neonicotinoids.
- Sensitivity of target pests:	World wide assessment of baselines and monitoring of sensitivity over time.
- Relevance of monitoring data:	Monitoring data are compared with field
	performance for calibration: resistance
is	i de la companya de la
	defined as a loss of field
	Serviciante.
- Life stage specific sensitivity:	nonulations is correlated with field

performance. Use recommendations according to IRM principles:

High resistance risk is expected in pests with short life cycles like aphids, whiteflies and cpb under long (soil application) or high (repeated foliar application) selection pressure. thiamethoxam should be used to control target pests not longer than half of the treatment period. In a block application system neonicotinoids should be placed in the same window. If thiamethoxam is used as long lasting soil application, products of other modes of action should be used as foliar spray if needed.

Index terms: Thiamethoxam, pest sensitivity, use recommendation.

[1280] DEVELOPMENT AND APPLICATION OF AN INSECTICIDE RESISTANCE IMPACT MINIMISATION STRATEGY FOR COTTON PEST CONTROL IN INDIA

D.A.Russell¹, K.Kranthi², D.Jadhav³, J.Singh⁴, A.Regupathy⁵, T.Surulivelu², ¹Natural Resources Inst., Chatham Maritime, ME4 4TB, UK. E-mail d.a.russell@gre.ac.uk ²Central Institute for Cotton Research, Nagpur, 440022 India. ³ICRISAT, Patancheru, 502324, India. ⁴Punjab Agric. Univ, Ludhiana, 141004, Punjab, India. ³Tamil Nadu Agric. Univ, Madurai, India

Significant resistance has been demonstrated in Spodoptera litura, Pectinophora gossypiella and Bemisi tabaci in India. However, Helicoverpa armigera is the major pest of cotton in India, contributing strongly to the average of 44% of cotton growing costs spent on insecticides. Pyrethroid resistance in H.armigera was first demonstrated in 1988 and national resistance laboratory network was set up to operate from 1993 using discriminating dose assays for major chemistries. This work has shown pyrethroid resistance to be high (e.g. averaging 80% survival of discriminating dose for feuvalerate) and stable and ubiquitous across the sub-continent, mediated by esterase and oxidative metabolic mechanisms and by nerve insensitivity and reduced cuticular penetration. In areas of Southern India where pyrethoid use is declining, resistance is falling. OP resistance (quinalphos) is more modest at around 20% in central India, with cyclodiene (endosulfan) resistance rising from c.20% to 40% across the season. When taken with poor insecticide quality and application practices, insecticide resistance in bollworms is a major production constraint. A consortium of research partners developed an insecticide resistance impact minimisation 'best bet' package from 1993-1996. The use of sucking pest tolerant genotypes and imidocloprid as a seed treatment allowed broad spectrum foliar applications to be delayed to at least 60 days from planting. With appropriate scouting practices and a careful sequence of bollworm chemistries (designed for efficacy, reduction of impact beneficial arthropods and resistance development minimisation) reduction of impact beneficial articropods and resistance development minimisation) applied in a fully village participatory framework it was possible to demonstrate very substantial benefits on an expanding scale, reaching over 1,200 farmers in 23 villages in 4 states in the Indian Union in 1998. Not only was insecticide use reduced by 44 to 95% and yields increased by 17 to 70% but there was a 30 to 98% reduction in the human health hazard associated with spraying across the states and very substantial profitability increases in all villages. As a consequence, the principles are being pursued under Indian government funding in the 25 districts which are the heaviest insecticide users in eight states in the 2000 cotton season and a major regional research project on resistance management for *Helicoverpa armigera* has commenced in India, China and Pakistan from 2000 under funding from the Common Fund for Commodities. Index terms: participatory, best-bet, Bemisia tabaci

[1281] INSECTICIDE RESISTANCE MANAGEMENT APPLICATION TO THE CONTROL OF MALARIA VECTORS

J. Hemingway', A.D. Rodriguez^{1,2}, R.P. Penilla^{1,2}, M. Rodriguez², ¹ Cardiff School of Biosciences 1, Main College Building, Cardiff University, Park Place, Cardiff, CF1 3TL, South Wales, U.K. ²National Institute of Public Health, Cuernevaca, Mexico.

Rotations and spatial mosaics of organophosphates, pyrethroids and carbamates have been compared to long-term single-use of DDT or a pyrethroid in an operational malaria control programme in Southern Mexico. The 4-year programme monitored resistance levels by bioassay and mechanistically pre-intervention, and over a 3-year treatment period. All treatments were duplicated. Resistance to DDT was high at the start of the project, while resistance to other insecticide classes could not be detected pre-intervention by bioassay, although An. Albimanus in Mexico has a history of broad-spectrum resistance through agricultural insecticide use in the 1970s. Resistance to DDT remained stable even in areas where this insecticide was no longer used. The rate of resistance development in the mosaic and rotation areas was slower than that in areas sprayed continuously with a pyrethroid. Results will be discussed in the broader context of long-term operational malaria control programmes.

Key words: Anopheles, pyrethroid, organophosphate

Padua Dias, Piracicaba, SP, 13418-900 Brazil

Development of acaricide resistance in leaf spider mites is one of the most serious problems in the horticulture in Japan. Kanzawa spider mite, *Tetranychus kanzawai* is one of the most important pests for the pear production in Japan. Acaricides used to control Kanzawa spider mite have been replaced to newly introduced acaricide due to the development of resistance to acaricides. Generally, most of acaricide could be used to control Kanzawa spider mites for only few years. Thus, to prevent the development of acaricide resistance, pear growers were recommended to use acaricide by rotation. When we observed mite density in pear orchards, we found that the number of mite is larger in pear orchards where growers sprayed acaricides many times than in pear orchards where growers sprayed acaricide less times. Especially, in latter pear orchards, growers did not spray acaricides after August. We also found that in pear orchards where less acaricide application was performed, more number of predators such as six-spotted thrips, Scolothrips takahashii or predacious mite, Amblyseius womersleyi. were observed. When we tested acaricidal activity against Kanzawa spider mite, only few were effective as adulticidal (dicofol, milbemectin, brofenprox and chlorphenapyr) and ovicidal (dicofol, milbemectin, tetradifon, brofenprox chlorphenapyr and etoxazole) among acaricides tested. This result indicates many growers sprayed acaricides which were not effective due to the development of resistance. From above mentioned results, if we can wait to spray effective acaricides until the mite population increases and can preserve natural enemies, we can control Kanzawa spider mite in pear orchard in Japan. Usually we do not need to spray acaricides to control Kanzawa spider mite after August.

Index terms: Tetranychus kanzawai, Amblyseius womersleyi, Scolothrips takahashii

[1284] CHALLENGES WITH MANAGING INSECTICIDE RESISTANCE IN THE APHID, *MYZUS PERSICAE*

<u>S. P. Foster</u> & I. Denholm, Dept. of Biological & Ecological Chemistry, IACR-Rothamsted, Harpenden, Herts., AL5 2JQ, UK. E-mail: stephen.foster@bbsrc.ac.uk

The peach-potato aphid, Myzus persicae Sulzer, a major pest on a wide range of agricultural and horticultural crops, provides one of the clearest demonstrations of how genetic and ecological factors can interact to determine the dynamics of resistance and influence success with resistance management. Control of this species with insecticides is being threatened by an increasing diversity of resistance mechanisms, based on both enhanced detoxification of insecticides and modifications to their target sites. This is progressively eroding the supply of effective products, and highlights the importance of ensuring sufficient chemical variety and restricting the use of novel insecticides in order to sustain their effectiveness. Advances in understanding the different resistance mechanisms at the genotypic, biochemical and molecular levels have facilitated the development of rapid and precise methods for their detection. These methods are proving to be invaluable for monitoring changes in the incidence of several different resistance mechanisms in M. persicae populations around the world; a prerequisite for pest management. Resistance problems in UK *M. persicae* populations are enhanced by the predominance of year-round parthenogenesis, leading to non-random associations between mechanisms. In effect, they hitch-hike' together from generation to generation enjoying or suffering any fitness advantages or costs that each may confer. This has important implications for the rate at which resistance can accumulate in populations under selection by insecticides, and also for its decline through counter-acting selection when insecticides are not used. Recent investigations of fitness drawbacks associated with resistance have revealed that these are predominantly expressed during times of stress, such as during harsh winter weather. Furthermore, fitness studies of knock-down resistance (kdr) in M. persicae suggest that this mechanism imposes a direct negative pleiotropic effect on important aspects of behaviour, including response to aphid alarm pheromone. Indeed, there is growing evidence that insecticide-resistant M. persicae, in the UK at least, suffer adverse selection strong enough to maintain them at manageable frequencies in most seasons despite prolonged and often intense selection by insecticides.

Index terms: fitness advantage, fitness cost, maladaptive behaviour.

[1283] DEVELOPMENT OF A RESISTANCE MANAGEMENT STRATEGY FOR COLORADO BEETLE IN POLAND: A SUCCESSFUL IRAC-SPONSORED PROJECT

<u>R. Dutton</u>¹, M. Pawinska², A. Przybysz - Szczesna³ & P. Wengorek⁴, ¹ Dow AgroSciences, Wantage, OX12 9JT, UK; ² Institute of Plant Protection, 76-009 Bonin; ³ Institute of Organic Chemistry, ul Annopol 6, 03-236 Warsaw; ⁴ Institute of Plant Protection, ul Miczurina 20, Poznan, Poland

The IRAC (Insecticide Resistance Action Committee) Field Crops and Vegetables Working Group sponsored a project in Poland to define the extent of resistance of Colorado Potato Beetles (CPB) (Leptinotarsa decemlineata Say) following field failures with some organophosphate and pyrethroid products. DDT was the major product for control of CPB into the 1960's until resistance became widespread. Chlorfenvinphos was as effective for 15 years, but its use has been declining. Synthetic pyrethroids introduced in 1980 have been widely used, with resistance problems beginning in 1992. At present, bensultap is a favoured product. Potatoes are a major crop in Poland therefore it was important that the resistance situation be monitored and managed. The objectives of this IRAC-sponsored programme were: (a) to test the validity of a leaf-dip bioassay (IRAC # 7) on CPB larvae and compare this with topical application against adults, using chlorfenvinphos, cypermethrin and bensultap as representative standards from their respective chemical groups; (b) to develop the technique of using a 'discriminating dose' for resistance monitoring; and (c) to define a resistance management strategy for CPB, initially in Poland. Results have indicated that the IRAC #7 method is easy to use, produces consistent results for all the products, and that data can be used to define a discrimination dose. Within Poland there are 'hot spots' of resistance to both pyrethroid and organophosphate insecticides, associated with previous history of use. A resistance management strategy has been developed, communicated to farmers and advisors, and was published by the Plant Protection Institute in Poznan in 1998. The effectiveness of this strategy will be discussed.

Index terms: Leptinotarsa decemlineata, organophosphate; pyrethroid

(1285] INDUSTRIAL APPROACH FOR MANAGING RESISTANCE TO NOVEL INSECTICIDES A GLOBAL RESISTANCE MONITORING PROGRAM

D. A. Marsden & C. E. Clark, E.I. DuPont Co, P. O. Box 30, Newark, DE 19711, USA, Email David.A.Marsden-1@usa.dupont.com

With the large investment of time and the resources involved with the commercialization of a new insecticide, companies are developing resistance monitoring programs prior to the commercial launch of new products in order to better manage resistance and extend the life of this valuable new chemistry. An example of this type of pre-commercialization effort is the Global Resistance Monitoring Program developed and implemented by DuPont Ag. Products for the new insecticide, indoxacarb. DuPont has developed a bioassay monitoring technique which; closely resembles the mode of exposure of the insects to the insecticide in the field, is simple to perform, and provides informative data within a short period of time. This data can then be used for management decisions based on detected changes in susceptibility levela. This bioassay technique can be used to test several foliage feeding lepidopteran species notorious for resistance development including; Spodoptera exigua, Helicoverpa armigera, Heliothis virescens, and Plutella xylostella. This program has already been started in 16 countries, representing the major Ayronetta. This program has arready ocen started in to condities, representing the higher agricultural production regions of the world. Baseline susceptibility to Indoxacrib has been established for the 4 species listed above globally and for seven additional species of economical importance in specific regions. These include: *Tuta absoluta, Alabama argillacea, Spodoptera frugiperda* in Brazil; *Cydia pomonella, Phthorimaea operculella* in Europe; Erias sp., Spodoptera litura in Asia. By determining the baseline LC₃₀ and LC Europe, Erras sp., opodoptera titura in Assa. By determining the oasenine LC₉₀ and LC₉₀ values for Indoxacarb on key Lepidopteran pests in key regions of the world, a single discriminating concentration can be developed for routine monitoring of pest susceptibility. Slight changes in susceptibility will be a warning for intensified monitoring and significant changes in susceptibility will indicate the need for changing the use pattern of Indoxacarb before field performance problems occur; thus prolonging the effective use of this novel chemistry. In addition, the growing importance of resistance monitoring and baseline efficacy documentation is an area of increasing interest to regulatory authorities like the EU EPPO and the US EPA for new product registration, Currently, these agencies are viewing this type of testing as the responsibility of the industries developing the new pesticide. In the future, these voluntary programs may become part of the required registration package. The establishment of baseline susceptibility data for each species by geography before the commercial launch will be the foundation for indoxacarb's global monitoring program in years following its introduction. Index terms: indoxacarb, Lepidotera, bioassays

[1286] DEVELOPING PRACTICAL RECOMMENDATIONS FOR MANAGING INSECT RESISTANCE TO BT TRANSGENIC MAIZE

R. L. Hellmich¹, **R. A. Higgins³ & E. E. Ortman³**, ¹USDA-ARS, Corn Insects and Crop Genetics Research Unit and Dept. of Entomology, 109 Genetics Laboratory, c/o Insectary, Iowa State University, Ames, IA 50011, USA, E-mail rhhellmi@iastate.edu; ³Dept. of Entomology, Waters Hall, Kansas State University, Manhattan, KS 66506, USA; ³Agricultural Research Programs, 1140 Agriculture Administration Building, Purdue University, West Lafayette, IN 47907, USA

Managing resistance of insects to Bacillus thuringiensis (Bt) transgenic maize is necessary because Bt maize is valuable and all stakeholders want to preserve its efficacy. Currently, the high-dose/refuge strategy is the resistance management strategy of choice. There are potential problems with this strategy, yet research is underway to try to better define these problems and to offer solutions. A Regional Research Committee has fostered dialouge between industry, producers, academics and regulators. The NC205 committee formally addresses research on the AEcology and Management of European Corn Borer and Other Stalk-Boring Lepidoptera.@ For the past six years this committee has sponsored several meetings and symposia with industry and the Environmental Protection Agency to discuss insect resistance management issues. The NC205 Resistance Management meeting provides a forum for all parties to discuss general and specific issues concerning managing the resistance of European corn borer, Ostrinia nubilalis. The meetings have provided opportunities for sharing information, fine-tuning programs, establishing research priorities, reducing redundancies, and building understanding among participants. The dialogue has allowed the committee to identify science-based practical resistance management strategies. The importance of resistance management strategies that are practical cannot be overemphasized because NC205 recognizes that the ultimate stewards of the Bt technology are the growers. So the committee has tried, whenever possible and without compromising the scientific integrity of resistance management, to consider grower realities. Topics discussed include monitoring for insect resistance, education, extension, grower surveys, managing resistance of other insects (especially rootworm), ongoing research, and future needs for research.

Index terms: Ostrinia nubilalis, resistance management, NC205 committee.

[1287] BT RESISTANCE SURVEILLANCE AND DETECTION IN MAJOR MAIZE INSECT PESTS

B. D. Siegfried¹ & P. Marçon², ¹202 Plant Industry Bldg., Dept. of Entomology, University of Nebraska, Lincoln, NE 68583-0816, USA, E-mail bsiegfried1@unl.edu; ²DuPont Productos Agricolas, Estacao Experimental Agricola Rua Bortolo Ferro, No-500, Paulinia, SP 13140-000, BRAZIL

One of the most important operational research needs in resistance management programs for transgenic plants that express the insecticidal protein from Bacillus thuringiensis (Bt) is the development of techniques for detecting changes in susceptibility in key insect pest species. A number of techniques have been proposed to determine resistance frequencies, although each is associated with certain limitations that reduce sensitivity and precision of estimates. A standardized bioassay technique has been used for the last 5 years to measure susceptibility of European corn boyer, Ostrinia nubilalis (Hübner) populations to a number of Bt toxins. Neonate corn borer larvae are exposed to artificial diet treated with increasing Bt concentrations, and mortality and growth inhibition are evaluated after 7 days. The range of variation in Bt susceptibility indicated by growth inhibition is similar to that indicated by mortality. Although inter-population variation in susceptibility to both proteins has been observed, the magnitude of the differences is small (< 4-fold) and comparable to the variability observed among generations within a particular population (<3-fold). Additionally, there is no indication that Bt susceptibility is influenced by pheromone race, voltime ecotype, or geographic location. Diagnostic concentrations of Bt corresponding to the LC_{ss} for European corn borer were determined based on the previously described baseline data. Validation experiments using field-collected previously described baseline data. Validation experiments using field-collected populations from across North America showed that for Cry1Ab, a concentration corresponding to the upper limit of the 95% confidence interval of the LC_{99} , produced mortality > 99% for all populations tested. Development of Bt resistance monitoring programs that rely on diagnostic techniques will be discussed. Based on the results of dose-mortality assays and diagnostic bioassays, it is unlikely that the small differences in susceptibility are the result of prior selection and are more likely to have resulted from natural variability in susceptibility among populations. These results in combination indicate that in the four years of Bt corn availability, there has not been a detectable change in susceptibility among corn borer populations as a result of selective pressures resulting from the introduction of transgenic maize.

[1288] AN INDUSTRY INSECT RESISTANCE MANAGEMENT PLAN FOR BT CORN

<u>J. Stein</u>, Novartis Seeds, 3054 Cornwallis Road, Research Triangle Park, NC 27514 USA, jeff.stein@seeds.Novartis.com

Since the 1996 growing season, farmers in the United States have been planting corn hybrids that express a Bt protein that protects the plant against feeding damage caused by several lepidopteran pests, including the European corn borer. Prior to commercialization, biotechnology companies initiated research efforts directed towards the development of resistance management practices for this new Bt corn technology. This cooperative industry effort, jointly conducted with grower groups and other stakeholders, resulted in a plan that maximizes a grower's opportunity to benefit economically from Bt corn, while preserving the efficacy of this technology for the long term. Key elements of the plan include the requirement for the planting of a non-Bt corn refuge on every farm, a focused insect monitoring effort, and a comprehensive education program to promote grower adoption of the plan. In addition, mitigation measures have been developed in the unlikely event that target pest populations develop resistance towards the plant-expressed Bt protein. The industry group will continue to work with farmers to properly manage and protect the longevity of this important agricultural technology.

Index terms: transgenic plants, Bt corn, Ostrinia nubilalis

[1289] TRANSGENIC BT MAIZE AND RESISTANCE MANAGEMENT: FARMER ATTITUDES AND PRACTICES IN THE CORN BELT OF THE UNITED STATES

M. E. Rice, Department of Entomology, 103 Insectary, Iowa State University, Ames, IA 50011, USA, E-mail merice@iastate.edu

The European corn borer, Ostrinia nubilalis, is one of the most damaging pests of maize in North America. Farmers first planted transgenic Bt maize in 1996 to control this pest. Bt maize farmers were encouraged by seed companies to implement a resistance management plan by planting at least 20% of their acres as a refuge with non-Bt hybrids. The refuge concept is intended to help delay the development of resistance in the European corn borer to Bt maize. Following the third year (1998) of commercial production, written surveys were mailed to Bt maize farmers in 6 states (Illinois, Iowa, Kansas, Minnesota, Nebraska, and Pennsylvania) and 1,966 responses were returned. The objective of the survey was to evaluate farmer perceptions and practices regarding Bt maize, especially resistance management and insecticide use. Responses to several questions are presented. Survey Question: If a seed company, seed dealer, or Extension specialist recommended a *Question:* If a seed company, seed dealer, or Extension spectation recommended a resistance management strategy, would you follow it? 1. No, I have no interest in delaying European corn borer resistance to Bt maize (1.4%); 2. No, I don't think European corn borers will develop resistance to Bt maize (1.2%); 3. Yes, if the strategy can be easily worked into my farming operation (58.9%); 4. Yes, whatever the best strategy would be to delay resistance (25.5%); 5. I don't know (12.9%). A large majority (84.4%) of Bt maize farmers are willing to implement resistance management recommendations, while a very few (2.6%) are unwilling. Survey Question: What planting pattern did you use with your Bt maize hybrid? It was planted as: 1. a block in one field (46%); 2. several blocks in several fields (27%); 3. single or several rows alternated with single or several rows of a non-Bt maize hybrid (6%); 4. large strips alternated with large strips of a non-Bt maize hybrid (15%); 5. a seed mixture of Bt and non-Bt seed (<1%); 6. a border around a field of non-Bt maize (4%); 7. other (2%). Most farmers planted in blocks (73%) or large strips (15%), both of which are suggested for resistance management. A few farmers mixed seed and alternated rows of Bt and nonBt corn; these practices are thought to accelerate the development of insect resistance to Bt maize and are not recommended. Survey Question: Did insecticide use for European corn borer on your farm increase, stay the same, or decrease when compared to insecticide use during the previous five years? 1. Decreased (26.0%); 2. Stayed the same (17.9%); 3. Increased (2.4%); 4. Didn't use an insecticide (53.7%). Farmers planting Bt maize have reduced the amount of insecticide formerly applied to control this pest.

[1290] STRATEGIES FOR MANAGEMENT OF RESISTANCE IN BT TRANSGENIC MAIZE IN BRAZIL

<u>I. Cruz</u>, Embrapa National Maize and Sorghum Research Center - P.O Box 151, 35700-970 Sete Lagoas, MG, Brazil – E-mail: ivancruz@cnpms.embrapa.br

The use of Bt transgenic plants can be a new and efficient approach to control some maize pests in Brazil. However, it should be considered the complexity of the pests and the diversity of climatic conditions that exist. An in-depth evaluation of the effect of the Bt transgenic plants over the main group of insect pests should be done. Even for the principal pest, S. frugiperda, the existence of genetic variability within its natural population related to the susceptibility of transgenic plant is possible. Plant-pest-natural enemy balance should be considered to prevent any disruption in favor of the pest, increasing the selection pressure over the transgenic plant and facilitating the build up of resistant pest strain. In order to make the transgenic plant last longer, strategies such as the constant monitoring (susceptible population from different locations should be maintained in the laboratory for comparison with advance field generations of pests subjected to transgenic plants) or the use of natural enemies should be encouraged. A good complementary action could be achieved by egg parasitoids such as Telenomus remus and Trichogramma spp. or predators such as the earwig Doru luteipes from natural population or even through artificial releases from laboratory culture. The successful of the transgenic technology also will depend upon joint action involving the private and governmental institutions working closely together with the farmer. These actions necessarily include the insteduction of integrated pest management concepts to be applied to those pest controlled by the transgenic plants as well as to other insects. The strategy to set up the distribution of refuse area depends on the production region and the level of technology used. In Brazil a large portion of farmers still use unimproved seed. Usually they are small farmers and the use of transgenic maize will probably depend upon seed prices. All these maize production regions could be considered as a natural refuse area. In the case that this new technology is adopted, one strategy should be the use a common area based on cooperative efforts from all farmers.

Index terms: Spodoptera frugiperda, Diatraea saccharalis, Helicoverpa zea, resistance management, biological control

[1292] EFFECT OF THE MICROENCAPSULATED FORMULATION OF LAMBDA-CYHALOTHRIN FOR THE CONTROL OF THE BLACK CUTWORM, AGROTIS IPSILON (LEPIDOPTERA: NOCTUIDAE), IN CORN

<u>F. J. Almeida¹</u>, F. J. Celoto¹ & G. Papa¹, ¹ Dept. of Biology, Univ. Estadual Paulista, Av. Brasil 56, Zip 15.385-000 - Ilha Solteira/SP, Brazil, E-mail: gpapa@bio.feis.unesp.br

Pests that are of sporadic occurrence on corn crop, and that use to stay under the soil, where the farmers cannot see them, are not given much attention from the farmers. Black cutworm, A. ipsilon, fits into this profile and when it occurs, it causes losses because it cuts the new plants, resulting in reduced stand. The increasing search for safer alternatives for pests control, which are less aggressive for the environment, has brought a significant development of new insecticide formulations, with possibilities of use in agricultural pest management, contributing to a safer and more efficient way of pest control. The objective of this work was to evaluate the performance of the microencapsulated formulation of lambda-cyhalothrin, for the control of black cutworm on corn crop. The experiment was established under field conditions, in Ilha Solteira/SP/Brazil, using the cultivar Ag-405. The design was of randomized blocks, with 9 treatments and 4 replicates. Each plot ocnsisted of 10 rows of crop, each row was 20m long, and the spaced 1m among each other, with the total of 160m². Two spray operations were conducted for each treatment, at 7-day intervals, using a knapsack sprayer at the volume of 300 l/ha. Spray operations were initiated as a preventive treatment, 13 days after sowing. The treatments consisted of the microencapsulated formulation of lambda-cyhalothrin at the concentrations of 5 and 25% Karate Zeon), at the doses of 15, 25 and 30g a.i./ha, carbaril as a concentrate suspension formulation (Sevin 480 SC) at the dose of 960g i/ha and chlorpyiriphos, as an emulsifiable concentrate formulation (Lorsban 480 BR), at the dose of 720g a.i./ha and control. Evaluations were done up 7 days after the second application, by counting the total number of plants attacked by the pest, observing all plants in each plot. Results showed that the microencapsulated formulation of lambda-cyhalothrin, at the doses of 25 and 30g a.i./ha, was efficient for the control of black cutworm, similar to the standard treatment with chlornvriphos.

Index terms: chemical control, pyrethroid, organophosphate, carbamate

[1291] INSECTICIDE RESISTANCE IN HELICOVERPA ARMIGERA AND STRATEGIES FOR ITS MANAGEMENT IN PAKISTAN

M. Ahmad, M. I. Arif & Z. Ahmad, Central Cotton Research Institute, PO Box 572, Multan, Pakistan, E-mail: mush_a@yahoo.com

The American bollworm, *Helicoverpa armigera* (Lepidoptera: Noctuidae) has become a major threat to cotton production in Pakistan. Regular monitoring since1991 reveals that there has been a development of high resistance to endosulfan and pyrethroids in this pest, which has led to control failures of these insecticides. However, resistance to some organophosphates and carbamates is still low to moderate, but it is also showing an increasing trend. To restore the economic viability of cotton crop in Pakistan, an insecticide resistance management strategy is being promoted. It emphasizes on the education of farmers in pest scouting, better pesticide application techniques, non-chemical control methods, conservation of beneficials by delaying the first spray and applying soft insecticides early in the season, and use of new chemistries with novel modes of action in rotation with the still-effective conventional chemistries. Index terms: *Helicoverpa armigera*, insecticide resistance, management, Pakistan

[1293] EFFECTS OF IVERMECTIN ON THE FAT BODY MORPHOLOGY OF CULEX QUINQUEFASCIATUS LARVAE

S.N. Alves¹, G. Mocelin³, A. L. Melo¹ & J. E. Serrão³, ¹Dept. of Parasitology, Federal Univ. of Minas Gerais, P.O. Box 486, Belo Horizonte, 30161-970, MG, Brazil. E-mail: snalves@icb.ufmg.br²Dept. of Chemical Eng., Federal Univ. of Parana, P. O. Box 19011, Curitiba, PR, Brazil. ³Dept. of General Biology, Federal Univ. of Viçosa, 36571-000, Viçosa, MG, Brazil. Support: CAPES, CNPq

Culex quinquefasciatus a cosmopolitan and a high anthropophylic mosquito is an important species for human and animal health. It is the main vector of Wuchereria bancrofti in Brazil. Nowadays chemical insecticides are regularly used to mosquito population control, but the development of species resistant to synthetic insecticides has now been described. Ivermectin is a chemical modification of avermectins, a macrocyclic lactone derived from Streptomyces avermitilis. It was previously tested to control mosquito larvae population in our laboratory. The aim of this present study was to observe effects of the ivermectin in the fat body of C. quinquefasciatus larvae. Groups of 3th instar were transferred to recipients containing a solution of ivermectin 1% w/v in a final concentration of 1 ppm during 30 minutes. Control groups were placed in recipients containing just dechlorinated water. After the period of the exposition, the larvae were rinsed with tap water and them fixed in 4% paraformaldehyde in phosphate buffer, pH 7.4, 0.1M, dehydrated in graded ethanol and embedded in historesin, five μ m thick sections were stained with toluidine blue. The larvae exposed to ivermectin lavae. There was also a decrease of lipid storage, what could be demonstrated by a more homogeneous staining of the cells, contrasting with a vacuolated cytoplasm in the control group. These results suggest a mobilization of stored resources (especially lipids) for a possible drug detoxification, which may be occur by enzymatic action, as has been reported for other

Index Terms: Culicidae, mosquito, avermectin.

[1294] EFFECT OF CHEMICAL CONTROL OF *BEMISIA ARGENTIFOLII* (HEMIPTERA: ALEYRODIDAE) ON THE INCIDENCE OF BEAN GOLDEN MOSAIC VIRUS IN COMMON BEANS AND ITS YIELD

<u>F. R. Barbosa</u>¹, K. M. M. Siqueira³, E. A. de Souza¹, W. A. Moreira¹, F. N. P. Ilaji¹ & J. A. de Alencar¹, ¹Embrapa Semi-Árido, Caixa Postal 23, CEP 56300-970, Petrolina-PE, E-mail: flavia@cpatsa.embrapa.br; ²UNEB. Dept. de Tecnologia e Ciências Sociais, CEP 48900-000, Juazeiro-BA.

The control of the silverleaf whitefly, Bemisia argentifolii, Bellows & Perring in common beans (Phaseolus vulgaris) and the incidence of bean golden mosaic virus (BGMV) were evaluated by using seed treatment with imidacloprid or thiamethoxam followed by four or six sprays with insecticide, at weekly intervals. The field experiment was carried out in an six sphars with insecticity, at weekly intervals. The field experiment was carried out an inter-irrigated area, at Petrolina-Pernambuco (Brazil). A randomized complete block design with four replicates was used and each plot had an area of 160 m^2 . The treatments, and concentration, in grams or millilitres of commercial product /100 kg of seeds or 100 litres of water, were: 1) imidacloprid 200 SC (200g), acephate 750 BR (100g), metamidophos 600 CS (125ml), imidacloprid 700 GRDA (20g), cartap 500 PS (300g); 2) imidacloprid 200 SC (200g), acephate 750 BR (100g), metamidophos 600 CS (125ml), imidacloprid 700 GRDA (20g), cartap 500 PS (300g), acephate 750 BR (100g), lambdacyhalothrin 50 CE (50ml); 3) thiamethoxam 700 WS (200g), acephate 750 BR (100g), metamidophos 600 CS (125ml), thiamethoxam 250 WG (200g), cartap 500 PS (300g); 4) thiamethoxam 700 WS (200g), acephate 750 BR (100g), metamidophos 600 CS (125ml), thiamethoxam 250 WG (200g), cartap 500 PS (300g), acephate 750 BR (100g), lambdacyhalothrin 50 CE (50ml); 5) control, without insecticide. The chemical control decreased significantly the number of eggs, nymphs and adults and also the percentage of infection by BGMV, ranging from 1.48 to 2.95% against 46.29% in the control treatment. Grain yields and the percentage of yield increase for treatments 1, 2, 3 and 4, were respectively: 1,930 kg/ha, 29.53%; 2,395 kg/ha, 60.74%; 2,180 kg/ha, 46.31% and 2,405 kg/ha, 61.40%, while in the control the yield was 1,490 kg/ha. There was no significant difference among number of pods per plant, number of seeds per pod and weight of 100 seeds. Index terms: Insecta, BGMV, vector, *Phaseolus vulgaris*

[1295] OBSOLETE INSECTICIDES IN LATIN AMERICA: WHAT TO DO WITH THEM?

<u>S. Barbosa</u>, Food and Agricultural Organization of The United Nations, P.O.Box 10095, Santiago, Chile.

country of Latin America, there are accumulations of unwanted, obsolete insecticide stocks which represent serious risks to human health and the environment. The great majority of these accumulations come from bulk government purchases or donations by the international community to control insect pest outbreaks in agriculture and public health. Because these insecticides were banned or had their use restricted by regulatory authorities or because they were not used within their validity dates, they can no longer be used and are considered obsolete. They are found in urban and rural areas, usually under very poor storage conditions, in corroding and leaking metal drums or ragged paper or plastic bags. Government authorities tend to deny that they exist and take bold decisions to dispose of them in landfills, giving them away as donations to other countries or keeping them under hidden storage. High temperature incineration in dedicated hazardous waste furnaces is the most recommended method for disposal of these obsolete insecticides and other pesticides but most countries of the region do not count with these facilities. Obsolete pesticides need to be repacked, including used containers and contaminated soil, and transported to facilities in the country or abroad where they can be properly disposed of. The cost of the entire operation is estimated by FAO to run between US\$ 3000 and US\$ 4500 per ton. Conservative estimates indicate that over 10 000 tons of obsolete pesticides exist in Latin America, needing to be urgently disposed of due to the human health and environmental problems they are causing. FAO is conducting a regional survey on the situation in order to present the problem and suggest possible solutions to the Latin American governments and to the international donor community. The author presents case stories of the situation of obsolete pesticides in some countries, discusses possible disposal action scenarios and elaborates on ways to prevent future accumulations. Index terms: toxic wastes, pesticide disposal

[1296] EFFECT OF THIAMETHOXAM (ACTARA® 250 WG) ON ENTOMOPATHOGENIC MICROORGANISMS

<u>A. Batista Filho¹</u>, J.E.M. Almeida¹, C. Lamas¹, ¹ Lab. Controle Biológico, Centro Exp. do Inst. Biológico, P.O. Box 70, Campinas, SP, 13001-970, Brazil, E-mail batistaf@dglnet.com.br

The compatibility of entomopathogenic microorganisms with thiamethoxam (Actara@ 250 WG) and other insecticides was studied in *in vitro* and field assays. The microorganisms tested were a bacterium (*Bacillus thuringiensis*), a virus [*Baculovirus anticarsia* (NPVAg)], and eight fungi (*Aschersonia aleyrodis*, *Beauveria bassiana*, *Hirsutella thompsonii, Metarhizium anisopliae*, Nomuraea rileyi, Paecilomyces farinosus, Sporothrix insectorum, and Verticillium lecanii). Two concentrations of each product were tested in the laboratory, based on the maximum and minimum recommended levels for application under field conditions. The products were added to specific culture medium for entomopathogen growth. Reproductive and vegetative growth was evaluated for fungi, and colony forming units (CFU) were evaluated for bacteria. For the field test, CFU were considered for both fungi and bacteria and caterpillar mortality of the NPV of Anticarsia genuntalis. The action of the pesticides on the vegetative growth and sporulation of the microbial species: (1) thiametoxam was compatible with all microorganisms studied; (2) endosulfan, monocrotophos and deltametrin were the insecticides that most affected *B. thuringiensis*, *B. bassiana*, *M. anisopliae* and *S. insectorum*; (3) thiametoxam did not affect the inoculum potential of *B. thuringiensis*, and (4) thiametoxam did not affect the efficiency of the nuclear polyhedral virus of *A. gemmatalis*. Index terms: Insecticide, microbial control, compatibility.

[1297] MIGRATION AND SELECTION AFFECTING INSECTICIDE RESISTANCE IN PSEUDOPLUSIA INCLUDENS

<u>M. E. Baur</u> & D. J. Boethel, Dept. of Entomology. Louisiana State University Agricultural Center, Baton Rouge, LA 70803, USA.

Pseudoplusia includens is a migratory insect that overwinters in southern Florida and Texas, the Caribbean Basin and Mesoamerica. Incapable of diapause, P. includenss migrates into the soybean growing regions in the Mid South. Insecticide resistance is a consistent problem with this insect in soybean agroecosystems, however the cause of the resistance remains a puzzle because insecticide usage in soybean agroecosystems is low. Therefore, this project set out to determine the relative contribution of migration from overwintering sites to resistance development and the relative contribution of local selection to resistance development. Data on the susceptibility to 6 insecticides and genetic markers from twenty-two populations of P. includens from sites in Puerto Rico, Florida, Texas and Louisiana were collected in 1998. The AFLP technique was used to detect genetic markers and insecticide susceptibility data were collected from diet overlay bioassays using discriminating doses of the insecticides. Analysis of the genetic data indicated that P. includens populations in Louisiana are derived from overwintering populations in Texas and Puerto Rico, but probably not southern Florida. The insecticide bioassay data showed abundant variation in susceptibility to thiodicarb, chlorfenapyr, B. thuringiensis, and spinosad between populations. The variation in susceptibility to permethrin and emarnectin benzoate between populations was low. The correlation between the genetic distances and insecticide susceptibility was moderate, suggesting that both local selection and migration contribute to resistance observed in the soybean agroecosystems in the Mid South. [1298] NUCLEOTIDE SEQUENCE & EXPRESSION OF A SECOND PUTATIVE ACETYLCHOLINESTERASE GENE FROM ORGANOPHOSPHATE (OP)-SUSCEPTIBLE AND OP-RESISTANT CATTLE TICKS

G. D. Baxter & <u>S. C. Barker</u>, Department of Microbiology & Parasitology, & Institute for Molecular Biosciences, University of Queensland, Brisbane, Australia. Email: s.barker@cmcb.uq.edu.au

Control of the cattle tick, *Boophilus microplus*, relies heavily on acaricides - this has led to resistance to these pesticides. It has been proposed that resistance to organophosphates (OPs) in *B. microplus* is conferred by an acetylcholinesterase (AChE) that is insensitive to the effects of OPs. In 1998 we isolated an AChE cDNA from *B. microplus* but we found that resistance to OPs in *B. microplus* from Australia was not conferred by point mutations in alleles at this locus. This contrasts with the only other two organisms for which a mechanism of resistance to OPs or carbamates that involves AChE insensitivity, has been described - point mutations in the coding region of the AChE gene of *Drosophila melanogaster* and *Leptinotarsa decemlineata* confer resistance to OPs in these insects. Recently, a second AChE gene was discovered in *B. microplus* and a Mexican strain that are resistant and susceptible to OPs. We also present data on the role of gene expression of AChEs.

[1300] EFFECTS OF SEVERAL FUNGICIDES ON THE PREDACIOUS MITE AMBLYSEIUS FALLACIS (GARMAN) (ACARI: PHYTOSEIIDAE) IN QUEBEC APPLE ORCHARDS

N. J. Bostanian & G. Racette, Hortic. Res. Dev. Centre. Agric. and Agri-Food Canada, St. Jean sur Richelieu, Quebec, CANADA J3B 3E6 E-mail: bostaniannj@em.agr.ca

Four fungicides currently used in apple orchards and the new compound Sovran[®] 50WG were evaluated for their toxic effects on the very important phytoseiid *Amblyseius fallacis*. The results indicate that of the five fungicides evaluated, mancozeb (Dithane[®] M-45) was toxic to nymphs and reduced egg eclosion by 26%. Captan (Captan[®] 80WP), myclobutanyl (Nova[®] 40WP) metiram (Polyram[®] 80WP) and kresoxim-methyl (Sovran[®] WG) had no effect on any of the growth stages of this predator. All tests were done at several concentrations including field rates. Index terms: Toxicity, pesticides

[1299] RELATIONSHIP BETWEEN EXPRESSION, AMPLIFICATION AND METHYLATION OF FE4 GENE IN *MYZUS PERSICAE* (IIOMOPTERA, APHIDIDAE)

D. Bizzaro, E. Barbolini, E. Mazzoni*, M. Mandrioli, G. C. Manicardi, P. Cravedi*, <u>R. Crema</u>, A.M. Pagliai, U. Bianchi, Dept. of Animal Biology, University of Modena & Reggio Emilia, Via Campi, 41100 Modena, Italy; *Institute of Entomology & Vegetal Pathology, Catholic University "Sacro Cuore", Via Emilia Parmense 84, 29100 Piacenza. E-mail: bizzaro@unimo.it

The peach potato aphid, Myzus persicae is an important pest on many crops, causing direct feeding damage as well as transmitting virus diseases. The wide use of insecticides characterised by an esteric group (organophosphorous, carbammate and pyrethroid finaccticides) selected resistant *R. persicae* populations This resistance mechanism arise from the overproduction of one of two closely related carboxylesterases (E4 and FE4). Both E4 and FE4 genes possess methylated CpG sites in the coding region or in nearest genomic areas. In populations with the amplification of E4 genes, the disappearance of resistance is associated with the loss of methylation in these genes, that is the direct opposite of the situation in vertebrates, where methylation correlates with genes silencing. In order to furnish information regarding this peculiar phenomenon, 22 Italian populations of *M. persicae*, all showing variable levels of FE4 genes amplification have been analysed. The estimation of gene copy number, carried out by densitometric scanning of dot and southern blots, show that the different populations possess a variable number of FE4 genes ranging from 4 to 104. Statistical analysis shows the existence of a high positive correlation between gene copy number and total esterase activity. The estimation of methylation levels, obtained by comparing *MspI* and *HpaII* RFLP, put in evidence that FE4 genes generally result fully methylated in populations possessing low gene copy number (4-8). On the contrary, in populations with many FE4 genes, when comparing clone possessing similar number of genes, it is possible to observe different levels of FE4 methylation, thus suggesting the lack of strict relationships between gene copy number, methylation and total esterase activity in these populations. In fact, populations possessing high levels of esterase activity show a percentage of unmethylated genes, which result independent from esterase activity levels. These data as a whole suggest that, contrary to what found for E4 genes, the expression of amplified FE4 genes is not directly related with methylation pattern.

[1301] EFFECTS OF SEVERAL PESTICIDES ON THE PREDACIOUS MITE AGISTEMUS FLESCHNERI (SUMMERS) (ACARI: STIGMAEIDAE) IN QUEBEC APPLE ORCHARDS

N. J. Bostanian & N. Laroque, Hortic. Res. Dev. Centre. Agric. and Agri-Food Canada, St. Jean sur Richelieu, Quebec, CANADA J3B 3E6. E-mail: bostaniannj@em.agr.ca

Extensive laboratory tests showed that the following fungicides: Trifloxystobine (Flint^{*} 50 WG), myclobutanyl (Nova^{*} 40WP), flusilazole (Nustar^{*} 50DF) and kresoxim-methyl (Sovran^{*} 50WG) were not toxic to the adults or the eggs of this predator. Among the insecticides evaluated pyridaben (Pyramite^{*} 75WG) caused 70% mortality of adult female predators. The remaining compounds, lambda-cyhalothrin (Warrior^{*}) and imidacloprid (Admire^{*}) were non toxic. All tests were done at several concentrations including field rates.

Index terms: fungicides, insecticides, toxicity

[1302] INDOXACARB (DPX-MP062) A NEW OXIDIAZINE INSECTICIDE - ITS POTENTIAL IN QUEBEC APPLE ORCHARDS

N. J. Bostanian, C. Vincent & N. Larocque, Hortic. Res. Dev. Centre. Agric. and Agri-Food Canada, St. Jean sur Richelieu, Quebec, CANADA J3B 3E6 E-mail: bostaniannj@em.agr.ca

This is a new insecticide especially active against Lepidoptera. The sodium channel is very sensitive to this compound and intoxicated insects quickly stop feeding and eventually die. In Quebec apple orchards, it was found to be effective against OP resistant strains of the obliquebanded leafroller, *Choristoneura rosaceana*. The predacious mirid *Hyaliodes vitripennis* is not affected by this compound. The toxic effects on the two predacious mites *Amblyseius fallacis* and *Agistemus fleschneri* are currently under study and will be presented.

Index terms: Toxicity, Hyaliodes vitripennis, Agistemus fleschneri, Amblyseius fallacis, Choristoneura rosaceana

[1304] INVOLVEMENT OF VOLTAGE-DEPENDENT SODIUM CHANNELS IN DELTAMETHRIN RESISTANCE IN A STRAIN OF CYDIA POMONELLA

A. Brun-Barale¹, J.C. Bouvier², D. Pauron¹, J.B. Berge¹ & <u>B. Sauphanor²</u>, ¹ Resistance aux Xenobiotiques et Ecotoxicologie, INRA, F 06606 Antibes, France; ² Unite de Zoologie-Apidologie - INRA, Agroparc, F 84914 Avignon Cedex, France

The codling moth, Cydia pomonella, a major pest of apple, has developed resistance to different classes of insecticides including pyrethroids such as deltamethrin and chitin synthesis inhibitors such as diflubenzuron. In many insect species, an important mechanism that confers resistance to pyrethroids is the knockdown resistance (kdr) which is linked to point mutations in the sequence of one voltage-dependent sodium channel gene. In order to study kdr in codling moth, PCR were performed to amplify the region of domain II containing putative kdr mutations. In many pyrethroid-resistant strains of insects, the kdr mutation is a leucine to phenylalanine replacement in the transmembrane segment IIS6 at position 1014. In a C. pomonella strain resistant to deltamethrin, a kdr mutation (TTT) was present at position 1014 and as expected neither in the susceptible strain nor in a strain resistant to diflubenzuron which both contain the susceptible codon (TTT. An intron located just 3' to the mutation was identified as reported for other orders of insects. These data allowed us to develop a PCR-based diagnostic test (PASA) to determine the presence or the absence of the kdr allele in pyrethroid-susceptible and pyrethroid-resistant strains of codling moth. This test will constitute a molecular tool to rapidly determine the frequency of the kdr allele in various populations of C. pomonella. Key words: codling moth, knock-down resistance, point mutation

[1303] EVALUATION OF TEMEPHOS SUSCEPTIBILITY IN AEDES AEGYPTI IN RIO DE JANEIRO, BRAZIL

A. K. R. Galardo¹, <u>I.A. Braga</u>² & S. S. Soares³, ¹ Aluno do Curso de Mestrado em Biologia Animal da Universidade Federal Rural do Rio de Janeiro, Biólogo do Centro de Controle de Zoonoses, Paracambi, RJ/FUNASA/RJ; ² MSc, Gerente de Entomologia e Pesquisa Operacional da Fundação Nacional de Saúde/M.S; ³ Fundação Nacional de Saúde/RJ

Temephos susceptibility was evaluated in 7 municipalities in the state of Rio de Janeiro. this insecticide has been used intensively to control dengue epidemics since 1986. *ae. aegypti* were collected and pooled from several locations in each community using enhanced cdc ovitraps and the fl generation were compared with a standard rockefeller strain using the diagnostic dosage of 0.012 mg ai/l. The results indicate the occurrence of resistance in all of the municipalities evaluated. The resulting mortalities were 23,5% for São Gonçalo; 32,5% for Rio de Janeiro; 34,6% for Niterói, 34,8% for Caxias , 44% for São João de Meriti, 58,2% for New Iguaçu and 74% for Campos. The Rockefeller Strain was had a mortality of 100%.

[1305] BOTANICAL EXTRACT EFFECT ON Anastrepha fraterculus (DIP., TEPHRITIDAE) BIOLOGY

N. A. Canal, E. Murillo & P. E. Galeano. Univ. Of Tolima, A.A. 546, Ibagué, Tol., Colombia. E-mail: Erro! Indicador não definido.

Colombian fruticulture is an important factor in the agricultural sector of the country and its producing is being mainly developed at small orchards. One of the main problems of these products is fruit flies. The following results are the first of a series of studies which were started at University of Tolima looking for easy, safe and efficient alternatives in fruit flies management by small farmers. Both, ethanolic and aqueous extracts of *Melia azederach* (Meliaceae) (m.a.), *Anona squamnosa* (Anonaceae) (a.s.), *Ocimun americanum* (Labiatae) (o.a.) and *Brunfelsia pauciflora* (Solanaceae) (b.p.) were evaluated on the southamerican fruit fly biology. Flies were obtained from an artificial rearing of ICA (Colombian Agricultural Institute) in Ibagué. Ten couples were put into cilindric cages of 20 cm high and with a diameter of 10 cm. Flies were exposed to 24 hours of inanition and then the extracts were given. After five days, mortality was found between 22% (control a 52% (a.s.) for ethanolic extracts and between 14% (o.a.) and 44% (b.p.) for aqueous extracts (control = 32%). Nevertheless no statistic difference was found among the treatments. Oviposition was favored by some ethanolic extracts, however larval development was reduced by these ones. Ethanolic extracts can reduce fruit fly population, increasing their mortality. Botanical extracts can reduce fruit fly population, increasing their mortality and decreasing the reproductive rata. Among these four treatments *Anona* shows itself to be potential for *Anastrepha fraterculus* management. Variation of obtained results and similarity with the ones gotten at the beginning with *A. obliqua* suggest the need of making adjustments to the work methodology in order to obtain

Index Terms: South American Fruit Fly, Botanical insecticides, Control

[1306] INSECTICIDAL PROPERTIES OF CANATOXIN, A TOXIC PROTEIN FROM CANAVALIA ENSIFORMIS SEEDS, AND ITS ENTOMOTOXIC PEPTIDES

C. R. Carlini, C. T. Ferreira-daSilva, & M.E.C. Gombarovits, Dept. Biophysics, Univ. Fed. Rio Grande do Sul, Porto Alegre, RS, CEP 91.501-970, Brazil. E-mail: ccarlini@vortex.ufrgs.br. Supported by CNPq, PRONEX 76.97.10.70.00

Canatoxin (CNTX), a toxic protein (dimer of 95 kDa) isolated from seeds of *Canavalia* ensiformis (Carlini & Guimarães,1981, Toxicon 19: 667), is lethal by oral route to a group of insects, being proteolitically "activated" by their digestive enzymes. No effects were seen in insects relaying on tripsin-like enzymes. In the other hand the bruchid beetle *C.* maculatus and the blood-sucking bug *R.* prolixus, are susceptible to CNTX (Carlini et al.,1997, J.Econ. Entomol. 90: 340). These insects present cathepsins of type B and D as their major digestive enzymes, which hydrolize CNTX to form entomotoxic peptides. A diet containing 0.25% w/w CNTX aborted larval growth in *C. maculatus*. In *R. prolixus* fed CNTX solutions (2,5 g/mg weight body), 100% lethality was recorded 72 hours after feeding and fragments of the toxin were found in haemolimph and the midgut of the insect by Western-blot analysis. When *R. prolixus* were fed CNTX "meals" containing either E-64 (2,0 M), Pepstatin-A (2,0 M) or both, the insects were partially protected against CNTX's lethal effect. In other studies, CNTX was digested *in vitro* with enzymes obtained from *C. maculatus*, and resulting peptides (8 to 15 kDa) were shown to be lethal to *R. prolixus* by oral or metathoracic administration. In this case, however, no protective effect was seen with the addition of catchepsin inhibitors to "meals" containing CNTX-derived peptides. CNTX did not show any inhibitory activity toward *C. maculatus or R. prolixus*. Additional studies on CNTX effects in other insects models, displaying either alkaline or acidic digestive processes, are under way in our laboratory in order to establish the biotechnological potentials of CNTX as a bioinsecticide.

Index terms: Callosobruchus maculatus – Rhodnius prolixus – cathepsins – proteinase inhibitors

[1307] SUSCEPTIBILITY TO CARTAP AND ABAMECTIN IN DIAMONDBACK MOTH STRAINS FROM BRAZIL

M. Castelo Branco & C.A. Melo, Embrapa Hortaliças, Caixa Postal 218, 70.359-970. Brasília, D.F. Brazil. e-mail: marina@cnph.embrapa.br.

Diamondback Moth strains collected in the Federal District, Minas Gerais and Ceará were evaluated in laboratory bioassays to determine their susceptibility to cartap and abamectin. The most susceptible strain to both insecticides was collected in the Federal District in a field where no insecticide was sprayed for at least four months. Levels of resistance to cartap was between 2.8 and 7.1 fold in relation to the susceptible strain. The most strain to cartap was collected in a field which was sprayed several times with the insecticide. Levels of resistance to abamectin was between 1.1 and 12.1 fold. The Diamondback Moth strain with the highest level of resistance to abamectin was obtained from a field in Minas Gerais where abamectin was never sprayed. This high level of resistance may be explained by the immigration of abamectin resistant genotypes into the area which may have affected the local level of resistance.

Index terms: Plutella xylostella, insecticide resistance

[1308] CAN THE RESISTANCE TO INSECTICIDAL TRANSGENIC PLANT PRODUCE NEW SPECIES OF INSECT PEST?: IMPLICATIONS OF DEVELOPMENT ASYNCHRONY OF RESISTENCE PEST TO BACILLUS THURINGIENSIS TRANSGENIC CROP

H.Cerda 1,2 & D. Wrigth ², ¹Universidad Simon Rodriguez, Caracas, Venezuela; ³Imperial College, Silwood Park, Ascot SL5 7PY, UK. E.mail h.cerda@ic.ac.uk. HC was supported by CONICYT and CDCIHT-UNESR of Venezuela.

Recently, Darby et al. (1999), Liu et al (1999) evidence studies on laboratory-selected insects show developmental asynchrony between Bt resistant and susceptible strains of diamondback moth (*Plutella xylostella*) and pink bollworm moth (*Pectinophora gossypiella*). Such developmental asynchrony could lead to non-random (assortative) mating among resistant insects and through interactions with season length, produce premating isolation. Assortative mating is one of the condition to have a sympatric speciation process (Dieckman and Doebeli, 1999). Three transgenic crop that produce Bt toxins were grown commercialy in the USA during 1997: nearly 3Mha of Bt maize, 1 Mha of Bt cotton 10 kha of Bt potato. With the widespread planting of Bt transgenic plants, individuals of many pest species are being exposed to intense selection process when the insect pest are under intense selection pressure.

[1309] METANOLIC EXTRACTS FROM DIMORPHANDRA MOLLIS (BARBATIMÃO) AND THEIR ACTIVITY IN WORKERS OF APIS MELLIFERA

Priscila Cintra¹, Osmar Malaspina¹, Odair Correa Bueno⁴, Fernando Petacci², João Batista Fernandes³, Paulo Cezar Vieira¹, Edson Rodrigues Filho⁴, Maria Fátima das Graças Fernandes da Silva³, ¹ Center of Study of Social Insects, Unesp, Av. 24-A, 1515, CEP 13506-900, Rio Claro, SP, malaspin@rc.unesp.br; ² Department of Chemistry-Ufscar, Rod. Whashington Luiz, Km 235, CP676, São Carlos, SP, petacci@dq.ufscar.br.Financial.FAPESP, CNPq, PRONEX/MCT/FINEP

In Brazil we have a different kind of vegetation called "cerrado" and this vegetation is already one of the most important areas to apiculturists. A native tree: Dimorphandra mollis (barbatimão) has flowers at the same time as the beekeepers observe a great mortality in their bees. The fenomenon is named by the beekepeers as the "fall evil". This fact occurs also when the tree is without its bark , which is commonly used to make teas because of its adstringent effects. These problems got scientists to study the *D. mollis* to obtain substances with potencial toxic action. Our study was done with the flowers and the bark of *D. mollis*. We did metanolic extracts and incorporated them in small percentages (0,2%, 0,5% and 1%) to the diet of bees. The diet were offered to three groups of twenty bees confined in little boxes (11 cmx11cmx7cm). At the same time we did the control group in wich the bees received just sugar and water daily. The results obtained were statistically significant. The mortality of metanolic extract from flowers to bees was 100% to treatment groups at 14° , 16° , and 20° days, at the concentrations of 1%, 0,5% and 0,2%, respectively. For the metanolic extracts from the bark the mortality was 100% to the treatment group on 10° , 16° , and 20° days. (concentrations: 1%, 0,5% and 0,2%). Both results suggest that the metanolic extracts from the bark and the flowers from *D. mollis* had an important role at the toxic effects pointed by the experiments. The knowledge of substances present in this specie and their action on bees is the aim of the solution to the "fall evil". More tests with other extracts made with parts from the tree are currently being done.

Index terms: Dimorphandra mollis, Apis mellifera, toxicity, metanolic extracts

[1310] IDENTIFICATION OF A CHEMICAL FRACTION FROM AROMATIC HERBS WITH INSECTICIDAL ACTIVITY AGAINST *TRIBOLIUM CASTANEUM* (COLEOPTERA, TENEBRIONIDAE)

S. Clemente¹, A. Broussalis¹, V. Martino², G. Ferraro² & G. Mareggiani¹, ¹ Cátedra Terapéutica Vegetal. Cátedra Zoología Agrícola. Facultad Agronomía. UBA. Av. San Martín 4453. (1417)Bs.As. Argentina. TE: 524-8066/524-8046. E-mail: clemente@mail.agro.uba.ar; ² Cátedra de Farmacognosia-IQUIMEFA (UBA-CONICET) Fac. de Farmacia y Biequímica. UBA. Junín 956, 2° piso (1113) Bs As. Argentina. TE/Fax: 508-3642.

At present, the use of natural agrochemicals is well accepted because of the necessity of new compounds useful for control pests but without environmental deleterious effects. Aromatic herbs, empirically used in interculture or foliar applications to keep horticultural crops free from insects, were selected to test their potential insecticide activity against Tribolium castaneum Herbst (Coleoptera, Tenebrionidae, CIPEIN strain),an important stored grains pest. Ten plants were tested: Rosmarinus officinalis L, Thymus vulgaris L, Origanum vulgare L, Ocimun bacilicum L, Lippia alda Mill, Urtica urens L, Lavandula spica L, Borago officinalis L, Mentha rotundifolia L and Artemisia absinthium L. Three extracts of different polarity (methylene chloride, methanol and aqueous extracts) from each plant were applied to the diet of T castaneum first instar larvae, evaluating their effect on development delay and mortality, until adult emergence, using ANoVA and Probit analysis (p≤0.05). The best results were achieved with Lavandula spica L non polar extracts, which produced a development delay of 40% compared with the control. When mortality produced by non polar L.spica extracts was compared with that caused by aqueous Lspica extracts, Lspica essential oil (containing 40% cineole), pure 1,8 cineole (as standard), results showed that methanolic extract treatment mortality was significantly different ($p \leq 0.05$) from the control, but similar to the standard treatment with 1,8 cineole. These results suggests that the biological activity here observed may be due to the presence of a secondary metabolite in the methanolic fraction of L. spica. Index terms: Lavandula spica, Natural Pest Control, Stored Grain Protection

[1311] CHARACTERISATION OF AMPLIFIED ALDEHYDE OXIDASES FROM INSECTICIDE RESISTANT Culex quinquefasciatus

"<u>M. Coleman¹</u>, L. M^{*}Carroll², J. G. Vontas³ & J. Hemingway⁴, ¹²⁴School of Bioscience J, Main College Building, Cardiff University, Park Place, Cardiff, CF1 3TL, South Wales, UK.

Organophosphorus insecticide resistance in *Culex quinquefasciatus* (Say), the major vector of filariasis, is due to the elevation of carboxylesterase activity. The underlying molecular basis of the enzyme's elevation is gene amplification. Two major phenotypes exist which involve either the co-amplification of esterases $est\alpha 2^{\prime}$ and $est\beta 2^{\prime}$, which accounts for 95% of resistant *Culex* species worldwide, or the amplification of $est\beta 1$. Since the $est\alpha 2^{\prime}$ / $est\beta 2^{\prime}$ amplicon is much bigger than the two genes alone, it was postulated that other genes may occur on the amplicon, and indeed, play a major role in insecticide resistance. Two further genes have now been identified. One has been fully cloned and sequenced in both genomic and cDNA, and both appear to code for functional aldehyde oxidase (ao). As AO plays a role in insecticide resistance. The deduced amino acid sequence of the fully sequenced *ao* encodes a 142 kDa protein of 1264 amino acid residues. A comparison of partial *ao* sequences from resistant and susceptible strains of *C. quinquefasciatus* demonstrates distinct allelic versions of the enzyme. By using quantitative PCR it has been possible to demonstrate that one of these alleles is amplified in the resistant but not the susceptible strain. In order to determine the role of AO in insecticide resistance, purified enzyme was characterised following over-expression in the baculovirus expression system. Index words: *PelRR, molybdenum, filariasis, baculovirus expression, esterase*

[1312] RESISTANCE MECHANISM TO BUPROFEZIN IN B-TYPE BEMISIA TABACI (HEMIPTERA: ALEYRODIDAE) IN AUSTRALIA

E.L.A Cottage¹ & R.V. Gunning², ¹Dept. of Agronomy & Soil Science, University of New England, Armidale, NSW, 2351, Australia; ³NSW Agriculture, Tamworth Centre for Crop Improvement, RMB 944 Calala Ln., Tamworth, NSW, 2340, Australia.

B-type Bemisia tabaci (Hemiptera: Aleyrodidae) in a serious insect pest of many horticultural, nursery and field crops internationally. The insect inflicts plant damage by virus transmission and honeydew production in addition to direct feeding. B-type B.tabaci was first detected in Australia in October 1994, and has since become widely spread across the country, posing a threat to many plant production industries. This insect is highly resistant to conventional insecticides, such as organophosphates and carbamates. Insecticides with novel modes of action, such as buprofezin, are being investigated for use in controlling this pest in Australia. Buprofezin acts by interfering with chitin deposition during moulting, causing the death of nymphs. The ability of buprofezin to bind to esterase iso-enzymes in B-type B.tabaci was investigated in a buprofezin susceptible strain and a strain that had been selected for buprofezin resistance. It is suggested that the resistance mechanism used is detoxification of buprofezin by esterases.

[1313] A SUSTAINABLE AND ECONOMICAL INSECTICIDAL MANAGEMENT PROGRAM ON COTTON IN BRAZIL

P. E. Degrande, J. S. Ribeiro, J. A. Staudt, R. V. Venturini & M. H. Cordellini. Caixa Postal 533, Dourados, Ms, Brazil, 79804-970. E-Mail: degrande@nin.ufms.br.

ITA-90 cotton is a virus-susceptible variety. This virus is transmitted by Aphis gossypii. Control of A. gossypii is based on very restricted threshold, varying of zero until 10% of attacked plants, from the establishment of the crop to 120 days after the germination (dag). The study objective to establish a program for a maintainable management of insecticides, minimizing problems of resistance of the pest and excessive use of insecticides mixtures. In Rondonopolis-MT during 1998/99 season, two treatments were compared ("System of Rotation" - SR versus "Conventional System"- CS). Each plot had 1,53 ha, with four replications. The pest monitoring followed principles of integrated pest management. Up to 64 dag insecticide applications were done by tractor (100 Lha⁴) later on aerial application (20 Lha⁴). "SR" consisted of the use of application blocks for mode of action of insecticides (1st = neonicotinoides: Cruiser* in seed treatment and Actara* in spraying; 2nd = carbamate/cyclodiene sprayed: carboaulfan + endosulfan; 3rd = carbamate/thiourea sprayed: carbosulfan + Polo[®]), "CS" based on the carbamate/cyclodiene use and organophosphate. The statistical analysis indicated significant differences in the viruses organophosphate. The statistical analysis indicated significant differences in the viruses incidence (SR=2,61% and CS=4,92%); smaller number of applications in SR (6) than CS (9,5); larger interval of applications in SR (17 days) than CS (10,27 days) [arger medium percentage of efficiency on aphids control in SR (73,68%) than CS (48,06%) and smaller in the virus of a particular term of the percentage of t cost of pest control by hectare in SR (US\$ 174,31) than CS (US\$ 207,30). We didn't find significant differences in the height of plants, bolls number per plant and weight of picked cotton among the two treatments. The results showed that in function of the readiness of mode of action of available insecticides for the control of the aphids in ITA-90 variety, should be used insecticides in blocks (mode of action based): neonicotinoides (first 35 dag), carbamate/cyclodiene (35-55 dag) and thiourea (after 55 dag). Index ternis: Aphis gossypii, ipm cotton, insecticide resistance, irm

Session 07-- ECOLOGY OF PESTICIDES, RESISTEANCE AND TOXICOLOGY

[1314] INSECTICIDES TOXICITY TO DIURAPHIS NOXIA (HOMOPTERA: APHIDIDAE)

L.R. Descamps¹, M.E. Reviriego¹, A. Ferrero¹ & <u>A.A. Suarez</u>², ¹Univ. Nac. Del Sur, San Andrés S/N, (8000) Bahía Blanca, Argentina, e-mail Errol Indicador não definido. ²E.E.A.INTA Anguil, Ruta Nac. N°5 Km 580, C.C. 11, (6326) Anguil, La Pampa, Argentina; e-mail asuarez@anguil.inta.gov.ar.

Aphids reared under laboratory conditions without insecticide applications background were used in this experiment. The organophosphate insecticides fenitotrion and clorpirifos and the pyrethroid deltametrin were used. FAO N°17 Method modified was used to determine the insecticides TL_{50} for *Diuraphis noxia*. Insecticides concentration were 0.1, 0.01 and 0.001 mg/ml. Mortality was determined using a computer program based on Finney method. Fenitotrion showed a TL_{50} of 12, 161 and 839 minutes for the 0.1, 0.01 and 0.001 mg/ml concentrations respectively. For clorpirifos TL_{50} of 5 (0.1 mg/ml), 44 (0.01 mg/ml) and 240 (0.001 mg/ml) minutes were observed. Deltametrin showed TL_{50} of 195 (0.1 mg/ml), 274 (0.01mg/ml) and 1030 (0.001 mg/ml) minutes. Results of this laboratory experiment showed that reduced concentrations of organophosphste insecticides are highly effective against Russian wheat aphid compared to deltametrin. Index terms: *Diuraphis noxia*, insecticides, TL_{50} .

[1316] RESPONSE OF PLUTELLA XYLOSTELLA (L.) (LEPIDOPTERA: PLUTELLIDAE) TO THE SELECTION WITH BACILLUS THURINGIENSIS

Ovidio Diaz-Gomez,¹ J. C. Rodriguez-M., ² A. M. Shelton, ³ A. Lagunes-T.,² M. Barcenas-O.,³ & R. Alatorre R.², ¹ Facultad de Agronomia, U.A.S.L.P. Alvaro Obregon 64, San Luis Potosi, S.L.P., C. P. 78000, MEXICO. 2 Inst. fitosanidad, C.P. Km 35.5 Carr. Mexico-Texcoco. Montecillo, Edo. Mexico.³ Entomology, Cornell Univ. NYSAES, Geneva, NY 14456 U.S.A.

In Mexico, the diamondback moth Plutella. xylostella (L.) is the major pest of crucifers plants. Its control depend largely on the use of Bacillus thuringiensis Berliner and organosynthetic insecticide. Therefore, it is important to take measures to prevent the further buildup of resistance. In this research, five populations of P. xylostella, collected in three states of Mexico, were selected with B. thuringiensis subspecies kurstaki (Dipel 2X), B. thuringiensis subspecies aizawai (Xentari), delta endotoxinas CryIC of B. thuringiensis subspecies aizawai (MC), and CryIA(c) of *B. thuringiensis* subspecies kurstaki (MVP), and finally, with the mixture of toxins contained in *B. thuringiensis* subspecies kurstaki and aizawai (Agree). Their responses were evaluated by leaf-dip bioassay. When it was compared a susceptible population with the response of those selected, in four out of five populations were obtained statistically significant differences. The most remarkable cases in resistance were detected to the delta endotoxinas Cry1A(c) and Cry1C, and in smaller degree to the complex of toxins contained in the subspecies *kurstaki*. With the subspecies aizawai and the mixture of subspecies kurstaki and aizawai the developed resistance levels were low. To ensure the continued performance of B. thuringiensis in field, we suggest that a resistance monitoring program be implemented to detect any changes in susceptibility to *B. thuring iensis* products and specific toxins; that their use be restricted to one generation per crop and that they be rotated with other groups of insecticides and incorporated in a integrated pest management program of cole crops. Also, we suggest the development and implementation of biological and cultural strategies in order to reduce overall population pressure so that fewer pesticidal treatments will be needed. This research demonstrates the existence of genes for resistance to B, thuringiensis in populations of P, xylostella collected in Mexico. This implies a strong risk to the dependence of B. thuringiensis for the control of P. xylostella, and also, to the introduction of crucífers transgénicas if they express a single delta endotoxina, mainly if appropriate strategies of management of the resistance are not implemented.

Key Words: Diamondback Moth, Microbial Insecticides, Resistance

[1315] TOXICITY OF DELTAMETRIN TO A STRAIN OF TRIBOLIUM CASTANEUM (COLEOPTERA: TENEBRIONIDAE)

L.R. Descamps¹, M.E. Reviriego¹, A. Ferrero¹ & <u>A.A. Suarez</u>¹, ¹Univ. Nac. Del Sur, San Andrés S/N, (8000) Bahía Blanca, Argentina, e-mail descamps@criba.edu.ar; ²E.E.A.INTA Anguil, Ruta Nac. N°5 Km 580, C.C. 11, (6326) Anguil, La Pampa, Argentina; e-mail asuarez@anguil.inta.gov.ar.

Surveys in the area of Puerto de Ingeniero White (Buenos Aires, Argentina) indicates that the more abundant stored-grain insect pests are: *Tribolium castaneum* and *Sitophilus spp.*. Also, deltametrin is one of the main insecticides used to control them. Several control failures reported by deltametrin aplicators, indicated the possibility of insecticide resistance development. Insect samples, from facilities with insecticide application background, were taken and the *Tribolium castaneum* strain obtained was named LIMA. To study the case, LIMA strain insecti severe compared to a strain, named ULP, without insecticide contact history. In laboratory, CL₅₀ for deltametrin, resistance factor, CL₅₀ for deltametrin + piperonyl butoxide (PB) and synergistic factor were determined using FAO method N° 15 modified. Toxicity parameters were analized by a computer program based on Finney method. Ours results indicates that LIMA (CL₅₀=87.88 µg/cm²) was more susceptible to deltametrin than ULP (CL₅₀=85.29 µg/cm²) for ULP and 1.04 µg/cm2 for LIMA. Sinergistic factors were 14.64 for ULP and 84.5 for LIMA. The suggest an important deltametrin degradation by mixed function oxidases.

Index terms: Tribolium castaneum, deltametrin, piperonyl butoxide, CL₃₀, mixed function oxidases.

[1317] INHERITANCE AND FITNESS COST OF RESISTANCE TO LAMBDA-CYHALOTHRIN IN SPODOPTERA FRUGIPERDA (LEPIDOPTERA: NOCTUIDAE)

G. I. Diez-Rodríguez & C. Omoto, Depto. de Entomologia, Fitopatologia e Zoologia Agrícola, Escola Superior de Agricultura "Luiz de Queiroz", Av. Páduas Dias, 11, 13418-900 Piracicaba, SP, Brasil, E-mail: celomoto@carpa.ciagri.usp.br.

Spodoptera frugiperda (J.E. Smith) is a major pest of corn and other vegetable crops in Brazil. An approximately 15-fold resistance was detected in a laboratory-selected resistant strain of *S. frugiperda* to the pyrethroid lambda-cyhalothrin. Inheritance and fitness consequences of resistance to lambda-cyhalothrin were investigated in this study. A series of crosses and backcrosses were performed between susceptible and resistant strains to determine the level of dominance and the number of genes involved in the resistance, respectively. Dose-response lines were obtained with third instars by using topical application bioassay. The analysis of the progenies of the reciprocal F₁ crosses indicated that the resistance was autossomal and conferred by an incompletely recessive gene. Chisquare analysis of responses of progenies from backcrosses suggested that the resistance was determinated by a single major gene under a influence of some minor genes. An isogenic-resistant strain was built to separate the major locus from modifiers genes, and then to evaluate the fitness cost of resistance to lambda-cyhalothrin in *S. frugiperda*. Fitness components (fecundity, viability, developmental time and pupal weight) were measured on the susceptible, heterozygous and isogenic-resistant strains. The relative fitness of heterozygous individuals was also studied because they are the most common individuals at the early stages of resistance evolution. Implications of these results for insecticide resistance management of *S. frugiperda* to lambda-cyhalothrin will be discussed

Index terms: fall armyworm, insecticide resistance, fitness cost, pyrethroid

[1318] BIOASSAY TO COMPARE THE SYSTEMIC ACTIVITY OF THREE NEONICOTINOIDS FOR CONTROL OF *IIETERONYCHUS ARATOR* (COLEOPTERA: SCARABAEIDAE), IN MAIZE

T.W. Drinkwater, ARC-Grain Crops Inst., Private Bag X1251, Potchefstroom, 2520, South Africa. E-mail: tomdrw@igg2.agric.za

Two neonicotinoid seed dressing insecticides (imidacloprid and thiamethoxam) are presently in use in South Africa for the control of black maize beetle, Heteronychus arator, in maize. However, these two compounds were tested and became registered in years when beetle numbers were relatively low and their performance in years when beetle numbers reach pest status is still uncertain. Since the systemically translocated repellent activity of neonicotinoids is an important means of controlling black maize beetle in maize, imidacloprid, thiamethoxam and acetamiprid were compared in laboratory feeding bioassays. In all trials, seed was planted on alternate days in 3.5 1 pots in a greenhouse. Sixteen days after planting, roots and leaves of seedlings were removed and thirty stems (40 nm in length) per treatment were placed singly in glass vials containing soil and one *H. arator* beetle. Beetles were provided with fresh seedlings and soil on alternate days for 10 days - a total of five stems per beetle. Damage to maize stems (rolled leaf sheaths) was recorded by determining the number of damaged sheaths, ranking from zero to six. Only the most severely damaged stem out of the five tested against each beetle was taken into account, demonstrating the ability of a beetle to damage treated seedlings. The compounds were tested at 1.75 g (registered dosage rate) and 0.88 g a.i. kg⁻¹ seed. In all trials imidacloprid proved to be the most effective in controlling black maize beetle, although differences were not always significant. However, the efficacy of the systemically translocated activity of this neonicotinoid (and others?) is affected by factors which are still unknown and which may relate to the reproductive status of the beetles. In twelve trials carried out with imidacloprid at a dosage rate of 1.75 g a.i. kg⁻¹ seed, the percentage of severely damaged stems varied from 3.3 to 60.0 % (n = 30). Therefore, in these type of trails, results with neonicotinoids should never be compared between, but always within trials.

Key words: Acetamiprid, imidacloprid, thiamethoxam, black maize beetle

[1319] DIFFERENT DOSAGES OF IMIDACLOPRID 60 FS (GAUCHO 60 FS) IN ONION SEED TREATMENT ON THE GERMINATION AND THE EMERGED PLANTS

A. C. Dughetti and D. L. De Carli, National Institute Technology Agriculture (INTA), Agric. Hilario Ascasubi Exp. Station, Hilario Ascasubi, Bs. As.- 8142, Argentina, E-mail adughetti@inta.gov.ar

The seed corn *Delia platura* and the onion maggot *Delia antiqua* larvaes are one of the most important problems in the implantation onion crops at direct seeding. The imidacloprid formulated for seed treatment is an alternative management less contaminates than soil treatments for these pests. The experiment objective was to test the imidacloprid's phytotoxicity on the onion's seed germination, in different dosages, by seed treatments. The treatments were the imidacloprid to 4, 6, 7.5 and 9 kg formulated product per 100 kg onion seeds, by slurry treatments; and the untreated check. Germination and phytotoxicity effect appraised through the germination power betten paper towel, in laboratory; and also for the emerged plants number, in experimental plots. In the laboratory's experiment, the igermination power's untreated check was more important than imidacloprid's treatments in different dosages, analyzed by Tukey test ($\alpha = 0.05$). In the field's experiment, the information was analyzed by the Friedman's test ($\alpha = 0.05$) in different dates. At the last date, the untreated check and treatments imidacloprid 4% and 6% the emerged plants resulted higher than imidacloprid 9%.

Index terms: Imidacloprid, seed treatment, phytotoxicity, onion, Delia sp.

[1320] AN RNA HELICASE OF THE "DEAD BOX" FAMILY CLONED FROM A LEPIDOPTERAN SPECIES, THE SPRUCE BUDWORM (CHORISTONEURA FUMIFERANA)

O.L. Feng¹, A. Retnakaran¹, T. R. Ladd¹, S.-C. Zheng¹, M. Primavera¹ & S. R. Palli², ¹Great Lakes Forestry Centre, Canadian Forest Service, P. O. Box 490, 1219 Queen Street East, Sault Ste. Marie, Ontario, Canada, P6A 5M7.E-mail: qfeng@nrcan.gc.ca;²Rohm and Haas Research Laboratories, 727 Norristown Rd. Spring House, PA 19477, USA.

Helicases are a family of enzymes that unwind nucleic acid duplexes, such as DNA/DNA, RNA/RNA and RNA/DNA, in a 3' to 5' direction to single-stranded polynucleotides. The function of helicases is involved in processes such as replication, DNA repair, recombination, transcription and translation. We screened CF-203 cell cDNA library using polyclonal antibodies produced against a methoprene-tolerant (*mel*) gene identified from *Drosophila melanogaster* and identified a clone that showed highest amino acid similarity with D. melanogaster helicase. This cDNA (CfrHel) was the first RNA helicase clone reported from lepidopteran species. The deduced protein had 555 amino acids and contained 8 domains that are conserved in the DEAD box family of RNA helicase, indicating that it was a member of this DEAD family. The cDNA has been expressed to produce an active protein with a molecular mass of 61kDa as expected from the deduced amino acid sequence. Developmental expression studies of CfrHel mRNA in *C. fumiferana* revealed that 1st instar larvae had the lowest background levels of mRNA, whereas diapausing 2th instar larvae showed the highest levels of mRNA and the 3rd-6th instar larvae and pupa also showed moderate levels of mRNA. Higher levels of CfrHel mRNA was detected in the fat body and midgut than in the epidermis of 6th instar larva. Female adults showed higher levels of CfrHel than male adults. The CfrHel mRNA expression pattern was similar to the maternally expressed *vasa* gene isolated from *D. melanogaster*.

Index terms: cDNA, cloning, expression, nucleic acid duplex

[1321] PEPPER WEEVIL CONTROL WITH ACTARA 25WG

J. S. Ferguson' & D. S. Lawson', 'Novartis Crop Protection Inc., 7145 58th Avenue, Vero Beach, FL 32967, USA, E-mail scott.ferguson@cp.novartis.com; ² Novartis Crop Protection Inc., P. O. Box 18300, Greensboro, NC 27419-8300, USA.

The pepper weevil, Anthonomus eugenii (Coleoptera: Curculionidae) is a severe pest of peppers in the Southern U.S.A., Mexico, Central America and several Caribbean Islands (most notably Puerto Rico). Adult female pepper weevils lay eggs on flowers, buds and fruit. Fruit infestation results in premature fruit drop and can result in crop losses of up to 50% or higher. Actara[®] 25WG (thiamethoxam, CGA 293343) is a new neonicotinoid insecticide under development by Novartis Crop Protection. In field trials, Actara[®] at 50 and 70 g ai/ha applied at 7-day intervals provided highly effective control of the pepper weevil in bell and jalapeno peppers, resulting in increased yields. Control was superior to that of the current standard, Vydate[®](oxamyl), at 1120-g ai/ha. Additionally, Actara[®]provides control of other pepper pests, including aphids, leafhoppers, stink bugs and whiteflies.

Index terms: Anthonomus eugenii, pepper weevil, Actara, thiamethoxam

M.C. Fernandes¹, S.A. De Bortoli² & R.J. Ferreira¹, ¹Depto. de Biologia, Univ. de São Paulo, CEP 14040-901, Ribeirão Preto, SP, Brasil. ²Depto. de Fitossanidade, Univ. Estadual Paulista, CEP 14870-000, Jaboticabal, SP, Brasil. E-mail: bortoli@fcav.unesp.br.

This work was aimed to evaluate the tolerance of lab populations of *Chrysoperla externa* to spinosad, clorpiryphos, lambdacyalothrin and abameetin, trying to improve the relationship between biological and chemical control. The trials were carried out in the Biology Lab at the University of Sao Paulo State, Jaboticabal, SP, Brasii.. The experimental conditions were: $25 \pm 2^{\circ}$ C, 14:10 (L:D) and $70 \pm 10\%$ R.H. The Bioassay 1 (immersion in the insecticides solutions) used 1^a instar larvae of *C. externa* with until 24 hours of age fastened on microscope slides. The insecticides solutions were: 12, 24 and 48 ppm (spinosad); 640 ppm (clorpiryphos); 30 ppm (lambdacyalothrin); and 3.3 ppm (abameetin). The evaluations, larvae mortality, were made 24, 48 and 72 hours after treatments by checking larvae mortality. To the Bioassay 2, the larvae's food (*Sitotroga cerealella* eggs) was treated by the same insecticides solutions during 5 seconds, and, after dried the larvae were exposed to the treated food, and checking the nortality at the same times. To the both bioassays were evaluated pupae period and adult viability, too. According to the results, *C. externa* larvae showed high tolerance to spinosad dosis tested and they had their life cycle completed forming perfect adults.

Index terms: crisopid, spinosad, clorpiryphos, lambdacyalothrin, abamectin

[1323] UPTAKE AND DISTRIBUTION OF THIAMETHOXAM AFTER SEED TREATMENT

W. Fischer & A. Steinemann, Novartis Crop Protection AG, CH-4058 Basel Switzerland, E-mail: willi. fischer@cp.novartis.com

Following application as seed treatment a crop protection agent will be taken up by the imbibing seed and the growing roots. A substantial part of the product will be removed from the seed by water and be partitioned into the soil. This part will behave like product applied by soil drench or other soil incorporation methods. Part of the product may be lost by soil degradation and washout by rainfall and part of the product will be taken up into the plant. Inside the plant the product will be redistributed, translocated and meabolized. The chemodynamic behavior of an active ingredient is determined by its chemical and physicochemical properties. These properties determine the use of the product and the environmental fate of the active ingredient. A low molecular weight, low

[1324] COMPARATIVE LARVICIDAL ACTIVITY OF THE ENDECTOCIDES, DORAMECTIN, EPRINOMECTIN, IVERMECTIN, AND MOXIDECTIN AGAINST THREE SPECIES OF PEST FLIES (DIPTERA: MUSCIDAE) IN DUNG OF TREATED CATTLE

K. D. Floate, R. W. Spooner & D. D. Colwell, Agriculture and Agri-Food Canada, Lethbridge Research Centre, P.O. Box 3000, Lethbridge, AB, Canada, T1J 4B1 E-mail: floatek@em.agr.ca.

Two experiments were performed to assess the larvicidal activity of endectocide residues in cattle dung against horn fly (*Haematobia irritans* (L.)), house fly (*Musca domestica* L.) and stable fly (Stomoxys calcitrans (L.)) (Diptera: Muscidae). In Experiment 1, cattle were treated with ivermectin, moxidectin, or left untreated. In Experiment 2, cattle were treated with doramectin, eprinomectin, ivermectin, or moxidectin. All treatments were applied in topical formulations at recommended dosages (500 mcg/kg body weight). Fresh dung was collected from cattle immediately before (0 wks) and one to nine weeks after application (Experiment 1), or one to four weeks after application (Experiment 2). Containers of dung were 'seeded' with eggs or first-instar larvae of horn fly, house fly or stable fly and held in the laboratory for adult emergence. Results identified horn fly as being most susceptible to endectocide residues, with reduced emergence in dung voided four to six weeks post-application. In contrast, emergence of house fly and of stable fly was not reduced in dung voided more than two weeks post-application. Ranked in descending order of larvicidal activity, doramectin > ivermectin = eprinomectin >> moxidectin. This study: 1) confirms previous reports that the larvicidal activity of ivermectin is greater than that of moxidectin, 2) is among the first to provide information on the larvicidal activity of doramectin and eprinomectin, and 3) is the first to perform simultaneous bioassays of the four endectocides currently available on the market against a group of important pest flies breeding in dung. Index terms: Haematobia irritans, Musca domestica, Stomoxys calcitrans, off-target effects octanol-water partition coefficient and relatively high water solubility characterize the neonicotinoid Thiamethoxam. All these parameters are favorable for an efficient uptake by the roots and for an efficient transport in the xylem. Thiamethoxam when applied as seed treatment on maize (Zea mays) is rapidly taken up into the seedling and young plant. Rather high concentrations of Thiamethoxam can be detected in all seed compartments and also the organs of the young seedling contained high amounts of the active ingredient 14 and 21 days after sowing: pericarp 30ppm, embryo 100ppm, endosperm 86ppm, coleoptile 33ppm, primary root 2.6ppm, and leaves 5.6ppm. Thiamethoxam was applied as seed treatment also on winter rape (*Brassica napus*) and on summer rape (*Brassica campestris*). A rapid and efficient uptake was found in both varieties over an extended time period. It was found that due to the high water solubility dry soil conditions did not impair uptake of Thiamethoxam. Uptake of the compound is significantly increased at higher temperatures. The rate of degradation in the plant is dependent on various factors, such as plant species, temperature, and humidity. Similar studies with cotton (Gossypium hirsutum) will be conducted. The results will be reported and discussed.

Index terms: Thiamethoxam, seed treatment, uptake, distribution.

[1325] EFFECT OF THIAMETHOXAN ON BEAN CROP DEVELOPMENT

M. J. Fornazier', D. S. Martins' & M. A. G. Ferrão', 'EMCAPER- Empresa Capixaba de Pesquisa, Assistência Técnica e Extensão Rural. BR-262, km 94, Venda Nova do Imigrante/ES, CEP 29375-000, Brazil, E-mail crdrcserrano@emcaper.com.br.

This experiment was carried out from November 1999 to February 2000 in the highlands of Espírito Santo State to determine the effects of different formulations and application methods of thiamethoxan (a neonicotinoid insecticide) on bean crops. A randomized complete block with sub-plots experimental design was used with three bean cultivars of different color groups: black, cream-beige solid and small dark red, and four insecticide treatments: granules (Actara 10GR*, 150 g a. i.fna), seed treatment (Cruiser 700 WS*, 105 g a. i.fna), plant row spray (Actara 250 WG*, 50 g a. i.fna) and untreated control. The experiment was irrigated three times every seven days in December and sprayed twice with tebuconazole (250 g a. i./ha) and six times with methamidophos (600 g a. i./ha) from November to January. Evaluations were done at 10, 16, 23 and 36 days after germination with the following parameters evaluated: number of leaves, fresh and dry leaf weight, fresh and dry root weight, total fresh and dry plant weight, plant height and number of Rhizobium nodules. There was an interaction between bean color group and thiamethoxan formulation. Actara 10GR had the greatest effect on black bean; Cruiser 700 WS in seed treatment on cream-beige solid group and Actara 250 WG plant row spray on small dark red group. Total plant weight was greater with thiamethoxan treatment initially but differences decreased from first to fourth evaluation showing effects of thiamethoxan on initial growth of bean crop. Number of Rhizobium nodules were not significantly reduced in any treatment by the use of thiamethoxan. Beneficial effects of thiamethoxan on beans in increasing initial crop development were noted.

Index terms: Phaseolus vulgaris, growth, neonicotinoid insecticide

[1326] EFFECTS OF TRANSGENIC HYBRID MAIZE ON ADULT WESTERN CORN ROOTWORM EMERGENCE AND ROOT RATINGS

B.W. French¹, L.D. Chandler², D. Hartman¹, D.W. Beck¹, P.M. Davis³, & J. Pershing⁴, ¹USDA, ARS, NGIRL, 2923 Medary Ave., Brookings, SD 57006, USA E-mail wfrench@ngirl.ars.usda.goy; ²USDA, ARS, RRVARC, 1307 N, 18^{*} Street, Fargo, ND 58105, USA; ³Monsanto Co., 3302 SE Convenience Blvd. Ankeny, IA 50021, USA; ⁴Monsanto Co., 800 N. Lindbergh Blvd., St. Louis, MO, 63167, USA.

The larvae of Diabrotica sp. feed on the roots of maize, which can cause plants to lodge and thus prevent harvesting. Each year in the United States, millions of hectares are treated with insecticides in attempts to reduce corn rootworm populations below economically damaging levels. No other agricultural pest accounts for as much insecticide application as do corn rootworms. The indiscriminant use of insecticides can have adverse effects on beneficial insects, wildlife, the environment, and humans. To reduce the amount of insecticide applied to maize, the Monsanto Co. has developed several varieties of maize that have a rootworm toxin-producing gene (Cry3Bb) inserted into the genome. This gene is derived from the soil bacterium Bacillus thuringiensis tenebrionis. In order to test the efficacy of these varietics against corn rootworms, we established a randomized complete block experimental design that included 9 maize varieties replicated 4 times. Seven varietal events (designated Event A-G) were transgenic corn. Two non-transgenic varieties acted as controls; one was treated with insecticide (Force 3G) (Control 1) and the other received no applied rootworm control method (Control 2). We infested each subplot with *D. virgifera virgifera* eggs at the V2-V3 growth stage. We then placed cages within the rows to capture the emerging beetles. At the end of beetle emergence, we rated the damage to roots caused by the larvae. Significantly more male beetles emerged than females, however, for both males and females, fewer beetles emerged from the transgenic maize plots than from either control. Events C-G were the most effective at reducing rootworm populations. The number of beetles emerging from insecticide-treated maize did not differ from the number emerging from plants not treated with insecticide. Root damage only exceeded economically damaging levels (3.0 rating) in the no treatment plots. These results are discussed in terms of management strategies for slowing the rate of resistance development in corn rootworms.

Index terms: Diabrotica, resistance management, agricultural landscapes.

OF IMIDACLOPRID, THIACLOPRID AND EVALUATION [1327] METHIOCARB TO CONTROL Myzus persicae (HOMOPTERA: APHIDIDADE) **ΙΝ ΡΟΤΑΤΟ**

R. S. Furiatti¹, P.R.V.S. Pereira¹ & A. R. Pinto Jr.², ¹ Depto de Fitotecnia e Fitossanidade, Univ. Est. de Ponta Grossa, Caixa Postal 992, 84100-970, Ponta Grossa, PR, e-mail: furiatti@centerline.com.br, prvalle@netpar.com.br; 2 Agrius Capac. e Análises Agronômicas, Curitiba, PR, e-mail: arpinto@netpar.com.br.

The efficacy of imidacloprid (nitroguanidine), thiacloprid (cloronicotinil) and methiocarb (carbamate) was determined against Myzus persicae (Sulzer, 1778) exposed to treated potato plants. The potato strain used was Atlantic, planted 0,3 m between lines and 0,75 m between plants. The doses of the insecticides tested were 0,07 kg a.i./ha (imidacloprid); 0,0336 and 0,048 I a.i./ha (thiacloprid) and 0,25 and 0,375 I a.i./ha (methiocarb). The statistical design was casualized plots with 4 replicates, the data was submitted to analysis of variance (ANOVA) and the mean number of data compared using Tukey's. The efficacy of the insecticides was evaluated by the number of live aphids/plant using the Ascombe's Three Leaves Method. The evaluations were done 1, 3, 7, 10 and 15 days after treatment, using 5 plants per replicate. The results showed that imidacloprid (0,07 kg a.i./ha) and thiacloprid (0,048 l a.i./ha) were efficient in all evaluations. Thiacloprid (0,0336] a.i./ha) was efficient after the third day after treatment. Index terms: Chemical control, potato, Myzus persicae

[1328] INSECTICIDE AND REPELLENT EFFECTS OF MELIA AZEDARACH EXTRACTS AGAINST AEDES AEGYPTI (DIPTERA: CULICIDAE)

Coria Genovese¹, F. Ludueña Almeida¹, W. R. Almirón¹ G. Valladares¹, S. Palacios², ¹Centro de Investigaciones Entomológicas de Córdoba. Facultad de Ciencias Exactas, Físicas y Naturales. Universidad Nacional de Córdoba. Avda. Vélez Sarfield 229. 5000 Córdoba. ²CEPROCOR. Av. Arenales 230. 5000 Córdoba. Argentina. E-mail: walmiron@onenet.com.ar

Dengue Fever cases have been recently reported from various provinces in Argentina the outbreak. The emphasis is currently on prevention and control programs aimed mainly against its vector. Aedes aegypti. Temephos and Bil are used to treat the mosquito breeding sites. In this study, extracts of Melia azedarach (Meliaceae) were tested against Ae. aegypti, thus aiming to provide a natural, easily obtainable, low-cost, and environmentally safe management tool. Larvicidal effects were investigated by analysing mortality rate and development time of larvae reared in water treated with *M. azedarach* leaf and fruit extracts. Three extract concentrations (1g/l, 0.75g/l, 0.50g/l) and five replications (each a cohort of 30 first instar larvae) were used for each extract. Ovitraps were used to evaluate oviposition deterrent activity of the extracts. Five females recently emerged and blood-fed were allowed to choose between ovitraps containing either 1 g/l or 0.50 g/l of leaf extract, 1 g/l or 0.50 g/l of ethanol, or just water. Treatments with fruit extracts included ovitraps with 1 g/l, 0.75 g/l, 0.50 g/l and a water control. Five replicates were conducted for each extract. The data were analysed by ANOVA and X⁴. Treatments with leaf extract resulted in 100% larval mortality at all the concentrations tested. Mortality and development time did not differ significantly between treatments with ethanol or water. In the treatments with fruit extract only the higher concentration (1 g/l) showed a significant increase in mortality rate (48%) and development time (17.7 d) in comparison with either lower concentrations of extracts or the water controls (about 14% mortality and 14 days to reach adult stage). When considering the extracts as repellents for oviposition, the leaf extract showed again the strongest activity, with significantly fewer (less than 7%) eggs being laid in ovitraps containing extract, in comparison with those containing either water or ethanol. The number of eggs was also significantly reduced in ovitraps with fruit extract, the latter receiving about six times fewer eggs than those with water. The number of eggs did not differ among ovitraps with different fruit extract concentrations. According to the results obtained, both leaf and fruit extracts of *M. azedarach* could provide an interesting tool for the management of Ae. aegypti, since they can negatively affect survival and development time of the mosquito, as well as inhibiting its oviposition.

[1329] EXPLORING THE INFLUENCE OF INSECTICIDE ON INSECT PEST-PREDATOR INTERACTIONS USING A THEORETICAL TWO-FIELD MODEL

P. F. Giordano¹, <u>E. V. Trumper</u>² & J. Holt³, 'Cátedra de Ecología, Fac. Cs. Exactas Fis. y Nat., U.N.C., Av. Vélez Sársfield 299, (5000) Córdoba, ARGENTINA. ³Sección y Nat., U.N.C., Av. Vélez Sársfield 299, (5000) Córdoba, ARGENTINA. ³Sección Entomología, E.E.A. Manfredi, INTA, Ruta Nacional 9 Km 636, (5988) Manfredi, Córdoba, ARGENTINA, E-Mail: etrumper@arnet.com.ar. ³Natural Resources Institute, University of Greenwich, Central Avenue, Chatham Maritime, Kent ME4 4TB UK.

Insect pest resurgence has been attributed to a variety of factors. One of the mechanisms most frequently invoked is the elimination of natural controls of pest populations, as a side-effect of pesticide applications. A modified Lotka-Volterra predator-prey model was proposed in which two fields where related through dispersal of both pest and predator. In proposed in which two fields where related intrough dispersion of both pest and predator in one of these fields insecticide spraying was represented. To investigate the influence of the predator functional response, alternative versions of the model employed type I, II and III functional response equations. The model was parameterised according to a survey of literature for the period 1984-1998. A sensitivity analysis was carried out to explore model behaviour. With certain parameter combinations, the consequence of spraying was a marked reduction in pest number. Pest population resurgence was found only in particular circumstances: no resurgence occurred in the sprayed field when an unselective insecticide was used, but in the unsprayed field, resurgence could occur. Resurgence was most apparent with a type III functional response and least apparent with a type II response, though these differences were relatively small. N general, simulated pest control outcomes were more sensitive to rates of predator assimilation and mortality than to rates of predator and pest dispersal. The relevance of these results is discussed in the context of general and pest unpersal. The relevance of interview and a second pest unpersal. The relevance of making. guidelines of pest management decision making. Index terms: ecotoxicology, pest resurgence, functional response, predation, simulation.

[1330] EFFECT OF VEGETAL AQUEOUS EXTRACTS ON IMMATURE STAGES AND FEMALES OF THE CASSAVA GREEN MITE *MONONYCHELUS TANAJOA*

M.E.C. Gonçalves¹, <u>I.V. Oliveira</u>¹, R. Barros & J.B. Torres¹, ¹Fitossanidade, Univ. Fed. Rural de Pernambuco, Av. Dom Manoel de Medeiros s/n, Dois Irmãos, 52171-900, Recife, PE. E-mail: jvolivei@elogica.com.br

It was studied the bio-activity of neem Azadirachta indica A. Juss., clove Syzigium aromaticum L. and cinnamon Melia azedarach L. aqueous extracts on immature stages and female mortality of the cassava green mite Mononychellus tanajoa (Bondar). The essays were carried at $27 \pm 0.5^{\circ}$ C, $69 \pm 4\%$ RH and photophase of 12 h. Egg treatment consisted of dipping cassava leaf discs with 30 eggs into each vegetal extract and concentrations. For treatment control, the leaf discs were dipped into destilled water. The treated and control leaf discs were dried for 30 min under environmental conditions. The effect on immature stages and females were studied by exposure of 40 individuals to each vegetal extract and concentrations. Neem extract at concentrations 0.5, 2.5 and 5% caused mortality of 16.8, 59.2 and 60% for embryonic stage, while the clove concentration 5% and control treatment caused mortality of 10.8 and 4.2%, respectively. Larvae, protonymphs and deutonymphs treated with neem extract at concentrations 2.5 and 5% showed mortality ranging from 57.5 to 100% and 85 to 100%, respectively. Neem extract at concentration 2.5% increased significantly protonymphs and deutonimphs mortality from 24 to 48 h evaluations, while for the later stage it was observed only to concentration 5%. The neem extract at 0.5% and clove at 5.0% did not show significant mortality for immature stages. Females of *M. tanajoa* treated with 2.5 and 5% of neem concentrations showed mortality of 97.5 and 100%, while the cinnamon and glove extracts at these concentrations, caused mortality of 5 and 7.5%, and 5 and 12.5%, respectively. Index terms: Phytophagous mite, cassava pest, plant extract, natural insecticide.

[1332] METABOLIC RESISTANCE TO PYRETHROIDS IN AUSTRALIAN HELICOVERPA SPECIES

R. V. Gunning¹, G. D. Moores² & A. L. Devonshire³, ¹NSW Agriculture, Tamworth Centre for Crop Improvement, RMB 944, Calala Lane, Tamworth, NSW, Australia, 2340; ²³ IACR-Rothamsted, Harpenden, Herts., AL5 2JQ, UK.

Helicoverpa armigera (Hübner) and Helicoverpa punctigera (Wallengren), are major pests of cotton, and other crops in Australia. H. armigera (Wallegera (balance), are major insecticide resistance (DDT, pyrethroids, carbamates, organophosphates and endosulfan.) Some populations of H. punctigera are resistant to pyrethroids, carbamates and endosulfan. Chemical insecticides are considered essential for control of H. armigera and H. punctigera on cotton and, due to the variable performance of transgenic cotton, are likely to remain an important component of control strategies for the foreseeable future. Insecticide resistance has greatly increased over recent years and is a major threat to the economic production of cotton in Australia. Pyrethroids were first introduced for control of Helicoverpa spp. in Australia the late 1970's and resistance was first diagnosed in H. armigera, in late 1983. The initial pyrethroid resistance mechanism, a massive nerve insensitivity was associated with a severe fitness deficit and was quickly replaced in the field by a metabolic mechanism. This mechanism could be partially suppressed by piperonyl butoxide (PBO). Pyrethroid synergism by PBO, led to a widely held assumption, that pytethroids were metabolised by monooxygenases in *H. amigera*. However, it has become increasingly clear that instead, an overproduction of esterase isoenzymes is responsible for pytethroid resistance in *H. armigera*. The esterases sequester and metabolise pyrethroids and furthermore, biochemical studies showed that PBO was an esterase inhibitor in H. armigera. Some organophosphates are effective esterase inhibitors and can restore pyrethroid susceptibility. Pyrethroid/ esterase binding studies showed that pyrethroids which contained a halogenated benzyl group bound more readily to *H. armigera* esterases and were more resisted, in comparison to pyrethroids, where the benzyl ring was replaced by a dihalogenated aliphatic entity. Pyrethroid resistance in H. punctigera was also shown to be the result of an esterase mediated resistance mechanism.

[1331] INFLUENCE OF INSECTICIDES ON THE SPIDERS COMMUNITY IN A SOY CULTIVATION (BUENOS AIRES, ARGENTINA)

A. González, E. Minervino, D. Castro, A. Armendano & S. González, Cepave. 2 nº 584, 1900 La Plata, Argentina. alda@netverk.com.ar

There is experimental evidence on the action of spiders as regulators of populations of plague insects in agriculture, so as on the need of biocontrol agents (Greenstone, 1999). Indiscriminate use of agrochemical favors the elimination of natural enemies (Kajak, 1978). The aim of this paper is to determine the effects produced by insecticides on the spider population of soy cultivation and relate density fluctuations to those of the plague groups. The work was carried out in two parcels, one without treatment, and the other with two fumigations (on middle of February and end of March). 40 samples were taken weekly, randomly, on plant packaging from January to March. Diversity (equitability and Shannon & Weaver indexes) and density of spiders and plagues of the fumigated parcel was compared with those of that not fumigated (test t). The weekly net increase of spiders (i) was calculated for both parcels. Diversity and density of spiders were significantly lower in the treated parcel (only 50% of the families appeared), being low the diversity index and high the equitability index. The first fumigation occurred when the area was not completely colonized. This fact prevents the settlement of some spider species on one hand, and the elimination of most preys, on the other. After fumigation, density of spiders became zero, for fifteen days, then the colonization began again, as at the beginning of cultivation, but with less diversity and density. The weekly increasing rate shows similar trends in both parcels in the first three weeks. In the parcel not treated, density increased, but in the funigated parcel was zero (weeks 3 and 4). This situation repeated after the second funigation (weeks 7 and 9). Later it was similar in both parcels. Comparing spider and prey defoliators and drillers densities, preys appear in the first weeks, together with the spiders, but then, defoliators are drastically affected by fumigation, as spiders, while in the not treated parcel they reached high densities and then decreased, surely affected by natural enemies. Drillers are not highly affected by fumigation, and when spiders disappear, they show a high peak in density. In the not treated parcel, the permanence of factors of natural mortality probably prevented the second peak. Index terms: Spiders, soy culture, insecticides.

[1333] METABOLIC MECHANISM OF RESISTANCE TO IMIDACLOPRID IN BEMISIA TABACI, IN AUSTRALIA

R. V. Gunning, NSW Agriculture, Tamworth Centre for Crop Improvement, RMB 944, Calala Lane, Tamworth, NSW, Australia, 2340

B-biotype Bemisia tabaci is a serious pest of cotton and horticultural pests world wide. This insect has spread thought the world via the international trade in poinsettia cuttings. B-biotype B. tabaci was first discovered in Australia in 1994 and since, has become widely distributed. This whitefly has already achieved a major pest status in some horticultural crops in Australia. Imidacloprid is one of the newer insecticides developed for the control of sucking insects, including whiteflies. Imidacloprid is registered for whitefly control in Australia. Initially bioassays showed that B-type Benisia tabaci in Australia were susceptible to imidacloprid. However, since then, there have been some problems with field control of B. tabaci in Queensland using imidacloprid. Bioassays showed a rapid development of resistance. Biochemical studies indicated that imidacloprid bound readily to esterase isoenzymes in resistant B. tabaci. Detoxification of imidacloprid by esterases is suggested as a mechanism of resistance in Australian populations of B. tabaci.

Symposium and Poster Session

[1334] EFFECT OF WHEAT CURL MITE SOURCES ON TRANSMISSION OF HIGH PLAINS VIRUS

T.L. Harvey' & D.L. Seifers', 'Dept. of Entomology, Kansas St. Univ., Manhattan, KS 66506, e-mail tharvey@oz.oznet.ksu.edu; 'Kansas St. Univ., Agricultural Research Center-Hays, Hays, KS 67601, e-mail dseifers@oz.oznet.ksu.edu.

The High Plains virus (HPV) is vectored by the wheat curl mite (Aceria toshichella) (WCM). This study was done to determine if differences exist among sources of WCM in vectoring of HPV isolates. WCM were obtained from five states and cultures free of wheat streak mosaic virus (WSMV) were established by raising the WCM from eggs on wheat free of HPV and WSMV. WCM from each location were then separately maintained on healthy and WSMV-infected wheat. HPV isolates were isolated from infected corn from five states and were maintained free of WSMV in corn by vascular puncture of the embryonic tissue of corn seed. Each WCM culture (viruliferous and aviruliferous) was tested against each HPV isolate for ability to vector HPV. WCM from Kansas, South Dakota, and Texas were not able to transmit any HPV isolate. However, WCM from Montana and Nebraska could vector all HPV isolates in all experiments in both viruliferous and aviruliferous culture.

[1335] ANALYSIS OF THE PROMOTERS OF THE β ESTERASE GENES ASSOCIATED WITH ORGANOPHOSPHATE-RESISTANCE AND – SUSCEPTIBILITY IN TWO STRAINS OF CULEX QUINQUEFASCIATUS

<u>N. J. Hawkes</u> & J. Hemingway. School of Biosciences, Cardiff Univ., Main College, Museum Avenue, Cardiff, CF10 3TL, UK e-mail:- sabnh@cf.ac.uk

The mosquito Culex quinquefasciatus is a major vector of filariasis and arboviruses. Widespread resistance to organophosphate insecticides is primarily due to the over-expression of non-specific carboxylesterases which sequester the insecticide. Excess esterase production is usually caused by amplification of the structural esterase gene(s). Co-amplification (1:1) of two genes on a single amplicon, $est\alpha 2'$ and $est\beta 2'$, is the most common genotype (~95%). In the resistant strain Pel RR $est\alpha 2'$ and $est\beta 2'$ are oriented head-to-head, and separated by 2.7 kbp of intergenic sequence, whereas in the susceptible strain Pel SS the intergenic spacer between the corresponding genes $est\alpha\beta^{\prime}$ and $est\beta l^{\prime}$ is only 1.8 kbp.. This spacer DNA must, therefore, contain the promoter elements for divergent transcription of both esterases, and the additional sequence in the resistant spacer may affect transcriptional control. We are studying these four esterase promoters (RRA2, RRB2, SSA3, SSB1) using transient transfection of luciferase reporter gene constructs into a C. quinquefasciatus cell line. After optimisation of transfection conditions, it was necessary to construct a β-galactosidase vector control, as a commercially available plasmid was insufficiently expressed. The B-galactosidase gene was ligated into a plasmid containing the Drosophila actin 5c promoter (derived from a vector kindly supplied by P. Eggleston). This construct was expressed at acceptable levels by the Culex cells. Transfection of equimolar amounts of the four promoter-luciferase constructs showed that both resistant and susceptible β -esterase promoters were highly active in these Culex cells (150x and 130x relative to a promoter-less control) but that both α promoters were essentially inactive (0.4x and 0.3x as active as the same control). This inactivity may be due to the requirement for tissue-specific factors or induction, or conversely the \beta-esterase promoters may contain constitutively-regulated promoter elements lacking in the α promoters. Panels of progressive promoter deletions were created by exonuclease III deletion and PCR for both RRB2 and SSB1 promoters. Transfection assays have revealed several regions in both promoters where binding sites for positive and negative transcriptional regulators may be located; for example the 230bp of DNA proximal to the initiating Met retains ~25% of the transcriptional activity of the full-length promoter, but deleting a further 60bp closer towards the ATG reduces this activity to \sim 5%. In addition, mutagenesis studies have revealed that the arthropod initiator site TCAGT 130bp upstream of the ATG, which is perfectly conserved in both B-esterase promoters, is essential for directing transcription.

Key words: Culex quinquefasciatus, resistance, esterase, promoter, initiator

[1336] DIAZINON AND PYRETHROID RESISTANCE TO THE HORN FLY IN TEXAS

C. E. Hoelscher', D. M. Kammlah², & D.C. Sheppard³, ¹Dept. of Entomology, Texas A&M Univ. Heep Center, College Station, TX 77843, USA, E-mail c-hoelsch@tamu.edu; ³USDA Knipling-Bushland US Livestock Insect Research Lab. Kerrville, TX, USA; ³Dept. of Entomology, Univ. of Georgia, Tifton, GA, USA.

The horn fly, Haematobia irritans irritans (L.) is the major insect pest of livestock in Texas. This blood feeding biting fly occurs in all livestock producing regions of the state. Horn fly populations on beef cattle normally exceed established economic thresholds of 200-250 flies per animal in spring and fall periods. Economically damaging populations cause significant reduction in the thrift and vigor of the host animals. Blood loss caused reduced milk production thus the weaning weight of calves is reduced. Producers use a variety of whole body sprays, pour-on formulations, and self-treatment devices to control the horn fly. Self-treatment devices such as insecticide impregnated ear tags put daily selection pressure on the fly population. Routine treatment can lead to the development of insecticide resistant populations. The treatment dosage is high when the tags are attached to the animal's ear and decrease with age of tag. Pyrethroid resistance was documented in the horn fly in Texas in the early 1980's. Cross-resistance was observed to all pyrethroid insecticides labeled for use on beef cattle. Resistance to diazinon was documented in Robertson County, TX in September 1996. Horn flies were approximately 16x resistant to diazinon in September 1996. Resistance levels were determined by the treated filter paper method for both classes of insecticide. Patriot® car tags contain 40% diazinon. These insecticide impregnated ear tags failed to provide satisfactory control of the target fly population. Data will be presented on the management of resistant flies to lower resistant gene levels in field populations. Avermectin pour-on provided the best reduction of fly population for the control of resistant horn flies

Index terms ...matobia irritans irritans (L.), insecticide resistance, horn fly and livestock.

[1337] THIAMETHOXAM (CRUISER[®]) AS SEED TREATMENT – VALUE BEYOND INSECT CONTROL

D. Hofer, F. Brandl, L. Zang & A. Fougeroux, Novartis Crop Protection AG, CH-4058 Basel Switzerland, E-mail: dieter.hofer @cp.novartis.com.

Thiamethoxam (CGA 293'343) is a novel broad-spectrum insecticide currently under worldwide development by Novartis Crop Protection. The molecule belongs to a new chemical class - the neonicotinoids. Neonicotinoids have a new mode of action interfering with the nicotinic acetylcholine receptor of the nervous system of insects. CRUISER® is highly active on a broad spectrum of insects. Compared to the most important competitor in the same chemical class, CRUISER® can be used at lower dose rate to achieve the same or even higher level control effects with longer lasting activity. Furthermore, the unique technical advantages of CRUISER® may be separated into 3 general areas: Robust performance under different elimatic conditions; strong initial crop vigor which results in increased yield effects; and carryover of treated seed. Each of these unique technical advantages provides added value to crop genetics, farmers and environment. The constant performance of CRUISER® is due to the water solubility designed to perform well under most different climatic conditions. CRUISER® is well distributed in the soil and taken up by the plants under very dry up to wet conditions. This feature gives CRUISER® a clear advantage over the current available solutions. CRUISER® treated seeds benefit from robust crop vigor due to crop safety, rapid systemic uptake into young seedlings, highly consistent activity, and broad-spectrum insect control. Strong early season crop vigor leads to fast and uniform stand establishment, early uniform crop ripening, and therefore maximized potential for yield increase. CRUISER® shows excellent performance of seed safety on seeds carried over from one season into the next. Canola seed for example can be stored for at least 18 months without loosing viability and germination power.

Index terms: Thiamethoxam, Cruiser, seed treatment

MANAGING INSECTICIDE RESISTANCE IN AUSTRALIAN [1338] HELICOVERPA ARMIGERA

J. W. Holloway' & N. W. Forrester', 'NSW Agriculture, Australian Cotton Research Institute, Narrabri, NSW, Australia, 2390, E-mail jonathanh@mv.pi.csiro.au; ²Deltapine International, P.O. Box 196, Narrabri, NSW, Australia, 2390.

Components of the Australian cotton Insecticide Resistance Management (IRM) strategy for monitoring and managing insecticide resistance in *H. armigera* are discussed, including chemical and non-chemical approaches. This species currently has high frequencies of resistance to members of several of the older insecticide groups, including the pyrethroids, carbamates, endosulfan and organophosphates. A hackground of resistance and cross-resistance to older groups places increased pressure on newer chemistry and emphasises the need for pro-active resistance management. Chemical approaches include separation of the target pest species and insecticide selection pressure in time (rotations or window strategies) and separation of the target pest species and insecticide selection pressure in space (alternation or mosaic strategies), use of synergists or mixtures to overcome metabolic resistance and restrictions in the total number of applications of a particular insecticide group used. The success of these approaches will depend on the range (and cost) of chemical groups available, their impact on the major beneficial insect and the resistance status, major resistance mechanisms and ecology of the pest. Complementary non-chemical approaches empasise a systems approach to help to reduce pest population pressure and insecticide use. This includes matching the variety and its agronomic management to the region, optimising planting windows, realistic early season thresholds, an understanding of the crops compensatory capacity for damage, classical or genetically modified host plant resistance, use of trap crops to concentrate pests for management, refuges for preservation of susceptible genes, physical destruction of over-wintering pupae and area-wide management. These components have been incorporated into integrated pest management guidelines designed to complement and support IRM and to reduce the risk of selection for resistance being channeled toward any single component. The challenges encountered in integrating these approaches into a coordinated strategy and regularly updating this strategy to cope with the dynamic nature of the problem will be discussed using the Australian Cotton Insecticide Resistance Management (IRM) Strategy as an example.

[1339] THE STUDIES OF THE INSECTICIDE SUSCEPTIBILITY AND DETOXIFICATION ENZYMES OF APIS CERANA AND APIS MELLIFERA

E. L. Hsu & S. S. Liu, Dept. of Entomology, Natl. Taiwan University, Taipei (112), Taiwan, ROC, E-mail elhsu@ccms.ntu.edu.tw.

Both apis cerana and apis mellifera are important species for apiculture industry in taiwan. Due to taiwan is located in subtropical area with hot and humid weather. insect pests are seriously damaged the crops. Pesticides are necessary used in crop protection. Honeybees are frequently contaminated by insecticides. Topical appli-cation and feeding method were used for insecticides susceptibility test. Ten insecti-cides, carbaryl, coumaphos, dimethoate, mevinphos, thiometon, phenothrin, perme-thrin, cypermethrin, decamethrin and avermectin were tested in this experiment. Coumaphos was low hazard to apis cerana eighter apis mellifera. Both species were very susceptible to dimethoate and avermectin, moderately susceptible to synthetic pyrethroids. Apis mellifera was more susceptible to insecticides in comparison with apis cerana. The specific activities of microsomal oxygenases such as aldrin epoxidase, n-demethylase and o-demethylase of apis cerana were higher then apis mellifera. This could be the reason why apis cerana more tolerate to insecticides then apis mellifera.

Index terms: Apis cerana, Apis mellifera, insecticides, detoxification enzyme

[1340] OSTRINIA NUBILALIS ADULT MOVEMENT AND RESISTANCE MANAGEMENT

T.E. Hunt' & L.G. Higley', 'Dept. of Entomology, Univ. of Nebraska, 202 Plant Industry Bldg., Lincoln NE, 68583, USA.

The European corn borer, Ostrinia nubilalis (Hubner), is a significant pest of corn. (Zea mays L.). Current modeling efforts that address the management of European corn borer resistance to Bt transgenic corn require information on adult corn borer dispersal and factors affecting such movement. In 1996 through 1998 we conducted mark-releaserecapture, release-recapture, and mating studies to directly measure and compare dispersal patterns of European corn borer moths from corn of different phenological stages and in and around irrigated and rain-fed cornfields. Releases of marked moths were made corresponding to the first and second flight of European corn borer in eastern Nebraska. Moths were recaptured in blacklight traps positioned around the release fields. Dispersal was random with respect to direction for males and females on both release dates. Dispersal models fit a negative exponential decay, but could not be generalized by using a common model. Release date, corn phenology, agronomic practice (irrigated or rain-fed), sex, and mating status contributed to the variability observed in adult dispersal. Mean recapture distance during the June release was greater than that of the August release, greater at unattractive than attractive (with respect to ovipositional preference) cornfields, and greater for males than the females. Over 95% of the unmated females recaptured were recaptured within 48.0.6 m from their release site. Moth dispersal was significantly different between irrigated and rain-fed cornfields. Released moths tended to remain in and near irrigated cornfields, and disperse out of and away from rain-fed cornfields. Mating efficiency in a late-season cornfield was not significantly different than in dense variables and their interaction with European corn borer life history. The poor The poor predictability of dispersal reflects the importance of local conditions, such as plant community and microclimate, to designing resistance management protocols and identifying areas that may have a higher risk of resistance developing.

Index terms: Ostrinia nubilalis, Zea mays, transgenic, resistance management

[1341] DETECTION OF INSECTICIDE RESISTANCE IN PEACH POTATO APHIDS MYZUS PERSICAE AND IN TOBACCO APHIDS MYZUS NICOTIANAE BLACKMAN

P. M. Ioannidis, Hellenic Sugar Industry S.A., Plant Protection Department, 59032, Plati Imathias, GREECE

The Myzus persicae is considered as a serious pest in peach orchards and sugarbeets, and Myzus nicotianae in tobacco in Greece. Laboratory bioassays were conducted to evaluate the LC₃₀, using the dip-test method recommended by FAO with assessment of mortality after 24 hours. The most commonly applied insecticides by farmers, pirimicarb, methamidophos, carbosulfan, L-cyhalothrin and imidacloprid were used. Both the species were very resistant to pirimicarb and methamidophos. These two insecticides have been used extensively for controlling these insects. Some populations of the tested species were tolerant to imidacloprid with 5 tol1 resistance ratio (RR) and some had 12 to 25 RR. This tolerance to chloronicotinyls in certain populations of Myzus spp. can be considered as a natural variation in response due to the nature of the insecticide or can be considered as resistance because in some bioassays the x^2 (chi square) values were high showing heterogenicity in the response of the population to imidaeloprid. More research is needed to clarify this situation. The average LC_{26} for susceptible *Myzus persicae* was 0,63 ppm. And for *Myzus nicotianae* 4,18 ppm. Consistently the *M. persicae* has lower values of LC_{26} the method of the method. LC., than the susceptible M.nicotianae . Despite that the distinction between the two species is very difficult. Recently these two species are considered as two biotypes of the same species. All the tested populations of *M.nicotianae* were resistant to carbosulfan with values from 37. To 125 ppm. While some population of M. persicae were LC,00 LC₃₀ values from 5.7. To L25 pm. White some parameters of the LC₃₀ values from 0.63 to 33 ppm. Pyrethroids are sprayed usually to the above mentioned crops for controlling lepidoptera. As a consequence a selection pressure to aphids is applied and some resistance to L-cyhalothrin had been noticed with 6 RR. From the regression equations which have been established for the susceptible populations the discriminating doses which kill the 99% of the susceptible population can be detected.

Index terms : carbosulfan, pirimicarb, imidacloprid.methamidophos

[1342] NOVALURON (RIMON EC-10), A NOVEL IGR FOR CONTROLLING AGRICULTURAL INSECT PESTS

I. Ishaaya, S. Kontsedalov, D. Masirov & A. R. Horowitz, Dept. of Entomology, Agricultural Research Organization, The Volcani Center, Bet Dagan 50250, Israel, E-mail: vpisha@netvision.net.il, Fax: +972-3-9683835.

Novaluron (Rimon Ec-10),1-[3-Chloro-4(1,1,2-Trifluoro-2-Trifluoro-Methoxyethoxy) phenyl]-3-(2,6-difluorobenzoyl)urea, is a novel benzoylphenyl urea that acts by both ingestion and contact. As such it is a powerful suppressor of lepidopteran larvae such as Spodoptera littoralis, S. exigua, S. frugiperda, Helicoverpa armigera and Tuta absoluta attacking field crops such as cotton, corn and vegetables. It is also a powerful toxicant against whiteflies such as *Bemisia tabaci* and *Trialeurodes vaporariorum* and leafminers such as Liriomyza huidobrensis and Perileucoptera cofeella. Our studies indicated that the LC-50 value of Rimon on 3rd-instar S. littoralis fed on treated castor bean leaves is ~0.1 mg a.i./litre. This value resembles that of Atabron (chlorfluazuron) and is about 10-fold lower than that of Nomolt (teflubenzuron). An application of 250 g a.i./ha in a cotton field resulted in 100% mortality of both S. littoralis and H. armigera larvae upon exposure to treated leaves, up to day 8 after application and about 60% and 30% mortality, respectively, at day 15. Novaluron affects to a much greater extent larvae of B. tabaci than chlorfluazuron and teflubenzuron. Total larval mortality was obtained by dipping infested cotton seedlings in 1mg a.i./litre Rimon. Artificial rain at a rate of 40 mm/h applied 5 and 24 h after treatment in cotton field had no appreciable effect on the potency of Rimon on S. littoralis larvae. Hence Rimon can be used in tropical areas and in rainy seasons. Rimon has similar potency on susceptible and pyriproxyfen and buprofezin resistant B. tabaci strain indicating that no cross resistance occurs between Rimon and other leading compounds against whiteflies. Rimon has no effect on parasitoids such as *Encarsia formosa* and is considered to *have* a relatively mild effect on other natural enemies. As such it is an important addition to be used in integrated pest management (IPM) and insecticide resistant management (IRM) for controlling pests in various field crops, vegetables and ornamentals.

Key words: Benzoylphenyl urea, selective insecticide, whiteflies, lepidopteran pests

[1344] HOW TO BE OPTIMAL UNDER TOXICANT STRESS: OPTIMAL ENERGY ALLOCATION AND ECOTOXICOLOGY OF INSECTS AND OTHER ARTHROPODS

M.K. Janczur, Institute For Environmental Sciences. Jagiellonian University, Ul. Oleandry 2a, 30-063 Kraków, Poland, E-Mail: Maj@Datasys.Com.Mx.

Among terrestrial arthropods, some organisms (e.g. beetles) are known for maintaining low concentrations of toxicants in their bodies, while other (e.g. spiders) exhibit high concentrations. Some toxicants (like metals) are non-degradable so their decontamination is a two-stage process: first they are converted to less toxic forms (e.g. metalothioneins) and then removed outside the organism. I present an optimal energy allocation model, which takes into account both internal properties of an organism and its demography. Using the dynamic programming procedure i find the optimal fractions of energy allocated to growth, reproduction, heavy toxicant immobilisation and removal in order to maximise the lifespan reproductive success. Toxicants are absorbed from food with the rate proportional to the assimilation rate. i consider two models: Toxicant affect 1) mortality, and 2) both mortality ant the assimilation rate. Optimal energy allocation determines such characteristics as toxicant concentration in the body, optimal lifespan, age at maturity and adult body size. I obtained three qualitatively different solutions: 1) allocation to growth, reproduction, toxicant immobilisation and removal, 2) allocation to growth, reproduction and metal immobilisation, 3) allocation to growth and reproduction only. Higher allocation to decontamination results in a lower energy allocation to growth and/or reproduction which is paid back by a longer lifespan due to a reduced toxicant-dependent mortality. The model predicts that animals living under higher external mortality pressure accumulate higher toxicant concentration in the body. The predictions of the model concerning interdependence among life-history traits are consistent with experimental and field results obtained on such arthropods as chironomus riparius (diptera: chironomidae), folsomia candida (collembola: isotomidae), orchesella cincta (collembola: entombryidae), porcelio scaber (isopoda: porcellionidae), poecilius cupreus (coleoptera: carabidae). Results concerning the effect of intrinsic properties on decontamination pattern are consistent with empirical studies carried out on ephemeropterans. The model is also consistent with some studies concerning insect (and other arthropods) abundance (inter- and intraspecific) along the toxicant concentration gradient. The model explains some results of experimental and/or field studies that were not fully understood by their authors. Additionally it allows to put forward accurate null hypotheses for future empirical work. It seems to predict particularly well the optimal decontamination strategies in insects and in other invertebrates.

Index terms: carabidae, chironomidae, collembola, porcelionidae, optimal energy allocation, decontamination, matematical model

[1344] CONTROL OF DIAMONDBACK MOTH (*PLUTELLA XYLOSTELLA*) BY SPINOSAD AND ITS INFLUENCE ON PARASITIC WASPS

K. Kaneshi¹, H. Himei¹, G. Nakamura¹, K. Morita¹ & T. Noda².¹ Dow Chemical Japan Ltd. Dow AgroSciences division, Tennoz Central Tower 2-24, Higashi Shinagawa 2chome Shinagawa-ku, Tokyo 140-8617, Japan; ² Tohoku National Agricultural Experiment Station, Laboratory of Insect Pest Control, 4 Akahira, Shimo-Kuriyagawa, Morioka, Iwate 020-0123, Japan.

Plutella xylostella is one of the most troublesome pests in Cole crops. It has developed resistance to a wide range of chemicals and management of this insect has been a challenge since 1960s in Japan. Various integrated pest management (IPM) methods to control P. xylostella have been proposed but chemical application is still the most popular way to control this insect among Japanese cabbage growers. Spinosad is the first insect control agent from NATURALYTE* class of naturally derived product from Dow Spinosad is produced by fermentation by a novel actinomycete AgroSciences. Saccharopolyspora spinosa. Spinosad has high activity to mainly Lepidopteran and Thysanopteran insects but also has favorable mammalian and environmental characters. More than 50 field studies conducted from 1995 to 1998 in Japan showed that spinosad as 25% WDG at 2.5gai/hl provided excellent control of P. xylostella. Spinosad was also tested against two indigenous parasitic wasps of P. xylostella, Cotesia plutellae and Comyzus sokolowskii, and an introduced natural enemy, Diadegma semiclausum in lab and semi field conditions. Even though spinosad was toxic to adults of these parasitoids with direct contact, its toxicity was reduced on cocoons and on adults in semi-field conditions. Cocoons of the parasitoids showed a high survival rate even with direct spray and there was no significant difference in mortality of adults between the treated and untreated plots. This result suggests that spinosad can preserve populations of these parasitoids in the field and play an important role in IPM for control of *P. xylostella*. Index terms: spinosad, Plutella xylostella , parasitic wasps

[1345] STATUS OF INSECTICIDE RESISTANCE IN HELICOVERPA ARMIGERA POPULATIONS FROM AREAS WITH DIFFERENT INSECTICIDE-USE REGIMES

V. Kathuria¹, R. K. Saini² and P. Ram³, Department of Entomology, College of Agriculture, Ch. Charan Singh Haryana Agricultural Univ., Hissar 125 004, Haryana, India; 'Present address: Tata Energy Research Institute, Darbari Seth Block, Habitat Place, Lodhi Road, New Delhi 110 003, India, e-mail: vanitk@teri.res.in

Bioassay studies on relative susceptibility of Helicoverpa armigera populations from three districts (viz. Hissar, Sirsa and Bhiwani) of Haryana, following cotton-chickpea crop rotation but with a different insecticide-use pattern, were conducted during 1998-99 at CCS Haryana Agricultural University situated at Hissar. The other two districts were 90 and 50 km away from the central district (i.e. Hissar). Larval populations were collected from chickpea fields in 15 km radius of each district headquarter and reared separately on chickpea foliage to obtain moths. Apart from this, with a view to expose a wider gene pool to different insecticides, moths were collected during different nights with the help of artificial light from at least three locations from each of the three districts to supplement the moths obtained from laboratory rearing of the pest. First instar larvae from the three populations were exposed to dry films of different insecticides on glass surface and mortality was recorded after four hours. The whole experiment was repeated three times. On the basis of LC_{30} values for each of the three populations, it was found that population from Bhiwani was the most susceptible one to all the insecticides tested, while that from Sirsa exhibited the highest resistance to these insecticides. Population from Sirsa had developed 4.0-, 3.8-, 3.8-, 2.5- and 1.6-fold resistance to monocrotophos, cypermethrin, endosulfan, quinalphos and fenvalerate, respectively, as compared to population from Bhiwani. On the other hand, population from Hissar manifested 1.9-, 2.8-, 1.9-, 1.1- and 1.9-fold resistance to the above insecticides, respectively, vis-à-vis population from Bhiwani. Greater insecticidal tolerance in population from Sirsa, followed by that from Hissar, closely corresponded with the pattern and intensity of insecticide use in these districts. It was concluded that areawise control strategy for this pest would be more useful in view of the differential susceptibility of the populations from different districts. Keywords: Helicoverpa armigera, insecticide, resistance

[1346] SUSCEPTIBILITY OF HELICOVERPA ARMIGERA EGGS TO SOME COMMONLY USED INSECTICIDES

<u>V Kathuria</u>¹, R K Saini² & P Ram³, Department of Entomology, College of Agriculture, Ch. Charan Singh Haryana Agricultural Univ., Hissar 125 004, Haryana, India; ¹Present address: Tata Energy Research Institute, Darbari Seth Block, Habitat Place, Lodhi Road, New Delhi 110 003, India. e-mail: vanitk@teri.res.in

Laboratory studies on the ovicidal activity of different insecticides against Helicoverpa amigera populations from Hissar district of Haryana were conducted during 1998-99 at CCS Haryana Agricultural University, Hissar. Nine commonly used insecticides were evaluated by egg dipping method taking eggs of different ages. Synthetic pyrethroids, namely, fenvalerate and cypermethrin gave the highest egg mortality (>80%) followed by methomyl and triazophos (>75%). The next group of promising insecticides included quinalphos, monocrotophos and endosulfan (60 – 70%) while carbaryl and malathion constituted the inferior category, though quite significant (>50%) egg mortality was afforded by them. One-day-old (0-24h) eggs exhibited greater susceptibility to all the insecticides followed by two-day-old (24-48h) and three-day-old (48-72h) eggs. In the young (0-24h) eggs, much of the ovicidal action by most of the insecticides was recorded within the first 12h after the treatment. However, methomyl and quinalphos showed significant incremental egg mortality during the next 12h also. This tread was less pronounced in the older eggs. No additional mortality was recorded after 36h of treatment. It is concluded that insecticides with good ovicidal action may be selected for inclusion in the control programmes involving insecticides and their application must be synchronised with the peak ovigosition period of the pest in the field.

Keywords: Helicoverpa armigera, insecticide, ovicidal action

Symposium and Poster Session

[1348] TICK CONTROL: EVIDENCE TO SUPPORT RESISTANCE MANAGEMENT RECOMMENDTIONS

D.H. Kemp¹, R. Thullner² & N.N. Jonsson³, ¹CSIRO Tropical Agriculture, Molecular Animal Genetics Centre, Gehrman Bldg., Univ. of Queensland, Brisbane, Australia 4072, e-MAIL David.Kemp@tag.csiro.au. ²Alte Obervolkacherstr. 9, D-97332 Volkach, Germany. ³Dept. of Veterinary Clinical Studies, Univ. Glasgow, Bearsden Rd., Glasagow G61 1QH, UK.

The cattle tick, boophilus microplus, is a serious problem in many tropical countries and it has developed resistance to all except for the newest acaricides. Modeling of resistance management has been limited and experiments and field trials are almost non-existent so it is difficult to make recommendations on particular resistance management strategies. Modeling has suggested that increasing treatment frequency will promote the emergence of resistance and this was confirmed in a recent field survey. An earlier survey showed fewer cases of sp resistance in regions where introduction of tick immune cattle (zebu) reduced the need for acaricides. Recommendations for greater use of immune cattle, introduction of the recombinant anti-tick vaccines and other biological control methods to delay acaricide resistance are probably justified. Trials with a combination of macrocyclic lactones and the tickgard anti-tick vaccine showed some synergistic effects and this may also have potential to delay resistance. Mixtures of acaricides/insecticides are used in some countries for improved control of ticks and insects but there is no information on potential risks or benefits for managing resistance. Likewise, recommended saturation strategies with high concentrations of acaricides or alternatively, strategies that use concentrations lower than currently recommended, have not been tested. Recent trials on dominance of tick resistance to amitraz, a commonly used acaricide, suggest that higher concentrations would not be successful. This needs to be checked for each group of acaricides. Rotation of an op and sp acaricide did delay the establishment of resistance in a laboratory trial and this can be recommended for field testing. New initiatives are needed by companies, government authorities and farmer organisations to protect the valuable acaricides that are available.

Index terms: boophilus microplus, resistance management, recommendations

[1347] EFFECTS OF EUCALYPTUS AND CALLISTEMON LEAF EXTRACTS ON HELICOVERPA ARMIGERA LARVAE

<u>N Kaushik</u>, Bioresources and Biotechnology Division. TERI, Habitat Place, Lodhi Road. New Delhi 110 003, India. e-mail: kaushikn@teri.res.in

Helicoverpa armigera is one of the major insect pest in India. It attacks many economically important crop species viz. cotton, pigeonpea, chickpea, tomato, sunflower, etc. Currently, it is the most difficult species to control because of emergence of resistance to commercially available insecticides. This necessitates search for newer molecules to control the pest population. Plant biodiversity is of immense importance in this regard offering a wide range of biomolecules. In present study, extracts obtained from Eucalyptus and Callistemon leaves in different solvents were tested against Harmigera larvae using feeding bioassays. Preliminary bioassays were conducted by feeding the insects on the diet having the crude leaf powder of Eucalyptus and Callistemon. The larval development, molting, pupal weight and survival rate were studied from 1" instar larvae upto emergence of adults. Further bioefficacy experiments were conducted with different levels of the leaf powder in the artificial diet. Slow growth and development of larvae was observed. The powder in the automatical state of the stat deformity in adults. Leaf extract of *Eucalyptus* and *Callistemon* were prepare in different solvents. First instar larvae was released into the diet treated with the extract and rate of survival, development time, molting disorders, larval weight on 7th day were recorded as performance variables. Among various extracts maximum activity was recorded in alcohol extract. About 88 per cent growth inhibition was recorded in H.armigera larvae treated with the alcohol extract of the Eucalyptus leaves. All the larvae died without reaching pupation with stunted growth. Whereas, in the case of Callistemon leaf extract 20 per cent survival was recorded till pupation. Further studies related to bioassay mediated fractionation of the extracts are in progress.

[1349] INSECT ANTIESTERASE ACTIVITY OF NOVEL ORGANO-PHOSPHORUS COMPOUNDS AND CHANGES OF ENZYME LEVEL IN FIELD RESISTANT POPULATIONS *MUSCA DOMESTICA*

A.V. Khrunin & <u>O.Yu. Eremina</u>, Dep.of Entomology, Inst. of Disinfectology, Nauchny pr.,18, Moscow, 117246, Russia, E-mail: eremin@bochvar.ru

The insecticide effect, combined action of pyrethroids and potential synergists from two groups of organophosphate (OP) compounds: derivatives of 1,3,2 oxazaphosphorinan and derivatives of phosphorothio- and dithio acids containing fragments of N-carbalcoxylated glycine or --alanine, were studied. Interaction of novel potential synergists with cholinesterases (ChE) (housefly *Musca domestica* heads ChE, cockroach *Periplaneta americana* nerve cord ChE) and carboxylesterases (CE) (housefly CE, cockroach CE) were investigated by Ellman, Van Asperen and PAAG methods. It was determined 1,6 and k, and shown, that O-analogues has more anti-ChE activity, than S-analogues, and they have a combined or reversible type of inhibitory action in connection with their chemical structures. We compared novel compounds with paraoxon, GD-42, eserine wich have irreversible type of ChE inhibition. Nonspecific esterases (NE) activity was studied in five populations of houseflies *Musca domestica* from regions with different levels of industrial and pesticide pollution. Quantitative differences between total activity and esterase spectra of ChE and CE from heads and abdomens of houseflies were revealed. Both NE activity (determined according to Van Asperen) and activities of individual esterases proved to be highly resistant to OP, which may reflect the adaptation of flies to pesticide pollution. An increase in the activity of esterases from heads correlated with the high level of OPresistance, and from abdomen – the same to pyrethroid-resistance in fly populations. Changes in acid phosphatase activity were observed too, and we connected its change with environmental pollution.

Index terms: Periplaneta americana, Musca domestica, enzyme activity, synergism, OP, pyrethroids

[1350] BAS 620 H - A NEW GRAMINICIDE FOR POST-EMERGENCE GRASS CONTROL IN BROADLEAF CROPS

E. Kibler¹, M. Landes¹, <u>H. D. Briz¹</u>, H. Hosaka⁴, ¹BASF Agricultural Center, D-67114 Limburgerhof, Germany, ²Nippon Soda Co. Ltd., Chiyoda-ku, Tokyo 180, Japan

BAS 620 H is a new cyclohexenone herbicide of Nisso BASF Agro Ltd. containing the new active ingredient tepraloxydim (= proposed ISO common name). BAS 620 H is developed for broad spectrum post-emergence grass weed control in broadleaf crops. BAS 620 H is an inhibitor of the acetyl-CoA carboxylase (ACCase), which is responsible for the formation of lipids required for cell growth. The broadleaf crop selectivity is based largely on the lack of activity of BAS 620 H on this target site. Extensive field research conducted world wide 1990 - 1998 confirmed the excellent selectivity of BAS 620 H in all major broadleaf crops and vegetables at herbicidal use rates. At a use rate of 50 - 75 g a.i./ha, BAS 620 H controls very good all economically important annual grasses (e.g. Avena fatua, Brachiaria plantaginea, Digitaria sanguinalis, Echinochloa crus-galli) as well as volunteer small grains. BAS 620 H, at 75 - 100 g a.i./ha, is particularly strong on *Poa annua* and volunteer corn. At 100 g a.i./ha, BAS 620 H controls perennial grasses such as Sorghum halepense and Agropyron repeats and supresses Cynodon dactylon. Investigations showed that some annual grass biotypes with metabolism based ACCase inhibitor resistance are still sensitive to BAS 620 H. The standard formulation of BAS 620 H is a 200 g/litre EC formulation for use with an additive (e. g. DASH HC[®], oil concentrate) in soybeans, cotton, canola, peas, beans, mustard and flax. An adjuvant builtin formulation is under development in Europe for use in winter oil seed rape, sugarbeet, potatoes, cole and pulse crops. BAS 620 H has a favorable environmental and toxicological profile. First registrations of BAS 620 H (Tradename: ARAMO®) were granted in 1999 with the worldwide market introduction planned from 2000 onwards.

Key words: weed spectrum; does rate; crop spectrum; acetyl-CoA carboxylase inhibitor; sensitivity;

[1351] BAS 620 II - A NEW GRAMINICIDE FOR POST-EMERGENCE GRASS CONTROL IN BROADLEAF CROPS

E. Kibler', M. Landes', & H. Hosaka¹, 'Nippon Soda Co, Ltd., Chiyoda-ku, Tokyo 180, ² Japan; BASF Agricultural Center, D-67114 Limburgerhof, Germany.

BAS 620 H is a new cyclohexenone herbicide of Nisso BASF Agro Ltd. containing the new active ingredient tepraloxydim (= proposed ISO common name). BAS 620 H is developed for broad spectrum post-emergence grass weed control in broadleaf crops. BAS 620 H is an inhibitor of the acetyl-CoA carboxylase (ACCase), which is responsible for the formation of lipids required for cell growth. The broadleaf crop selectivity is based largely on the lack of activity of BAS 620 H on this target site. Worldwide extensive field earch conducted world wide 1990 - 1998 confirmed the excellent selectivity of BAS 620 H in all major broadleaf crops and vegetables at herbicidal use rates. At a use rate of 520 - 75 g a.i./ha, BAS 620 H controls very good all economically important annual grasses (e.g. Avena fatua, Brachiaria plantaginea, Digitaria sanguinalis, Echinochloa crus-galli) as well as volunteer small grains. BAS 620 H, at 75 - 100 g a.i./ha, is particularly strong on Poa annua and volunteer corn. At 100 g a.i./ha, BAS 620 H controls perennial grasses such as Sorghum halepense and Agropyron repens and supresses Cynodon dactylon. Investigations showed that some annual grass biotypes with metabolism based ACCase inhibitor resistance are still sensitive to BAS 620 H. The standard formulation of BAS 620 H is a 200 g/litre EC formulation for use with an additive (e. g. DASH HC[®], oil concentrate) in soybeans, cotton, canola, peas, beans, mustard and flax. An adjuvant builtin formulation is under development in Europe for use in winter oil seed rape, sugarbeet, potatoes, cole and pulse crops. BAS 620 H has a favorable environmental and toxicological profile. First registrations of BAS 620 H (Tradename: ARAMO[®]) were granted in 1999 with the worldwide market introduction planned from 2000 onwards.

Key words: grass control; BAS 620 H; post-emergence; weed spectrum; does rate; crop spectrum

[1352] CAN CAFFEINE BE USED AS AN AUXILIARY AGENT IN THE CONTROL OF AEDES AEGYPTI ?

A. T. Laranja & H. E. M. C. Bicudo. IBILCE/UNESP. Rua: Cristóvão Colombo, 2265-CEP: 15054-000 - São José do Rio Preto - SP - Brasil.

After being eradicated for a long time Aedes aegypti reinvaded Brazil in the last 15 years giving rise to a great deal of concern. The reason is that this mosquito is an important vector of dengue and yellow fever and has shown devastating effects in many places of de world. Public Health Service (SUCEN = Superintendência de Controle de Endemias do Estado de São Paulo) is doing campaigns and is trying to maintain mosquito population size within acceptable levels using insecticides that are sprayed in the streets of towns for killing adult mosquitoes. Larval and pupal stages are controlled by using grain shaped organophosphorous insecticides. The consequences for life and environment of using insecticides are well known from data in literature. Thus, the finding of alternative control agents would be very interesting. Data obtained in Drosophila studies performed in our laboratory showed that caffeine decreases fertility and longevity of flies, and increases development time. Such results suggested the present study in which different concentrations of caffeine were used for raising Aedes aegypti from eggs to adult stage. Treatments with 1,000 µg/mL and 2,000 µg/mL of caffeine and 0.025 g/mL (a tea spoon) of used ground coffee in water showed 85% of first stage larvae yielded in the control (only water), 88% in 1,000 µg/mL caffeine, 21% in 2,000 µg/mL caffeine and 52% in the form and 6% of the total number of eggs that were used in these experiments, respectively). We also observed a delay on developmental time in both caffeine concentrations and also in the ground coffee containing medium. Decreasing the caffeine concentrations to 200 μ g/mL and 500 μ g/mL, some adults were obtained in the first but not in the second treatment. Mortality larva-adult, developmental time and longevity are being analyzed in detail. As previously found for *Drosophila*, the effects of caffeine on these characteristics are dose dependent. (CAPES)

Index terms: diseases vector, alternative control, drug toxicity

[1353] MATRICAP®: NOVEL SYSTEMS FOR CONTROLLED DELIVERY OF PESTICIDES IN AQUATIC OR TERRESTRIAL HABITATS

R. Levy, M.A. Nichols & W.R. Opp LCMCD Technology Development Center, P.O. Box 60005, Fort Myers, FL 33906, USA, E-mail levy@lcmcd.org

Matricap@ controlled-delivery systems are based on the use of patented coating or coating complex formulations composed of one or more fatty acids, fatty alcohols or fatty acid esters, with or without one or more polymer binders and adjuvants to regulate the release rate and release profile of bioactive agents from solid carrier matrices (U.S. and overseas patents pending). Selection of a coating or coating complex is dependent on the type of aquatic or terrestrial habitat, the physicochemical characteristics of the bioactive agent, and the surface or subsurface orientation of the target pest. Specific gravity, solubility, hydrolysis, and biodegradation interactions of the coating(s), carrier, and bioactive agent(s) in an admixture are utilized to design specific Matricap@ compositions for aquatic or terrestrial pest-management applications. If the formulation components are properly matched, a Matricap® composition can deliver a bioactive agent to specific surface and/or subsurface areas of an aquatic or terrestrial habitat to target the orientation and/or feeding patterns of pest populations for prolonged periods. Matricap@ powdered, granular, or agglomerated matrices composed of materials such as silica, cellulose, clay, corn cob, sand, PVA or MHPC were initially designed for controlled delivery of insect corn cob, sand, PVA or MHPC were initially designed for controlled adivery of insect growth regulators (e.g., methoprene or pyriproxyfen), biolarvicides (e.g., Bacillus *huringiensis* var. israelensis or Bacillus sphaericus) or central nervous system inhibitors (e.g., temephos, chlorpyrifos, or phenyl-pyrazole). Matricap@ compositions were initially evaluated against mosquitoes and coekroaches. Controlled delivery of bioactive agents used to control mosquito larvae in surface (Anopheles spp.) or subsurface (Aedes or Culex com) argue column surface the phenomena of the tune and/or concentration spp.) areas of a water column were shown to be functions of the type and/or concentration of coating agents incorporated into a Matricap® composition. For example, slight variations in the ratio of fatty acid ester coatings in a coating complex were observed to significantly increase or decrease the duration of delivery from a solid matrix as well as alter the controlled-release profile and positional distribution of a bioactive agent in an aquatic habitat. The rate and duration of controlled delivery of bioactive agents used to control German cockroaches were dependent on the type and concentration of fatty acid ester(s) and polymers (e.g., PVA and/or MHPC) utilized to fabricate coated, extruded, or continuous film bait stations

Index terms: coatings, targeted release, insecticides, mosquitoes, cockroaches

[1354] TIMING INSECTICIDE APPLICATIONS FOR DUSKY SAP BEETLE (COLEOPTERA: NITIDULIDAE) CONTROL IN BT SWEET CORN

J. J. Linduska¹, G. P. Dively¹, M. Ross¹, M. Embrey¹, and T. Patton¹, 'LESREC, 27664 Nanticoke Rd., Salisbury, MD 21801-8437, USA, e-mail jl43@umail.umd.edu; 2Dept. of Entomology, Plant Sciences Bldg., Univ. of MD, College Park, MD 20742-4452, USA; WREC, P. O. Box 169, Queenstown, MD 21658-0169, USA.

CrylA(b) protein-expressing Attribute sweet corn developed by Novartis Seeds provides exceptional control of ear-invading lepidopteran pests. However, in the mid-Atlantic area, the dusky sap beetle, Carpophilus lugubris Murr., is a secondary pest of sweet corn and is not affected by CrylA(b) expression. Consequently, insecticide applications targeted specifically for sap beetles are necessary to meet ear quality standards for both fresh market and processing. The objective of this study was to determine the optimum timing and number of insecticide applications required to control sap beetles in Attribute sweet corn grown for processing. All experiments were conducted over 3-years in late plantings of Attribute GH-0937 sweet corn (hybrid 'Bonus') using different timings of lambdacyhalothrin (Warrior® 1CS) for control of sap beetle. Spray schedules were initiated at various plant growth stages varying from late tassel up thru the brown silk stage. The number of insecticide applications also varied from 1-4 treatments. The results of these trials showed that insecticide treatments initiated at the early silk stage (50% fresh silk) provided the best control of sap beetle and repeated applications (two applications) spread 4 days apart were generally more effective than a single application. Schedules involving greater than two treatments did not consistently result in increased control efficacy. Control efficacy was dependent on the infestation level which can vary greatly between fields and also on the method of insecticide application.

Index terms: Bt sweet corn, Carpophilus lugubris Murr, pesticide timing, pesticide efficacy

113561 AGRONOMIC EFFICIENCY OF NEW MOLECULES FOR CONTROL OF THE FIELD BEAN WHITE FLY

M. B. Lucas', D. R. Batista', C. A. Silveira' & B. V. Lucas', ' Instituto de Ciências Agrárias da Universidade Federal de Uberlândia - UFU, Av. Pará, 1720, CEP: 38.400-902 - Umuarama, Phone/Fax: (0xx34) 212-5566, E-mail carmeng@umuarama.ufu.br. ² Bayer S. A., Phone: (0xx11) 5694-5277. ³ Escola de Educação Básica da Universidade Federal de Uberlândia-MG, ESEBA-UFU, Phone: (0xx34) 218-2903.

The recognition by the scientific community that the complex Bemisia sp. (Biotypes A and B) has been one of the major crop pests of this century and also that presently there is no unique, efficient and universal method for its control, justified the assembling and conduction of this experiment which objective was to evaluate the agronomic efficiency of new insecticides on controlling this insect. The trial was conducted in the location of Uberlândia, MG, Brazil, during March and April 1999, using the cultivar "Perola" ("carioca" type) under irrigation (a self-propelled sprinkler system). The experimental design used was a randomized complete-block, with 7 treatments in four replications, with plots of 12.25 cm². Means were compared with Tukey's test at 5% probability level and agronomic efficiency was calculated by the formula used by Abbott. One day after seed treatment with the fungicide Euparen M 500PM, the following insecticide treatments were applied to seed: imidacloprid (Gaucho 700 PM – 0.2kg/100 kg seed) in some of the treatments, while the insecticides initial/oprin (Provado 2005C - 100g a.i./ha), thiacloprid (Calypso 480SC - 96g a.i./ha) betacyflutrin (Turbo 50CE - 5g a.i./ha) - 100g and methamidofos (Tamaron BR - 480g a.i./ha), were applied in a curative basis in four sprays per week using a manual pump sprayer with average flow rate of 4001 of solution per hectare. In the conditions in which this experiment was conducted, regardless the method of application, it was concluded that the insecticides imidacloprid (Provado 200 SC), metamidophos (Tamarom BR) and thiacloprid (Calypso 480 SC) added after seed treatment with imidacloprid (Gaucho 700 PM), confer excellent (>90%) efficiency for the control of the white fly biotype B (*Bernsia argentifolli*) on field bear crop. Seed treatment obly with imidacloprid (Gaucho 700PM) it is not effective. Independently of seed treatment with imidacloprid (Gaucho 700PM), betacyflutrin (Turbo 50CE) and thiacloprid (Calypso 480SC) both confer a good (80 - 90%) agronomic efficiency for the control of the fly. Regardless of method of application and for the doses tested, it was not evident any problems of phytotoxicity of the products.

Index terms; Bemisia argentifolli, vector, viruses, insecticides.

[1355] MOLECULAR BASIS OF INSECTICIDE RESISTANCE IN THE HOUSE **OFLY**. Musca domestica

N. Liu., Dept. of Entomology and Plant Pathology, Auburn University, 301 Funchess Hall, Auburn, AL 36849-5413, USA, E-mail nliu@acesag.auburn.edu.

A house fly strain, ALHF, was collected from a poultry farm in north Alabama, USA, with an initial 260-fold level of resistance to permethrin compared to a susceptible strain, aabys. After 5-generation selection with permethrin in the laboratory, resistance level was increased to 1,800-fold. We have found that ALHF has a great ability to develop resistance and cross-resistance to different insecticides. The possible genes involved in resistance in ALHF have been investigated by differential display. As a result, whereas most cDNA bands were equally detected from both ALHF and aabys strains, some were unique to samples from the ALHF strain. Five genes that specifically expressed in ALHF strain have been identified. One of them is consecutively expressed and others are induced by the treatment with permethrin. The possible roles of the genes in resistance in ALHF will be discussed.

Index terms: Musca domestica, insecticide resistance, differential display

[1357] AGRONOMIC EFFICIENCY OF THE INSECTICIDE THIAMETHOXAN FOR CONTROL OF THE PINEAPPLE MEALYBUG AND THE TERMITE

M. B. Lucas', D. R. Batista', J. S. Aizawa' & B. V. Lucas', 'Instituto de Ciências Agrárias da Universidade Federal de Uberlândia - UFU, Av. Pará, 1720, CEP: 38,400-902 - Umuarama, Fone/Fax: (0xx34) 212-5566, E-mail carmeng@umuarama.ufu.br. 'Novartis Biociências S. A., 'Escola de Educação Básica da Universidade Federal de Uberlândia, MG, ESEBA-UFU, Fone: (0xx34) 218-2903.

The pineapple constitutes a fruit of great internal commercial acceptance and importance for export purposes, and it has already its place in Brazilian economy, demanding a special sort of cultivation, in order to be economically viable. Apart from the cultivar used and considering it as a tropical culture, the presence of the termite *Procomiterms striatus* and the mealybug Dysmicoccus brevipes, have been the two major plagues seriously affecting the production, thus justifying this research. The experiment was conducted in the location of Capinópolis M.G. Brazil, using the cultivar *Smooth cayenne* 180 days after planting. The experimental design used was a randomized complete-block with six treatments in four replications. Each experimental block was comprised of two double lines with 100 plants in each plot, where the plants were pre-evaluated and later on, effective evaluations were made after 30, 60, 90 and 120 days after treatment. For this purpose, five plants were randomly taken per plot. The insecticide thiamethoxan (Actara Biodae 1% Gr - 100, 150 and 200 gr. a.i./h.a) was applied in two rows along the crop, while the insecticides thiamethoxan (Actara 25WG - 15g a.i./ha) and methyl parathion (Folidol 600 - 600ga.i./ha) were sprayed in the base of the plants. Under the conditions tested, using the Tukey's procedure at 5% probability level to compare means and the biologic efficiency calculate by Henderson & Tilton's formula, it was concluded that the insecticide thiamethoxan, regardless of the method of application, concentration, formulation and doses tested, did not present any evidence of phytotoxicity and also conferred an agronomy efficiency up to 90 days after application, with biologic results superior to the minimum demanded (70%) for soil plagues. It was also found that the granulated formulation presented a higher performance when comparing to the WG formulation at 150g a.i./ha was more economical and conferred agronomic results superior to the insecticide methyl parathion (Folidol 600) up to 120 days after application. Index terms: Dysmicoccus brevipes, Procorniterms striatus, Smooth cayenne,

thiamethoxan.

[1358] AGRONOMIC EFFICIENCY OF NEW MITICIDES FOR CONTROL OF THE COFFEE LEPROSIS

M. B. Lucas¹, F.F.M. Marra¹, A. C. Rezende¹ & R. V. Lucas², ¹ Instituto de Ciências Agrárias da Universidade Federal de Uberlândia - UFU, Av. Pará, 1720, CEP: 38.400-902 - Umuarama, Phone/Fax: (0xx34) 212-5566, E-mail carmeng@umuarama.ufu.br. ² Escola de Educação Básica da Universidade Federal de Uberlândia-MG, ESEBA-UFU, Phone: (0xx34) 218-2903.

The mite Brevipalpus phoenicis (Geijskes, 1939) (Acari: Tenuipalpidae) is a polyphagous pest and is associated to the ring spot disease or coffee leprosis. The increasingly incidence of this disease in the regions of the "Triângulo Mineiro" and "Alto Paranaíba" in the State of Minas Gerais, has already seriously threatened yields of coffee crops in 1995 and 1996 and therefore it is focus of great concern by producers in such regions, justifying the need of new research efforts for the control of the disease. This experiment was conducted with the objective of evaluating the biologic or agronomic efficiency of new miticides for the control of this pest, and it was located in the middle of a coffce plantation, in Uberlândia, MG. The cultivars "Mundo Novo" and "Catuaí-amarelo" were planted in alternated rows, under high plant density and irrigated by a drip system. The design used was a randomized complete-block with seven treatments and four replicates in which the plots were comprised by 80 plants. The Tukey procedure at 5% probability level was utilized to compare means and the biologic efficiency was calculated by the Henderson & Tilton formula. The miticides tested and their doses were: ketaenole (BAJ2740 - 240SC) - 48,60 and 72g. a.i./ha, azocyclotin (Peropal 500SC and Peropal 250PM) - 375g. a.i./ha; and dicofol + tetradifon (Carbax CE) - 400 + 150g. a.i./ha. They were applied twice, in a 60-day interval, with a motorized mist sprayer, allowing a flow rate of 1.2001 of solution per hectare. Under the conditions tested, it was concluded that the infestation levels on the treated plots were very low, conferring an excellent (>90%) agronomic efficiency of all products and doses tested for the control of the mite Brevipalpus phoenicis on leaves and branches of the coffee trees up to 60 days after the application. No visible signs of phytotoxicity were detected.

Index terms: leprosis, coffee, Brevipalpus phoenicis, miticides.

Symposium and Poster Session

[1360] TONIC EFFECT OF THIAMETHOXAN ON GROWTH OF DRY BEAN PLANT

D. S. Martins¹ & M. J. Fornazier¹, 'EMCAPER- Empresa Capixaba de Pesquisa, Assistência Técnica e Extensão Rural-Rua Afonso Sarlo, 160, Bento Ferreira, Vitória/ES, CEP 29052-010, Brazil, E-mail davidmartins@emcaper.com.br.

Dry bean (Phaseokus vulgaris L.) plants in early stages are damaged by some pests that cause direct and indirect very important losses as reduction of the stand and vectors of viruses. Some insecticides, in determined doses, can cause phytotoxic or tonic effects on plants when used on the control of the pests. A randomized complet block design experiment with 7 treatments and 4 replications was carried out during the rain season on the highland Region of Espírito Santo State to evaluate the possible effects of three doses of insecticide thiamethoxan (group neonicotinoid) two formulations under two aplication methods, soil spout and seed treatment, on the growth of dry bean plants cv. Xamego (black bean). Experimental plots had 6 rows of 3,0m apart and 0,5m into row, with 12 seeds/m. Thiamethoxan treatments were: Actara 250 WG at 100; 125 and 150g a.i./ha, spouled in the soil on botton the plants 3 days after seeds germination, and irrigated immediately; Cruiser 700 WS at 70, 140 and 240g a.i./100kg seeds as seed treatment; and untreated control. At 10, 17, 24 and 38 days after germination were evaluated: number of leaves, plant height, fresh and dry weight of vegetative part (leaves and stems) and roots, number of Rhizobium nodules and number of pods of 5 plants harvested by plot. The experiment was irrigated and sprayed with methamidophos insecticide and tebuconozole fungicide to uniformize and avoid pests and diseases interference at the experimental area. There were no significant differences to the number of *Rhizobium* nodules and number of pods (P+0.05). Plants treated with the two thiamethoxan formulations had greater in fresh pous (1903), realist dealed with the two infanctional tormonators had greater in fresh and dry weight, comparatively to the untreated plants, showing an tonic effect caused by the thiamethoxan, that was more evident with Cruiser 700 WG formulation on the early stages of plant development. With the growth of plants, the difference of this effect, among the two formulations, was decreasing until to make equal. All doses of both formulations, in growth early stages, were superior values to the untreated plants too; the best plant development were observed on the highest doses. At floweing time was not observed significantly difference on treated and untreated plots.

Index terms: Phaseolus vulgaris, neonicotinoid insecticide, development

[1359] TIME-DEPENDENT VARIATIONS IN ESTERASE 9b FREQUENCY AND MALATHION-RESISTANCE OF THE DIAMONDBACK MOTH (PLUTELLA **XYLOSTELLA) IN TAIWAN**

Maa, Can-Jen William, Institute of Zoology, Academia Sinica, Taipei, Taiwan, 115, ROC.

EST 9b was recognized as an esterase allozyme associated with malathion resistance in the diamondback moth (DBM), *Plutella xylostella L.*. In 1987, Geou-Fang DBM population was significantly (P < 0.05) differentiated from other 14 local DBM populations in Taiwan based on EST 9b frequency. Meanwhile, Geou-Fang DBM was the most susceptible population found in Taiwan. Two years later Geou-Fang DBM was no longer being differentiated from other DBM populations based on the EST 9b frequency. In fact, EST 9b frequency of Geou-Fang DBM increased from 13% to 35% within the two years of 1987~1989; and no insecticide was applied in Geou-Fang area during that time period. A statistically significant (P < 0.02) linear regression was existed between the EST 9b frequency and malathion resistance of the 14 DBM populations, and this correlation lasted till 1991. Although the two regression lines of 1989 and 1991, respectively, showed different slopes, they shared the same interception point to the horizontal axis of EST 9b frequency. This phenomenon implicated that EST 9b frequency of Taiwan DBM might vary from year to year, and accordingly, resistance of DBM might also fluctuate from time to time. So the EST 9b frequency could be suggested as an indicator protein for monitoring malathion resistance in the DBM. However, by 1997 the regression line between EST 9b frequency and resistance of the DBM was neither statistically significant nor sharing the same interception point with that of 1991 and 1989. This might implicated some variations between the EST 9b frequency and the resistant mechanism from 1989 to 1997. In view of these consecutive accounts of the variation in EST 9b frequency and malathion resistance through the passed ten years, significance of the above mentioned events was discussed. The adaptive phenomenon of the DBM to the changing circumstance in Taiwan was also discussed.

Index terms: Plutella xylostella L., esterase 9b, malathion-resistance, variation, adaptation

[1361] EFFICIENCY OF SEEDS TREATMENTS WITH THIAMETHOXAM TO CONTROL BEMISIA ARGENTIFOLII ON COTTON CROP

J.C. Martins' & G. Nakamura², 'Fundação Faculdade de Agronomia "Luiz Meneghel", P.O. Box 261, Area Code 86360-000 – Bandeirantes – Paraná – Brazil, E-mail jeelso@ffalm.br; ³Novartis Diociências – São Paulo – São Paulo – Brazil.

Recently found on cotton crop, *Bemisia argentifolii* specie is the responsible of "sticky" beyond transmitton of virotical diseases. This present trial was conducted in Miguelópolis City – São Paulo State – during summer crop of 98/99. With the purpose to evaluate efficiency and agromical use of seeds treatments with thiamethoxam in order control nimphs and adults of B. argentifolii on cotton crop, Deitapine cultivar, it were evaluated following treatments, which doses are on g a.i.Jkg of seeds; thiamethoxam (Cruiser 700 WS – 140, 210 and 280); furathiocarb (Promet 400 CS – 800); imidaeloprid (Gaucho 700 WS - 210) and control (with no insecticide). The experimental design was randomized blocks with 6 treatments and 4 replications, using Tukey's test for medium comparing and Abbott's formula to obtain efficiency percentage. On seeds treatments, done in plastic bags, it were added 5 ml of water per seeds kilogramme. At evaluations, done at 18 d.a.e. for adults, it was used a pitfall "witch-hat" type, counting catched adults on 15 randomized plants/plot, and at 28 d.a.e. for nymphs collected on 15 randomized plants/plot, taken one planespiot, and a zo date for hydrons corected on 15 function plants plot, taken one leaf at inferior third. Leaves were removed to laboratory and with a esteroscopic microscopic with 15 times of magnifications, it were counted alive nymphs number. Insecticide thiamethoxam, at doses 210 and 280 g a.i./100 kg of seeds was the most efficient on *B. argentifolii* control, with more than 85%, for nymphs and adults. Index terms: Bemisia argentifolii, chemical insecticide, cotton.

[1362] SELECTIVITY OF GROWTH REGULATORS, PHOSPHORATES AND PYRETROIDS UPON NATURAL ENEMIES OF PESTS ON SOYBEAN CROP

LC. Martins⁴, E. Nascimento³ & L.F. Weber³, ¹Fundação Faculdade de Agronomia "Luiz Meneghel", P.O. Box 261, Area Code 86360-000 – Bandeirantes – Paraná State – Brazil (FFALM), E-mail jcelso@ffalm.br; ²Agronomy Student at FFALM. ³Bayer S/A – Londrina City –Paraná State – Brazil.

With the purpose to reduce the effects of insecticides use, it is necessary to find methods for pests control that causes no damage on ambience and insecticide selectivity to preserve natural enemies. This trial was conducted in Bandeirantes City - Paraná State, during summer crop of 98/99. With the purpose to evaluate selectivity and agronomical uses of the insecticides: betacyfluthrin, triflumuron, chlorpyrifos and prophephos upon pest predators on soybean crop, BR-4 cultivar, it were evaluated following treatments, which doses are on g a.i./ha: betacyfluthrin (Turbo 50 CE - 2,5); triflumuron (Alystin 480 SC -14,4), chlorpyrifos (Astro 450 E - 112,5); betacyfluthrin (Bulldock 125 SC - 2,5); prophenophos (Curacron 500 -80) and control (with no insecticide). Used experimental design was randomized blocks with 6 treatments and 4 replications. It were used Tukey's tests for medium comparing and Abbott's formula to obtain efficiency percentage. For to insecticides applications, when plants were on stagium $R_{s,i}$ it was used a sprayer with constant pression equiped with $D_{s,i}$, nozzle, pression of 5,5 Bar and volume of 150 l/ha. At evaluations, on pre-applications and at 2, 4 and 7 d.a.a. it was used cloth method, with 4 randomized shakes/plot, doing identifications and remarks of alive predators number Insecticide betacyfluthrin 50 and chlorpyrifos, after shock effect, showed found. selectivity from 4 d.a.a. Although showing fluctuation on reduction percentage, triflumuron was selective at 7 d.a.a.

Index terms: selectivity, natural enemies, soybean, predators.

[1364] RESISTANCE IN NORWAY SPRUCE AGAINST THE GREEN SPRUCE APHID

F. Midtgaard, T. Skrøppa, G. Ogner A. Lønneborg. Norwegian Forest Research Institute, Dept. of Entomology, Høgskoleveien 12, N-1432 Ås, Norway.

Infestation experiments were performed in three clonal trials with Norway spruce planted Norway and Denmark. These trials belong to a joint Nordic series of clonal tests of 240 clones from 20 families planted at 9 sites in Norway, Sweden, Finland and Denmark in a randomised block design with 6 replicates in single 'ee plots at 2 m. spacing. Twenty-four clones were selected to be included in the green spruce aphid infestation experiment, 4 from each of 6 full-sib families, and from each clone 3 or 4 replicates. The families and clones were selected on the basis of earlier measurements in the experimental series. They represent all three categories of crosses, cover the range of variation in the timing of spring flushing and shoot growth cessation and had earlier shown different levels of attack after natural infestation of the spruce gall aphids in two experimental plantations. The mean tree height at the start of the experiment in the spring of 1997 were 162 cm, and in 1998 it was 209 cm. The mean tree height in Kaupanger spring 1998 was 157 cm. Samples for chemical analyses was taken in 1997, and for enzyme analyses in 1997 and 1998. Infestations were done in 1997 (2), in 1998 (2), and in 1999 (3). The results show a good fit between biochemical and enzyme results and genetics, but there is a great random variation in the aphid population development data. In spite of this , significant variation is present among families. One family has in particular high number of aphids, and another consistently low number of aphids. Interactions seem to be present between families and sites/years. The results indicate that there are genetic differences in survival of aphids on families of Norway spruce. These differences may to some extent depend on the site conditions.

Index terms: Elatobium abietinum, clones, host resistance

[1363] DIFFERENT FORMULATIONS OF THIAMETHOXAM USED TO CONTROL LARVAE AND ADULTS OF *DIABROTICA SPECIOSA* ON SMALL POTATO CROP

<u>I.C. Martins</u>¹, G. Nakamura¹, ¹Fundação Faculdade de Agronomia "Luiz Meneghel", P.O. Box 261, Area Code 86360-000 – Bandeirantes – Paraná – Brazil, E-mail jcelso@ffalm.br; ²Novartis Biociências – São Paulo – São Paulo – Brazil.

Among different insect-pests on small potato crop there are some coleopterous and one of them, *Diabrotica speciosa* (Coleoptera-Chrysomelidae) has the main economic significance. This trial was conducted in Guarapuava City-PR, during summer crop 98/99. Treatments on g a.i./ha, with thiamethoxam (Actara 25 WG – 150 and 200); thiamethoxam (Actara 10 G – 150 and 200); phorate and aldicarb (Granutox 5 G – 2000 and Temik 15 G – 2025); thiamethoxam (Actara 25 WG – 150 and Actara 10 G – 150 and Actara 25 WG – 150 and Actara 10 G – 150 and Actara 25 WG – 150 and Actara 10 G – 150 and Actara 25 WG – 200) and control (with no insecticide) were applied on different periods of plants development, with the purpose to evaluate efficiency and agronomical use to control larvae and adults of *D. speciosa* on small potato crop, Monalisa cultivar. Experimental-design was randomized blocks with 6 treatments and 4 replications using Tukey's test for medium comparing and Abbott's formula to obtain efficiency percentage. In order to apply liquid insecticides on treatments 1, 4 and 5, done at planting furrow and at plants before heaping, it was used a back manual sprayed with constant pression of 4,1 Bar, nozzle 11002, and 200 l/ha of volume. Granulated insecticides were handly applied on treatments 2, 3, 4 and 5, on planting furrow and asplied on treatments 2, 5, 4 and 5, one at platutions were done at 15 and 20 d.a.e. for adults, using 50 randomized leaves per plot and counting of found perforation. Just combination of thiamethoxan 10 G – 150 g a.i./ha applied on planting furrow with thiamethoxan 25 WG – 200 g a.i./ha applied before heaping did no reach 80% of efficiency.

Index terms: Diabrotica speciosa, chemical insecticide, small potato.

[1365] INSECTICIDE PROPERTIES OF ETHANOLIC EXTRACT ISOLATED FROM SEEDS OF PIPER TUBERCULATUM SEEDS (PIPERACEAE) ON DIATRAEA SACCHARALIS (LEPIDOPTERA: PYRALI DAE)

J. E. Miranda¹, A. T. Murata², H. M. D. Navickiene³, M. J. Kato⁴, V. S. Bolzani³, G. E. D. Paredes⁵, M. Furlan³ & S. A. De Bortoli¹, ¹Dept. de Fitossanidade, Unv. Estadual Paulista, 14884-900, Jaboticabal, SP, Brasil (Bolsista Fapesp), E-mail: miranda@fcav.unesp.br; ²Dept. de Biologia, Fac. Filosofia, Ciências e Letras de Ribeirão Preto, Univ. de São Paulo, Av. dos Bandeirantes, 3900, 14040-901, Ribeirão Preto, SP, Brasil (Bolsista Fapesp), ; ³Dept. Química Orgânica, Instituto de Química, Unesp, Araraquara, SP, Brasil; ⁴Dept. Química Fundamental, IQ, USP, SP, Brasil; ³FCB, Univ. Nacional Pedro Ruiz Gallo, Lambayeque, Peru.

Plants of the family Piperaceae, are broadly used in the pharmacology and alimentary industries. The genus of larger importance is *Piper*. Reports have been mentioned that some species of the genus Piper has been used as insecticide and molluscide. The leaves of *Piper tutokatsura*, originated from Taiwan and Japan are known as deterrents of feeding *Spodoptera litura*. The specie *Piper tuberculatum* Jacq. was collected at the Campus of INPA - Manaus, in July of 1998. The seed (24.33 g) were doubled extracted in CH2CI2: MeOH (2:1). The evaluations were made at 24, 36 and 48 hours after the application. The relationships answer-dose was compared by the analysis of Probit to determine the susceptibility rate, measured in mg i.a./insect. The test consisted of the topical application of the compounds on caterpillars of 3th instar. The concentrations tested were 100,000ppm 10,000ppm, 1,000ppm and 10 ppm. In relation to answer-dose obtained by the analysis of Probit, it can be observed that the value of DL50 was 9.57mg i.a./insect. It could be concluded that this extract presents insecticide potential. A trial of the substances of the seed extract of *P. tuberculatum* and, from de isolated substances, new susceptibility tests to found the active insecticide substance, are suggested.

Index terms: Diatraea saccharalis, susceptibility test, amide, insect control

[1366] RELATIVE TOXICITY OF INSECTICIDES TO COTTON LEAFIIOPPER POPULATIONS FROM VARIED ENVIRONMENTS

S.Mohankumar^{1,2} & M.S.Venugopal², ¹ CSES Dept., Virginia Tech, Blacksburg, VA24061, USA, ²TamilNadu Agricultural University, Coimbatore-641003, INDIA, E-mail: smk65@hotmail.com

Cotton leafhopper, Amrasca devastans (Distant) occurs as a potential pest in major agroclimatalogical cotton tracts namely winter irrigated, summer irrigated, rice fallows and ranifed environments. Foliar application of several insecticides belonging to different chemical groups (monocrotophos, methyl-o-demeton, dimethoate, phosphamidon, endosulfan, quinalphos, synthetic pyrethroids, botanical insecticides) were observed to be effective against *A.devastans*. But during recent years, the cotton leafhopper population showed a progressive increase with less susceptibility to various insecticides and hence it has become a problem to cotton cultivation in Tamil Nadu. The heavy incidence of leafhopper along with reduced effectiveness of commonly used insecticides has become a serious problem. Hence, the present study aims to determine the variability in toxicity of different insecticides against *A.devastans* population collected from five agro-climatic regions of Tamil Nadu. Leafhoppers collected from different agroclimatic regions of Tamil Nadu (Coimbatore, Theni, Srivilliputhur, Koilpatti and Madurai) were conditioned through maintaining in susceptible variety (LRA 5166). The insecticides namely dimethoate, methyl-o-demeton, monocrotophos, endosulfam, quinalphos, neem oil, neem seed kernel extract were tested for their efficacy against different populations separately by standard spray residue method. The LC50 values were worked out and with the base line as LC50 value of most susceptible population, the resistance ratio was worked out. The results revealed that the leafhoppers collected from Theni were least susceptible to methyl-o-demeton, dimethoate, endosulfan, quinalphos, fenvalerate and neem seed Kernel extract where as Srivilliputhur for phosphamidon and Coimbatore for monocrotophos and neem o'l . In general, Madurai population was highly susceptible to all insecticides except phosphamidon and botanicals. Koilpatti, Srivilliputhur and Coimbatore populations were highly susceptible for phosphamidon and fenvalerate, neem and neem seed kernel extract respectively. This generation of base line data pave the way for stressing the need for detailed studies on resistance development in cotton leafhopper.

Index terms: Amrasca devastans, population variation, resistance development

[1367] PRO-ACTIVE MANAGEMENT OF BEET ARMYWORM (SPODOPTERA EXIGUA) RESISTANCE TO THE IGRS, TEBUFENOZIDE AND METHOXYFENOZIDE

J. K. Moulton, D. A. Pepper, & T. J. Dennehy, Dept. of Entomology, Extension Arthropod Resistance Management Laboratory, 1140 E. South Campus Dr., Univ. of Arizona, Tucson, AZ 85721, USA, E-mail: kmoulton@ag.arizona.edu.

Susceptibility to tebufenozide and methoxyfenozide of beet armyworm (Spodoptera exigua) from the southern United States and Thailand was determined through exposure of first and third instar larvae to dipped cotton leaves. LC_{s_0} estimates of first instar larvae ranged from 0.377 to 32.7 micrograms of tebufenozide per milliliter and 0.034 to 11.5 micrograms of methoxyfenozide per milliliter. LC_{s_0} estimates of third instar larvae ranged from 4.37 to 715 micrograms of tebufenozide per milliliter and 0.393 to 47.4 micrograms of methoxyfenozide per milliliter. First and third instar larvae of a Thailand strain selected with these compounds were up to 87- and 164-fold less susceptible to tebufenozide and 338- and 121-fold less susceptible to methoxyfenozide, relative to the most susceptible of the strains evaluated. Among the United States field populations evaluated, a collection from Belle Glade, Florida, was the most susceptible and one taken near Parker, Arizona, was the least susceptible to bth IGRs. Selection of the Thailand population with tebufenozide or methoxyfenozide synergized tebufenozide and methoxyfenozide to approximately the same degree in a methoxyfenozide-selected Thailand strain. These results indicate a common mechanism of resistance. Crossing experiments between the methoxyfenozide-selected Thailand strain indicated multigenic and incompletely dominant inheritance. These findings and further isolation and characterization of resistance to tebufenozide and methoxyfenozide will provide helpful information for pro-active management of resistance to this valuable group of insecticides in the United States.

Index terms: Spodoptera exigua, tebufenozide, methoxyfenozide, resistance

Symposium and Poster Session

[1368] INSECTS ENEMIES OF THE BLACK SCALE, SAISSETIA OLEAE (BERNAD) ON OLIVE IN ARGENTINA

<u>G. Murúa</u> & P. Fidalgo, Instituto Superior de Entomología (INSUE) - Fundación Miguel Lillo, Miguel Lillo № 205, San Miguel of Tucumán, CP(4000), Tucumán -Argentina. E-mail: gmurua@yahoo.com.

Saissetia oleae is a poliphagous species widely distributed over the tropical and subtropical regions of the world and is a serious pest in citrus and olive trees. In Mendoza and San Juan provinces (Argentina) it is the most important pest together with Pollinia pollinii, while in La Rioja and Catamarca it is found with Parlatoria oleae. The parasitoids Metaphycus helvolus, M. Lounsburyi and Coccophagus caridei, were introduced in Mendoza in 1969 from Chile for it control. These species were recovered in very small percentages, and their establishment and were not evaluated. According to the bibliography, five species of parasitoids of S. oleae were registered in Argentina, but a study of the enemies of the pest was never carried out in olive. Collections of insects enemies of black scale on olive groves at La Rioja were carried out during January and October of 1999 and February of 2000. The materials colleted were observed in the laboratory and the insets obtained were identified and deposited as "vouceher specimenes" at the FML's collections. Four species of parasitoids and two species of predators were registered. The parasitods were: Lecaniobius utilis, Coccophagus caridei, Metaphycus stanleyi and Brasema sp.. The last two species were not found previously in Argentina. The predators obtained were the coccinellid Azya bioculata and Chrysopidae sp.. The parasites associated with black scale is not enaugh able to prevent the pest status attained in Argentina by S. oleae. The introduction of additional enemies is therefore highly recommended. In the world the encyrtid Diversinervus elegans (Silvestri) is the most important and efficient parasitoid in the control of S. oleae, but is not present in Argentina. The introduction of this species would be very important to obtain a complete biological control of this pest in olive.

Index word: natural enemies, Saissetia oleae, olive, Diversinervus elegans.

[1369] INSECTICIDES FOR PSEUDALETIA SEQUAX CONTROL IN WHEAT TRITICUM AESTIVUM.

Pedro Neves'; M.U. Ventura' & A. Pasini'. 'Depto. Agronomia, Univ. de Londrina, C.P. 6001, Londrina, PR 86051-970, Brazil. E-mail pmojneve@uel.br

The worm *Pseudaletia sequax* is an important pest in wheat in Brazil. This worm eats the leaves and the spikes of the plants. Damages to production can be bigger than 30%. This experiment was carried out to evaluate *P. sequax* control efficiency of some insecticides. Cultivar Igapó was used. Plots size were (6 m X 4.5 m) 27.00 m⁴ (4 replications). The experiment, in blocks, was carried out at Fischer farm in Rolândia-PR Brazil. Spraying volume was 190 l/ha. The treatments were: lambdacyalothrin (Karate 50CS Zeon) 5 g. a.i./ha, lambdacyalothrin (Karate 50CE) 5 g a.i. /ha, permetrim (Ambush 500 CE) 25 g a.i. /ha, the standard metamidophos (Tamaron BR) 180 g. a.i. /ha and a control (only water). The assessment were made 3 and 7 days after spraying by counting the worm number in the soil under the plants during 6 minutes. In all assessment treatments differed statistically from the control with efficiency levels greater than 80% (Abbott) except for Tamaron BR. For this treatment the efficiency was 59 and 27% respectively for the 3 and 7 days after spraying. Index terms: lambdacyalothrin, permetrin, chemical control.
[1370] BUTTERFLY DIVERSITY IN SERRA DO CIPÓ, BRAZIL: A PRELIMINARY SURVEY

<u>E. G. Oliveira</u>¹ & G. W. Fernandes¹, ¹Departamento de Biologia Geral, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, 30161-970, Belo Horizonte, MG, Brazil, E-mail evandro@mono.icb.ufmg.br.

Serra do Cipó is located in the southernmost portion of the Espinhaço Mountains, a high altitude mountain range in southeastern Brazil. It harbors one of the most diverse ecosystems in the world with high degree of floral endemism and morphological convergence. Low soil fertility, prolonged dry season, strong winds, and other harsh environmental conditions, which strongly influence its flora and fauna, characterize the region. In this scenario, we would expect to find a relatively poor butterfly fauna. On the other hand, due to its speciose flora and because the region has never been properly surveyed, we would also expect to find rare and new species. In an attempt to address these questions, for the first time we have sampled the butterflies in the region by (i) direct netting and (ii) trapping using rotting fruits as bait. We have also recorded migration (i.e., unidirectional flight) events, which had not been previously studied in the region. During the first three months of this study, we have collected butterflies belonging to all common families, and the preliminary list of species suggests that its diversity may be higher than previously postulated. Migration of Pieridae was observed in several occasions indicating that this is a common phenomenon in the region.

Index terms: Lepidoptera, species composition, mountain habitat, migration

[1372] INTERCROPPING SYSTEM AND THIAMETHOXAM SPRAYING FOR EMPOASCA KRAEMERI (HEMIPTERA: CICADELLIDAE) CONTROL IN COWPEA

J.V. Oliveira, M.S. Braga¹, M.P.L. Lima¹ & P.R. Machado¹, ¹Fitossanidade, Univ. Fed. Rural de Pernambuco, Av. Dom Manoel de Medeiros s/n, Dois Irmãos 52171-900 Recife, PE. E-mail: jolivei@elogica.com.br

The effect of intercropping system cowpea-corn with and without application of inseciticide for *Empoasca kraemeri* control was studied. The experiment was set up at Experimental Station of Empresa Pernambucana de Pesquisa Agropecuária, in Vitória de Santo Antão County, State of Pernambuco, Brazil in a randomized complete block with four treatments and five replicates. Each plot was consisted of 30 m² with plants spaced 0.5 m within row and 1.0 m between row with cowpea cultivar Sempre Verde and corn cultivar BR-476 planted in monoculture or in intercropping. For intercropping plots was used three lines of cowpea was surrounded by two corn lines. The insecticide thiamethoxam at rate of 37.5 a.i./ha and deltamethrin at rate of 12.5 a.i./ha were sprayed 20, 35 and 50 days after seeding. Nymphs of *E. kraemeri* were sampled on 36 trifoliate leaves before each spraying. Nymphs of 20 days after seeding lower *E. kraemeri* nymphs population was observed in cowpea treated plots and cultivated either in nonoculture or in intercropping. Likewise, in intercropping treated system was 98.5 and 98.4% lower than in untreated plots. Likewise, in intercropping treated system reduction of *E. kraemeri* was 98.4 and 99.3% in relation to untreated plots Independent of cropping system thiamethoxam reduced significantly *E. kraemeri* population. In addition, larvae, pupae and adults of ladybird predator *Cycloneda sanguinea* (Coleoptera: Coccinellidae) population was greater on untreated monoculture and intercropping plots accounting to 51.4 and 38.2, respectively. This predators occurrence was verified on the black aphid. Aphis cracicivora (Homoptera: Aphidiae) population. In Addition, Index terms: Cultural control, leafhopper, insecticide, predator.

[1371] CONTROL OF BEAN LEAFHOPPER *EMPOASCA KRAEMERI* (HEMIPTERA: CICADELLIDAE) WITH THIAMETHOXAM ON COWPEA

<u>J. V. Oliveira</u>¹, M. P.L. Lima¹, M.E.C. Gonçalves¹, P. R. Machado¹ & M.A.A. Mattos¹, ¹Fitossanidade, Universidade Federal. Rural de Pernambuco, Av. Dom Manoel de Medeiros, s/n, Dois Irmãos 52171-900 Recife, PE.

This research was carried out at the Luiz Jorge da Gama Wanderley Experimental Station, Empresa Pernambucana de Pesquisa Agropecuária, in Vitória de Santo Antão, PE. The objective was to test the insecticide thiamethoxam for control of *Empoasca kraemeri* nymphs on cowpea by using seed treatment (Cruiser 700 WS - 150 g/kg of seeds), seed treatment + spraying (Actara 250 WG - 150 g c.p. /ha) e spraying in comparison to monocrotophos pattern spraying (Agrophos 400 - 1, 0 1 c.p. /ha), and control. Seeds of the cowpea cultivar Sempre Verde were sowed in a 1,0x0,5m spacing and the plants irrigated through sprinkling. The plot area was 30m² and composed by five rows with the lateral ones used as borders. A randomized design was adopted with five treatments and our replications. The insecticide sprayings was made with a 20 liter costal sprayer and took place at 24, 46, and 60 days after sowing. Before each spraying, samples of *E. kraemeri* nymphs were observed under the leaf bottom side of 42 trifoliate leaves per plot. At 24 and 46 days after sowing it was observed a black aphid, *Aphis craccivora*, infestation followed by a larval, pupal and, adult incidence of the ladybird, *Cycloneda sanguinea* (Colcoptera: Coccinellidae). The results were analyzed statistically and the means compared by Tukey test (P < 0,05). The insecticide efficiency was measured with nymphal counting data available at 46 and 60 days by using Abbott's formula. The following efficiency percentages were obtained: 44.4 and 26.2% for thiamethoxam by using seed treatment; 94.4 and 97.2% for seed treatment + spraying; 64.8 and 100% for thiamethoxam spraying and 61.1, and 93.1% for monocrotophos spraying at 46 and 60 days after sowing, respectively.

Index terms: Insecta, Homoptera, chemical control, Vigna unguiculata.

[1373] SAFETY OF TWO TRACTOR CABINS IN APPLICATION OF INSECTICIDE AND ACARICIDE BY TRACTOR-TRAILED AIR-CARRIED SPRAYER IN CITRUS (Citrus sinensis)

M. L. Oliveira¹ & J. G. Machado Neto¹, ¹Dept. de Fitossanidade, FCAV/UNESP – Câmpus de Jaboticabal, 14.870-000, Jaboticabal, SP, Brazil. E-mail oliveiraml@hotmail.com; joaquim@fcav.unesp.br.

Pesticides applications in citrus by tractor-trailed air-carried sprayer provide low spray retention in plants and high environmental contamination and occupational risk. Safety of tractor driver in these applications can be achieved by the use of tractor cabins. In present work safety was evaluated calculating the margin of safety (MOS) from data of NOEL of pesticides and occupational exposure in a 6 hours work day. Working conditions of tractor driver (DE) was evaluated using or not two types of cabins (Real and Agroleite) spraying with Arbus 2000 Valência tractor-trailed air-carried sprayer in orchard of the Cambuhy Agrícola Farm, Matão-SP, Brazil in november/99. Cu⁻² of a cupric fungicide was used as tracer of spray. DE was quantified directly on long sleeved white overall, on hood and on cotton gloves. Exposure of face was evaluated on female sanitary pads attached on disposable face masks and exposure of feet was on same type of pads attached on upper part of rubber boots. DE in three working conditions were evaluated in ten replications for each activity during 30 to 40 minutes. After the exposure overalls were divided into parts and were immersed in solution of HCl (0.1 N) for extraction of the tracer. Same procedure was carried out on pads. Quantification of Cu⁻² was by atomic absorption spectrophotometer. The values of Cu⁻³ recovered in spray collectors and concentration of the tracer in the spray solution were used to estimate the DE. Dermal exposure of pesticides. These data were used to calculate MOS with the following equation: MOS = [NOEL x 70] / [1.1 DE]. The DE without cabin was of 496.8 mL/day. Using the Real cabin it was 25.3 mL/day and using the Agroleite cabin was 71.9 mL/day with 94.9% and 83.6% were classified as safe (MOS ≥ 1) without tractor cabin, 62.4% with the Agroleite cabin.

Index terms: sprayer, pesticides, tractor-trailed air-carried sprayer, tractor cabins, safety

[1374] SAFETY OF PROTECTIVE CLOTHING AND SEMI-CABIN IN INSECTICIDES AND ACARICIDES APPLICATIONS BY TRACTOR-TRAILED HAND GUN SPRAYER IN CITRUS

M. L. Oliveira¹ & J. G. Machado Neto', 'Dept. de Fitossanidade, FCAV/UNESP – Campus de Jaboticabal, 14.870-000, Jaboticabal, SP, Brazil. E-mail oliveiraml@hotmail.com; joaquim@fcav.unesp.br.

The safety of the tractor driver and spraymen applying pesticides in citrus by tractortrailed hand gun sprayer was evaluated calculating margin of safety (MOS) from data of NOEL of pesticides and occupational exposure in a 6 hours work day. Working condition of workers was classified as safe (if MOS ≥ 1) or unsafe (if MOS <1). Dermal exposure (DE) of tractor driver was evaluated with and without protective clothing (AZR clothing) and semi-cabin and of spraymen with and without protective clothing (AZR and Roupa UNESP clothing). AZR protective clothing was composed by AZR clothing (hood, long sleeve jacket, pants and acetate face visor). Roupa UNESP protective clothing was composed by the Roupa UNESP clothing (impervious garment protecting only the frontal part of body and opened in the back). Both protective clothing were completed by nitrila gloves, rubber boots and charcoal treated disposable respirator. For Roupa UNESP it was added straw hat. Evaluations were carried out using Rolanzir high pressure sprayer in citrus orchard of Marchesan Agroindustrial e Pastoril Farm – Fazenda Cambuhy, Matão-SP, Brazil, during august/99. Cu² of a cupric fungicide was used as tracer in spray. Dermal exposure were assessed in ten replications in each activity during 30 to 40 Derma exposure were assessed in the representation in deer deer deer a solution of HCI (0.1 N) for minutes. After the exposure, spray collectors were immersed in solution of HCI (0.1 N) for extraction of the tracer. The values of Cu² recovered in the spray collectors and the concentration of the tracer in the spray solution were used to estimate the DE. Dermal exposure to 135 recommended pesticides were estimated with DE to spray and the dose of pesticides. MOS were calculated by the equation: MOS = [NOEL x 70] / [1.1 DE]. The DE of the tractor driver working with tractor without semi-cabin and AZR protective clothing was 57.2 mL/day. Wearing AZR protective clothing the DE was 12.7 mL/day, and using semi-cabin, 55.7 mL/day, with 77.8% and 2.6% efficiences. DE of spraymen meas 356.5 mL/day with 77.8% and 2.6% efficiences. DE of spraymen were 356.7 mL/day without protective clothing, 24.7mL/day with AZR (93.1% efficiency) and 77.3mL/day with Roupa UNESP (78.3% efficiency). Among 135 recommended insecticides and acaricides 64.4% were safe for the tractor driver working without protective clothing and semi-cabin, 89.1% were safe if tractor driver used AZR and 64.4% when the semi-cabin was used. For spraymen without protection 43.6% of applications were safe. Wearing Roupa UNESP 59.4 % were safe and 82.2% were with AZR.

Index terms: spray, pesticides, safety, protective clothing, semi-cabin

[1375] BASES FOR AN INSECTICIDE RESISTANCE MANAGEMENT OF SPODOPTERA FRUGIPERDA IN CORN IN BRAZIL

C. Omoto¹, F. B. Schmidt¹, R. B. Silva¹, T. D. Zucchi¹, M. D. M. Risco¹, C. Travalini¹, T. Thomazini¹ & S. C. Trakaki², 'Depto. de Entomologia, Fitopatologia e Zoologia Agrícola, Escola Superior de Agricultura "Luiz de Queiroz", Av. Páduas Dias, 11, 13418-900 Piracicaba, SP, Brasil, E-mail: celomoto@carpa.ciagri.usp.br; ²Dow AgroSciences, Rua Alexandre Dumas, 1671, 04717-903 São Paulo, SP, Brasil.

Corn is one of the most important crop in Brazil with about 12 million hectares of cultivated area per year. This crop has been cultivated all the year round with up to 3 different growing seasons in some regions. Therefore, the problem of pests attacking corn has also increased. The fall armyworm (*Spodoptera frugiperda*) is one of the most important corn pests in Brazil. Approximately 60 million US dollars were spent with insectides in corn in 1998; and about 40% of this amount was to control fall armyworm. Field failures have been reported frequently with the use of conventional insecticides for controlling this pest. Then, a survey of the susceptibility of *S. frugiperda* to commonly used insecticides such as the organophosphate chlorpyrifos ethyl and the pyrethroids lambda-cyhalothrin and zetacypermethrin was conducted in 1996/1997. Populations of *S. frugiperda* were collected from some corn-growing regions located in the State of Paraná, São Paulo, Minas Gerais and Goiás. The frequency of the resistance to these compounds varied from <1% to >35%. A 16-fold resistance was detected to chorpyrifos and lambda-cyhalothrin have increased in a stair-step fashion through time. In response to these results, another survey of susceptibility of *S. frugiperda* was conducted in 1999/2000 to evalue the extent of the problem to other compounds such as thiodicard, spinosad, methoxyfenozide and lufenuron. In this paper, we will also present the baseline suceptibility data of *S. frugiperda* in Brazilian cornfields will be presented. Index terms: fall armyworm, for the resistance ethyl, lambda-cyhalothrin survey of succeptibility of such such as thodicard, spinosad methoxyfenozide and tufenuron. In this paper, we will also present the baseline suceptibility data of *S. frugiperda* in Brazilian cornfields will be presented. Index terms: fall armyworm, for the resistance they for an insecticide resistance management of *S. frugiperda* in Brazilian cornfields will be presented.

[1376] DDT- AND ORGANOPHOSPHATE-RESISTANCE IN ANOPHELES GAMBIAE MEDIATED BY GLUTATHIONE S-TRANSFERASE GENES

F. Ortelli, H. Ranson, N. Roberts & <u>J. Hemingway.</u> Dept. of Biosciences, Univ. of Wales Cardiff, P.O. Box 915, Cardiff CF10 3TL, UK, E-mail: Hemingway@cardiff.ac.uk.

Anopheles gambiae represents an important Sub-Saharan malaria vector. The extensive use of insecticides in agriculture and for anti-malarial purposes, selected for resistant strains. Three complex mechanisms underlying insecticide resistance are known: cuticular resistance, metabolic resistance (carboxylesterases, glutathione S-transferases (GST), mixed-function oxidases) and target site insensitivity.¹ GSTs are a large family of enzymes, which protect the cell from reactive electrophilic compounds by enhancing their solubility and aiding their excretion from the cell. GSTs are also competent for the dehydrochlorination of DDT and dealkylation of organophosphates (OP) insecticides¹², modulating the resistance level in insects. DDT- and OP-resistance in An. gambiae is mediated by stage-specific GSTs,³ where an increase in gene expression is responsible for resistance.³ Recent work on An. gambiae has demonstrated the diversity of GST enzymes present in this insect. Most class I GSTs are located together on a single chromosome and sequencing of this DNA revealed two full-length genes and five GSTs-like sequences. The first of these has high levels of identity to the 5' end of insect class I GSTs, while the other four are truncated at their 5' ends but have high sequence identities to the 3' region of GSTs. Expression studies show that this is an alternately splice gene with four different protein products. The factors determining the choice of the 3' splice site are still unknown, but they seem to be stage and tissue dependent. This gene splicing mechanism is responsible for some of the high GST variation in this insect class. Characterisation of the factors contributing to the choice of 3' splice site should lead to a better understanding of these enzymes, their role in insecticide resistance, and splicing systems in insect vectors. Index terms: gene over-expression, promoter analysis, reactive electrophilic compounds

[1377] EFFECT OF A SPECIAL THERMONEBULIZATION FORMICIDE FORMULATION FOR THE CONTROL OF THE LEAF-CUTTING ANT, ATTA CAPIGUARA (HYMENOPTERA:FORMICIDAE)

<u>G. Papa</u>¹, F. J. Celoto¹ & F. J. Almeida¹, ¹ Dept. of Biology, Univ. Estadual Paulista, Av. Brasil 56, Zip 15.385-000 - Ilha Solteira/SP, Brazil, E-mail: gpapa@bio.feis.unesp.br

Leaf-cutting ants of the genus Atta excel over the remaining groups of insects which cause damage to plants since they are highly active social insects that cause great losses to farmers in Brazil. The control methods used today present limitations that may compromise their control. Bait formulations require good soil conditions and low humidity, otherwise they will not be efficient. Applying water-based insecticides is not possible in large areas as well as fogging, which demands engine-propelled equipment that require constant maintenance, increasing the treatment cost. New approaches such as an insecticide formulation of a fumigant paste that produces a fog after being ignited and that exempt the use of fogging equipment, may offer a better solution for the control of leaf-cutting ants. The objectives of the present paper were to evaluate the results of a special formulation of fumigant paste for the control of Atta capiguara. The experiment was performed under field conditions, in a pasture area, from November 1999 through January 2000. The design was completely randomized, consisting of 5 treatments and 8 replications. Each parcel consisted of one colony (anthill). The sizes of the colonies varied from 6 to 40 m² of area of loose soil. The insecticide was applied introducing already lighted up tubes containing the funigant paste plus the insecticide into the active openings of the colonies. Each tube contained 65 g of the paste and 4.3 g of cypermethrin. The treatments consisted of one tube (FUMACÉ) per each 6, 8 and 10 m² of loose soil, one standard treatment with the conventional insecticide in a formulation in order to verify the soil removal and ant activities in each anthill. Colonies were classified as active, inactive or disturbed. The analysis of the results showed that the fungant paste applied at the dosage of 100 ml c.p.A of diesel oil with a back fogger and a control freatment. The explained shows control insecticide in a formulation in order to verify the soil removal and ant activities in ea

[1378] EFFECT OF CHEMIGATION THROUGH CENTRAL PIVOT. FOR THE CONTROL OF THE FALL ARMYWORM, SPODOPTERA FRUGIPERDA, (LEPIDOPTERA: NOCTUIDAE), IN CORN

G. Papa', <u>M. Rotundo'</u> & G. V. Tomquelski', ' Dept. of Biology, Univ. Estadual Paulista, Av. Brasil 56, Zip: 15.385-000 - Ilha Solteira/SP, Brazil, E-mail: gpapa@bio.feis.unesp.br

Among the main factors that affect corn production in Brazil, pests such as Spodoptera frugiperda constitute the greatest problem to farmers. As the areas irrigated by aspersion (central pivot) increase in Brazil, chemigation has become one of the most important mode of application of insecticides. However, there are only a few options of products recommended for this mode of application. The increasing search for safer alternatives for pests control, which are less aggressive for the environment, has brought a significant development of new insecticide formulations, with possibilities of use in agricultural pest management. Therefore, the current technological advancement in chemistry leads to safer and more adequate insecticides, contributing to a safer and more efficient way of control pests. The objective of this work was to evaluate the performance of the microencapsulated formulation of Lambda-cyhalothrin, applied through central pivot, for the control of the main corn pest in Brazil, S. frugiperda. The experiment was established under field conditions, during the period of May to August/99. The design used was in strips, with 11 treatments and 4 sub-plots. Each plot consisted of an area of 5 ha, subdivided to 4 equal sub-plots. Two applications were made through central pivot and injection pump. The pivot worked at full speed and at a pressure of 1.42 kg/cm^3 , distributing a water deep of 4.75 mm. The treatments consisted of a microencapsulated formulation of lambda-cyhalothrin at the concentration of 5 and 25% (Karate Zeon), lambda-cyhalothrin as an emulsifiable concentrate formulation (Karate 50 CE) at the doses of 7.5 and 12.5 g a.i./ha, chlorpyriphos (Lorsban 480 BR), lufenuron (Match CE), spinosad (Tracer) and zeta-cypermethrin (Fury 200 EW), at the doses of 288, 15, 24 and 20 g a.J.Aa, respectively, and control. Evaluations were done up to 15 days after each application, by checking the number of larvae found in 15 plants/sub-plot, with a total of 60 plants per treatment. Yield evaluation was conducted by harvesting all plants from two rows of 10m in length in each sub-plot and weighing stem + leaves + cob. Results showed that both formulations and concentrations of lambda-cyhalothrin were efficient for the control of *S. frugiperda* and provided for an increase in yield similar to the standard treatments (chlorpyriphos, lufenuron spinosad and zeta-cypermethrin).

[1380] RESISTANCE OF COMMON BEAN GENOTYPES TO Diabrotica speciosa (Germar) (COLEOPTERA: CHRYSOMELIDAE) ADULTS

M. J. F. O. Paron¹, F. M. Lara¹ & M. Yokovama², 'Dento, de Fitossanidade, Univ. Estadual Paulista, Faculdade de Ciências Agrárias e Veterinárias, Via de Acesso Paulo D. Castellane s/n, 14884-900, Jaboticabal, SP, Brazil. E-mail fmlara@fcav.unesp.br;² Centro Nacional de Pesquisa de Arroz e Feijão, EMBRAPA, C.P. 179, 74001-970, Goiânia, GO, Brazil

The gene pool of common bean (Phaseolus vulgaris L.) is related with two major domestication centers, the Middle American (MA) and Andean (AN). In this work, we use representative genotypes from these groups to determine their resistance to Diabrotica speciosa. Feeding non-preference in field and cages (26 genotypes) were evaluated in free choice tests, in 1997 and 1998, at the farm of UNESP-FCAV, Jaboticabal, SP, Brazil. The results of these tests showed different attack levels on the genotypes, and for the subsequent tests six genotypes were selected: Goiano Precoce, Jalo Precoce, PR 95105146, PR 95105142 (AN), Engopa 201 Ouro and IAPAR 57 (MA). The bean genotypes were planted in pots, covered with voil cages, and when 20 day-old, leaflets were collected. Foliar disks of 25,4-mm-diameter were taken out of each genotype for the tests. Two trials, a no choice test and a free choice test, were set up in BOD at temperature of 25°C, 70% air RH, photoperiod of 12:12 (L: D). The experimental unit of the free choice test was 2 disks of each genotype kept in a 140-mm-diameter Petri dish (total of 12 disks), where 12 adults were confined. The study was carried out in a completely randomized design with 15 replications. Consumption was determined after 24 hours or until 80% leaf area was destroyed from one of the genotypes. No choice test was conducted with the same genotypes. The experimental unit was a 60-mm-diameter Petri dish with 2 disks of one genotype and 2 insects, the evaluation and environmental conditions were according to the method described earlier. Another field experiment was conducted planting the 6 genotypes on June 10, 1999, in randomized blocks with five replications using normally recommended culture and fertilizing conditions. Fifteen leaflets per plot were collected 30 days after planting and the leaf area consumption was evaluated. On screening tests, Middle American genotypes were more preferred. The genotypes Emgopa 201 Ouro and IAPAR 57 (both MA) were the most preferred on feeding preference tests conducted at BOD, while the genotypes PR 95105146 and PR 95105142 (AN) were less damaged. The genotypes Emgopa 201 Ouro and IAPAR 57 also were the most preferred on field experiment, while Jalo Precoce (AN) had the lowest damage, and had not showed difference from the others AN genotypes. Index terms: Phaseolus vulgaris, feeding nonpreference, host plant resistance

[1379] STRATEGIES FOR THE USE OF THIAMETHOXAM ON THE MANAGEMENT OF THE APHID APHIS GOSSYPH IN COTTON

G. Papa¹, G. V. Tomquelski⁴ & R. B. Silva¹, 'Dept. of Biology/UNESP, Av. Brasil 56, CEP: 15.385-000 Ilha Solteira/SP E-mail: gpapa@bio.feis.unesp.br

The objective of this work was to evaluate the performance of thiamethoxam, in different dosagens, formulations and application strategies, aiming the aphid management and the reduction of foliar applications in cotton. Two experiments were deployed, the first in the 98/99 season and the second in the 99/00 season, both in the Brazilian cerrado, and with the cotton cultivar Delta Pine Ita-90. The design was of randomized blocks, with 8 treatments and 4 replications. Plot size was 12 rows by 15m length (162m²). In the first experiment the treatments consisted of: thiamethoxam (Cruiser 700 WS) applied as a seed treatment at the dose of 300 g c.p./100 kg of seeds + thiamethoxam (Actins 1 of M), applied at covering (granulated) at the doses of 15 and 20 kg c.p./ha, 35 and 45 days after planting; thiamethoxam (Actara 10 GR), at the doses of 15 and 20 kg c.p./ha and aldicarb (Temik 150) at 8kg p.c. /ha, applied in-furrow. In the second experiment the treatments consisted of: thiamethoxam (Cruiser 700 WS) applied as a seed treatment at the dose of 300 g c.p./100 kg of seeds + thiamethoxam (Actara 10 GR), applied at covering (granulated) at the dose of 20 kg c.p./ha, in different times for each treatment (at 10, 15, 20 and 30 days after planting); thiamethoxam (Actara 10 GR), at the dose of 20 kg c.p.. /ha, aldicarb (Temik 150) at 8 kg c.p./ha, applied in-furrow and imidacloprid (Gaucho 700 PM) applied as a seed treatment at 500 g c.p./100 kg + carbosulfan (Marshal 200) in foliar applications at 10-day interval, at dose of 600 ml c.p./ha. Results showed that the combination: seed treatment + application of granulated at covering was efficient for the control of the cotton aphid, and it reduced the number of diseased plants and it provided increment in the productivity in relation to the control treatment, being viable as a part of the cotton aphid management, as a replacement to sequential foliar applications. Index terms: mosaic, chemical control, IPM

[1381] RESISTANCE MECHANISMS IN ANOPHELES ALBIMANUS DURING A LARGE-SCALE FIELD TRIAL USING A SINGLE INSECTICIDE, ROTATION AND MOSAIC STRATEGIES IN MEXICO

R.P. Penilla^t, A.D. Rodríguez^t, J. Hemingway², A.D. López¹ & M.H. Rodríguez¹, ¹Infectious Diseases Research Center/Malaria Research Center, National Inst. of Public Health, P.O.Box. 537, Tapachula, 30700, Chiapas, México. School of Biosciences, Univ. of Wales, P.O.Box. 915, Cardiff CF10 3TL, Wales UK.

A three-year large-scale field trial for the evaluation of insecticide resistance management was conducted in Southern Mexico and the resistance gene frequencies of. Anopheles albimanus populations were investigated. Before the intervention, a broad-spectrum resistance to DDT, PYR (pyrethroids), OP (organophosphorus) and CAR (carbamates) was detected by WHO bioassays. Biochemical assays showed that such resistance was conferred by GST (Glutathione S-transferase), elevated esterases and AChE -based mechanisms (Penilla et al., 1998). Resistance gene frequencies in the distinct enzymes assayed were significantly different between villages and collection methods, suggesting the presence of sub-populations with different levels of resistance to the insecticides. During the three years evaluation significant variations in the enzymatic levels of this species between the different resistance management strategies were detected. GST activity increased after the 2rd and the 3rd year in villages under continuous DDT pressure, and in villages under the rotation strategy during the 2^{ad} year of treatment when a PYR was sprayed. Elevated esterases were detected during the 2^{ad} year in villages under the rotation strategy and through the three years study in some villages under the continuous PYR pressure. PYR apparently selected for monooxygenases (MFO) and esterases-based mechanisms, since both showed similar gene frequency patterns. Differences in gender also were detected in MFO and GST gene frequencies, with higher levels in females and males, respectively. Altered AChE gene frequencies decreased in villages under the PYR and rotation strategies by the 3rd year of intervention. The rotation of insecticides prevented MFO and GST levels to increase, while elevated esterases were observed in much low frequencies.

[1382] RESISTANCE TO THE TOMATO PINWORM, TUTA ABSOLUTA, BY INTERSPECIFIC GENETIC CROSSES OF TOMATO PLANTS

<u>N.E. Pereira'</u>, N.R. Leal', M.G. Pereira' & R. I. Samuels', 'Laboratório de Melhoramento Genético Vegetal, Universidade Estadual do Norte Fluminense, Campos dos Goytacazes, RJ, Brasil. ² Laboratório de Proteção de Plantas, Universidade Estadual do Norte Fluminense. E-mail norma@uenf.br;

The South America tomato pinworm, Tuta absoluta, is one of the major pests of the tomato crop in Brazil. The use of chemical pesticides is the most common method of controlling this insect. However, chemical control is expensive and causes environmental pollution. Genetic resistance to this insect is not seen in cultivated tomato species, but it is known to occur in wild/undomesticated species which are related to the cultivated tomato. This research studied the genetic resistance to Tuta absoluta in Lycopersicon esculentum cv IPA-6 and L. hirsutum f. glabratum Pl 134418 crosses. The parental, F_1 and F_2 generations were evaluated under greenhouse conditions. Artificial infestations of Tula absoluta were achieved by placing 1st instar larvae on the adaxial surface of the leaflets, which were then confined with dialysis tubing. The degree of insect damage was evaluated in relation to leaf area consumed. Larval development was also evaluated during the 15 days period following artificial infestation. Resistance was observed in the form of antibiosis. *Tuta absoluta* larvae showed abnormal development when exposed to wild/undomesticated parental and F, foliage. Larvae feeding on cultivated parental (L-esculentum) plants, completed their development within 15 days of infestation. A generation means analysis showed that the results can not be explained by a simple additive-dominant model, suggesting that the distortion could be due to interspecific incongruity or epistatic effects.

Index terms: Lepidoptera, plant breeding.

[1384] RELATION DOSE-LETHALITY OF THREE PESTICIDES ON VARROA AND APIS MELLIFERA VARROIDAE) JACOBSONI (GAMASIDA: (HYMENOPTERA: APIDAE): COMPARISON OF TWO ADMINISTRATION METHODS

G. Pérez-Santiago¹, G. Otero-Colina², D. Mota S²., M. E. Ramírez³ G. & R. Vandame⁴, 1.-Instituto Politécnico Nacional, CIIDIR Unidad Durango. A.P. 112, 34890 Vicente Guerrero, Dgo., México. Becario Cofaa. E-mail: gperezs@yahoo.com. 2.-Colegio de Postgraduados, Instituto de Fitosanidad, 3.- Instituto de Socioeconomia 56230, Montecillo, Méx. México & 4.- Université Claude Bernard-Lyon I. Institut d'Analyse des Systémes Biologiques et Socio-Economiques, Lyon France.

Two methods of toxicological bioassays were tested to determine the response doselethality of amitraz, flumethrin and fluvalinate on Varroa jacobsoni and Apis mellifera. The first bioassay method was aspersion by means of the Potter-Bourgerjon's tower; its results are expressed in mean lethal concentrations (LC_{a0}). The second one was topical application by means of microsyringe and manual applicator; its results are expressed in mean lethal doses (LD₅₀). In the study on varroa, values of LC₅₀ (mg L^{-1}) were the following: amitraz 0.23, flumethrin $8.75*10^{-4}$, fluvalinate 0.19. Values of LD₂₉ per individual mite (pg) were: amitraz 1.7, flumethrin 0.46, fluvalinate 15.42. Values of LC₃₉ (mg L⁻¹) in honeybees were: amitraz 1636, flumethrin 46.87, fluvalinate 1601. Values of

(ing L.) in noneypees were: anitraz 10.50, numerarin 40.67, nuvainate 1001, values of LD_{50} per honey bee specimen were: anitraz 2.55 *g, flumethrin 0.05 pg, fluvalinate 0.97 *g. Both LC_{50} and LD_{50} were considerably higher in varioa mites than in honey bees, showing that a wide security margin exists between effective doses against mites and dangerous doses for honey bees. Both methods gave similar confidence intervals; they showed a comparable sensivity to changes in dose or concentration of pesticides. Key words: amitraz, bioassays, flumethrin, fluvalinate, toxicity.

[1383] TOWARDS APHID RESISTANCE IN TRANSGENIC LUPINS

M. R. Perera & M. G. K. Jones, Western Australian State Agricultural Biotechnology entre, School of Biological Sciences and Biotechnology, Murdoch University, Perth, WA 6150, Australia. E-mail: mperera@central.murdoch.edu.au

The Australian pulse industry is worth about \$400 million per annum. Plant sucking insects such as aphids are serious pests of pulses which reduce crop yield and transmit phytopathogenic viruses. The new yellow lupin (*Lupinus luteus*) variety Wodjil is particularly susceptible to aphid damage, and this may limit its potential use. In Western Australia aphids are also vectors of two serious lupin viruses: cucumber mosaic virus (CMV) and bean yellow mosaic virus (BYMV). Aphid species, which frequently attack pulse crops in Western Australia such as cowpea aphid (Aphis craccivora), green peach aphid (Myzus persicae), bluegreen aphid (Acyrthosiphon kondoi) and potato aphid (Macrosiphum euphorbie) are the main focus of this project. The control of these pests currently relies heavily on cultural methods and applications of chemical pesticides. Some green peach aphid populations have resistance to organo-phosphorus and carbamate groups of insecticides. There is an opportunity for novel approaches to aphid control such as transgene-mediated resistance. The aim of this project is to develop transgenic legumes resistance to aphids. This project has several parts: (1) to develop different plant expression cassettes using constitutive, wound-inducible and tissue specific promoters; (2) to clone insect resistance genes into plant expression cassettes and generate stable transgenic lines expressing the insect resistant genes; (3) to assess the effectiveness of aphid resistance conferred by the introduced genes. The aim of this paper is to outline investigations that are being carried out and to describe the strategies that might be used to Investigations use are being carried off and to describe the strategies that might be dised to develop transgenic plants resistant to aphids. This research is in collaboration with the Centre for Legumes in Mediterranean Agriculture (CLIMA)), Agriculture WA (AGWEST) and KEYGENE N.V., Wageningen, The Netherlands, and financially supported by the Australian Grains Research and Development Corporation (GRDC). Index terms: Acyrthosiphon kondoi, Myzus persicae, Aphis craccivora, Macrosiphum euphorbie, Lupinus luteus.

[1385] DETECTION AND MONITORING OF INSECTICIDE RESISTANCE IN TRIATOMA INFESTANS AND RHODNIUS PROLIXUS

M. I. Picollo; C. Vassena; & E. Zerba, Centro de Investigaciones de Plagas e Insecticidas (CIPEIN/CITEFA-CONICET), Zufriategui 4380, (1603) Villa Martelli, Buenos Aires, Argentina. E-mail: cipein@citefa.gov.ar. This investigation received financial support from UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases.

Despite prolonged and intensive use of insecticides for the control of Chagas Disease Despite prolonged and intensive use of insecticides for the control of Chagas Disease vectors, few studies have been made on the possible development of insecticide resistance in Triatomines. We evaluated deltamethrin susceptibility in field populations of T. infestans and R. prolixus, for resistance detection and documentation. Sampling sites, sample size, life stage of collected insects were standardized in order to optimize sampling. Deltamethrin was chosen for the laboratory bioassays, as it was the major insecticide used in control campaigns from Argentina. The application of the World Health Organization (WHO 1994) protocol to determine resistance in T. infestans, and determine of the restored by R medium allowed the determination of LD, and adaptation of that protocol to R. prolixus, allowed the determination of LD_g and discriminating dose (DD) for the susceptible CIPEIN strains. The values obtained were userminating dose (DD) for the susceptible CIPEIN strains. The values obtained were LD_{sc} : 0.1 ng/insect and DD: 1.98 ng/i for *T. infestans*, and LD_{sc} : 0.01 ng/i and DD: 0.059 ng/i for *R. prolixus*. Topical application of DD on first nymphs obtained from field collected insects, were made on 123 *T. infestans* samples from 13 provinces from Argentina, 1 *T. infestans* sample from Brazil, 3 *R. prolixus* samples from Venezuela and 1 R. prolixus sample from Colombia. We found 100% mortality in field colonies collected in a province of Argentina, but number found in S. provinces of Argentina but number found in S. provinces. *k. protixus* sample from Colombia. We found 100% instanty in field colomes concrete in 8 provinces of Argentina, but survival was found in 5 provinces: San Luis, La Rioja, Mendoza, Catamarca and Salta. We also found survival insects in all *R. prolixus* field colonies collected in Venezuela. Resistant ratios for Argentinean colonies ranged from 3.0 to 4,8 and the same for Brazilian colony was 7. Resistant ratios for Venezuelan colonies ranged from 3,4 to 11.4. These results showed initial detection of resistance in field strains of Triatomines, and would allow the adoption of preventive resistance management tactics.

Index terms: Triatoma infestans, Rhodnius prolixus, field strains, monitoring insecticide resistance

[1386] THIAMETHOXAM TO CONTROL CITRUS LEAFMINER IN TANGOR MURCOTT

A. Raga, M.E. Sato, M.F. Souza Filho & R.C. Siloto, Biological Institute Experiment Center, P.O. 70, Campinas, SP 13001-970, Brazil, E-mail adalton@dglnet.com.br.

A field experiment was conducted on 'Tangor Murcott' spring flushes during 1999 to control citrus leafminer (CLM) *Phyllocnistis citrella* (Lepidoptera: Gracillariidae) in Cordeirópolis County, State of São Paulo, Brazil. Insecticides and respectively concentrations (g IA/100 liters of water) used were thiamethoxam 250 WG (3.0; 4.0 and 5.0) *thick and the sectore* 5.0), thiamethoxam (4.0) + petroleum oil (PO) 80EC (200.0), abametin 18EC (0.54) + PO (200.0), lufenuron 50EC (3.75) + PO (200.0), pyridaphention 400EC (30.0), pyridaphention (30.0) + PO (200.0) and PO (200.0 and 800.0). Two foliar sprays were made at interval of ten days. At 3 days after the 1st application, abamectin + PO and mate at interval of ten days. At 3 days after the 1st application, anametin + PO and lufenuron + PO, both considered as standards, provide significantly greater CLM larval mortality, with 86.8% and 93.3% of reduction, respectively. In the same date, only lufenuron + PO gave good control of larvae + pupae (86.2%). For all insecticide treatments, with the exception of thiamethoxam at 3.0g and 4.0g, the number of larvae per flush was lower than for untreated control at 7 days after the 1st application, ranging from 57.4% (PO - 200.0g) to 98.9% of reduction (abameetin + PO). In this evaluation, abameetin + PO caused the highest reduction (87.2%), thiamethoxam (5.0) provided good control (74.0%) while pyridaphention treatments were not significantly different from the check, based on the number of CLM larvae + pupae. At 5 days after the 2nd application, only abameetin + PO provided significant reduction in larva (93.9%) and larva + pupa (95.0%) populations. In the same date, lufenuron + PO showed significantly lower larva + pupa density per flush (75.4% of reduction). Although thiamethoxam + PO had been inferior to standard insecticides at 5 days after the 2nd application, the number of CLM larvae was reduced in 63.0%. At 11 days after the 2nd application no significant differences in larval or larval + pupal infestation were detected among treatments. The results suggest that studies with thiamethoxam to control P. citrella should be developed at 2.0 g AI/100 liter of water or higher doses with the addition of PO.

Index terms: citrus, Phyllocnistis citrella, Gracillariidae, chemical control.

[1388] EFFICACY OF GROWTH REGULATOR INSECTICIDES FOR THE CONTROL OF RACHIPLUSIA NU (LEPIDOPTERA - NOCTUIDAE) ON SOYBEAN

LL. Reichert¹ & J.C.L. Barbosa², ¹Lab. Entomology, College of Agronomy & Veterinary Medicine, Univ. Passo Fundo, P.O. Box 611, ZIP 99001-970 Passo Fundo -Brasil. E-mail Reichert @ upf.tche.br; 2 Agronomy Graduate Student

Rachiplusia nu is a major insect pest of flax, soybean, and sunflower in Southern Brazil. An experiment was carried out in the growth chamber, adjusted to 23±2°C and 14-hour photophase, to evaluate the efficacy of growth regulators insecticides on the control of *R*. *nu*. The following insecticides were tested: Novaluron 10 g a.i./ha; Lufenuron 10 g; Teflubenzuron 9 g; Methoxyfenozide 21.6 g; Chlorfluazuron 15 g, Triflumuron 14.4 g, and Diflubenzuron 10 g. The insecticides were applied onto experimental plots (3 m wide × 10 m long) by means of a CO, backpack sprayer adjusted to deliver 200 L/ha at a 45-PSI pressure. The larvae used in this test were from a stock population. The experimental units were arranged in a complete randomized design with eight treatments and five replications. Each replication consisted of 10 larvae (1-2 cm) kept in plastic containers $(11 \text{ w} \times 11 \text{ I} \times 3 \text{ cm h})$. The larvae were fed with leaves from the insecticide sprayed area. Insecticide efficacy was calculated according to the Abbott's formula at three, five, and seven days after insecticide application. For statistical analyses, data were transformed by $\sqrt{(x+0.5)}$. Teflubenzuron and Chlorfluazuron showed a strong initial effect over the young larvae and reached control efficacy of 87.7 and 86.6% at the first assessment. Lufenuron and Triflumuron provided control higher than 60%. All insecticides but Diflubenzuron showed control efficacy at five (> 85%) and seven days (100%). At 10 days, even Diflubenzuron controlled 100%. Overall, the control of young *R. nu* larvae was obtained by all insecticides, especially Teflubenzuron and Chlorfluazuron because of their quick effect. Diflubenzuron should not be recommended because it has a slow initial effect while R. nu is voracious and has a short larval phase.

[1387] GENETIC MAPPING OF LOCI AFFECTING RESISTANCE TO INSECTICIDES IN ANOPHELES GAMBIAE

H. Ranson¹, B. Jensen², J. Hemingway¹ & F.H. Collins², 'School of Biosciences, Cardiff Univ., PO Box 915, Cardiff, Wales, CF1 3TL, UK. ³Dept. of Biological Sciences, Univ. of Notre Dame, Notre Dame, IN 46556-0369, USA.

Malaria is the most debilitating vector-borne disease in the world today. Hundreds of millions are infected and more than 2 million are killed every year, mostly children and infants in Africa. Chemical control of the mosquito vectors is an integral part of malaria control campaigns but the emergence of insecticide resistance, is a continual threat to these control efforts. The two major insecticides employed in malaria control today are DDT and permethrin. Resistance to DDT is widespread and, in many areas, house spraying with this insecticide has been replaced by the use of permethrin impregnated bednets. However, permethrin resistance has already been detected in malaria vectors and, given the predicted increase in bednet usage, there are fears that this resistance could have a severe impact on this promising new malaria control method. We have used microsatellite markers to scan the genome of the major African malaria vector, Anopheles gambiae, for loci linked to resistance to DDT and permethrin. We have identified 2 major quantitative trait loci (QTL) associated with resistance to DDT in the ZAN/U strain from Zanzibar and two distinct QTL associated with permethrin resistance in a Kenyan strain of An. gambiae. Resistance in both these strains is associated with increased metabolism of the insecticide, catalysed by glutathione S-transferases (GSTs) in the case of DDT resistance or cytochrome P450s in the case of permethin resistance. An additional resistance mechanism, a point mutation in the voltage-gated sodium channel, the target site of both these insecticides, confers a low level of resistance in the permethrin resistance strain. We have cloned and physically mapped the target site gene and several members of the GST and P450 enzyme families to *An. gambiae* polytene chromosomes. By integrating the physical and genetic maps we can assess the role of these candidate genes in conferring resistance to insecticides. However, a major advantage of the genetic mapping approach is that it can detect novel resistance genes that would be difficult to isolate by functional based cloning. We are therefore isolating additional genetic markers to enable the isolation of the resistance genes by positional cloning.

[1389] EVALUATION OF GROWTH REGULATOR INSECTICIDES ON THE CONTROL OF RACHIPLUSIA NU (LEPIDOPTERA - NOCTUIDAE) ON SOYBEAN

J.L. Reichert', J.C.L. Barbosa² & R.D. Tanabe², 'Lab. Entomology, College of Agronomy & Veterinary Medicine, Univ. Passo Fundo, P.O. Box 611, ZIP 99001-970 Passo Fundo - Brasil. E-mail Reichert @ upf.tche.br; ² Agronomy Graduate Students

Rachiplusia nu is a major insect pest of soybean in Southern Brazil. An experiment was carried out in the growth chamber, adjusted to $23\pm2^{\circ}$ C and 14-hour photophase, to evaluate the efficacy of growth regulators insecticides on the control of *R. nu*. The evaluate the efficacy of growth regulators insecticides on the control of R. nu. The following insecticides were tested: Novaluron 10 g a.i./ha; Lufenuron 10 g; Methoxyfenozide 21.6 g; Triflumuron 14.4 g, and Diflubenzuron 10 g. The insecticides were applied onto experimental plots (3 m wide x 10 m long) by means of a CO, backpack sprayer adjusted to deliver 200 L/ha at a 45-PSI pressure. The larvae used in this test were from a stock population. The experimental units were arranged in a complete randomized design with eight treatments and five replications. Each replication consisted of 10 mature larvae (> 2 cm) kept in plastic containers (11 w \times 11 | \times 3 cm h). The larvae were fed with leaves from the insecticide sprayed area. Insecticide efficacy was calculated according the Abbott's formula at three, five, and seven days after insecticide spray. For statistical analyses, data were transformed by $\sqrt{(x+0.5)}$. At the first assessment, Novaluron provided coutrol of 86.3%, followed by Lufenuron (62.7%). At assessment, rowattron provided control of 80.3%, followed by Lufention (62.7%). At five days, the efficacy of Lufenuron reached 98%, followed by Triflumuron and Novaluron, both with insect control above 90%. At seven days, all insecticides but Diflubenzuron reached 100% control efficacy. At this evaluation, the pre-pupa living population was 52.9% for Diflubenzuron and 47.8% for the control treatment. At the last assessment, on the 10th day, 95.3% of the living population (control treatment) was in the pupal stage. At this point, Diflubenzuron presented a 95% efficacy over the pupal ecdysis. Index terms: Rachiplusia nu, growth regulator insecticides, chemical control

[1390] SULFOTINE[™], A NEW ACTIVE FOR BAITS AGAINST COCKROACHES AND PHARAOH'S ANTS

F. Retlich & V.Rupes, Nat. Inst. of Public Health (NIPH), Srobarova 48, Prague 10, 100 42 Czech Republic, E-mail: rettich@szu.cz , rupes@szu.cz . Research funded by SC Johnson, Inc.-NIPH joint scientific project

Lithium perfluorooctanesulfonate (LPOS, Sulfotine[™]) is an isomeric mixture containing Lamin performately 70% of linear isomer and 30% of branched isomers. Molecular formula for LPOS is C_1F_1 ,LiO,S, and acute oral LD₃₀ for rat is greater than 5,000mg/kg. LPOS exhibits promising oral efficacy to various domestic insect pests, mainly cockroaches and ants. An experimental solid bait (against cockroaches) and liquid bait mounted in plastic boxes (against Pharaoh's ants), both containning 1% a.i., have been used for laboratory and field tests. The solid bait has been evaluated against laboratory (susceptible) and wild strains (pyrethoids tolerant) of the German cockroach, Blattella germanica (L.) and succeptible Oriental and American cockroaches, Blatta orientalis L., Periplaneta americana (L.). The liquid bait has been evaluated against 18 small (totalling 68 females, 8,800 workers and broot) laboratory colonies of Pharaoh's ant (Monomorium pharaonis a_{5000} workers and broot latoratory colonies of Pharaon's and (*Monorium pharaonis* L.). LT₅₀ and LT₅₀ values for *Blattella germanica* ranged from 0.4 to 1.4 and 2.2-5.5 days, respectively. LT₅₆ for *B.orientalis* and *P.americana* ranged from 1.1 to 3.0 and 0.8 days, respectively. The LPOS bait exhibited a single feeding feature. When males and females of *B.germanica*, *B.orientalis* and *P.americana* were fed bait for 2 hrs (and then the baits were removed), mortality was 100%, 92-100% and 100% respectively, after a 5-7 day holding period. LPOS exhibited distinct secondary kill. Pharaoh's ant colonies were destroyed and all members killed, within 4 or 9 weeks (after 5.1 weeks on the average). When the liquid bait boxes were opened and aged at room temperature for 30 days before exposition, only 8 colonies from 10 exposed were destroyed within 5 to 14 weeks (after 7.6 weeks on the average). Two other colonies survived at least 35 weeks with limited numbers of workers but with doubled numbers of females and males of the new generation. In the field, cockroach solid bait has been tested in hospital kitchens infested by B.germanica using doses of 4-5 baits per 10 square meters of area. Ant liquid bait has been tested in apartments using 6 baits per apartment. Reduction of B.germanica (based on sticky trap counts) a week A.T.reached 90 or more%. Reduction ranging from 92% to 100% were observed during a one year post-treatment period. A total of 108 apartments at 6 apartment blocks all infested by Pharaoh's ants, were free of insects (check based on youlk trap counts) 27-128 days A.T., 96.3 days on average. Index terms: Lithium perfluorooctanesulfonate, Blattella germanica, Blatta orientalis,

Periplaneta americana, Monomorium pharaonis, baiting

[1391] EXTRACTS OF CHRYSANTHEMUM CINERARIAEFOLIUM AND QUASSIA AMARA: EVALUATION OF EFICIENCE AND EFFECT ON SITOPHILUS ORYZAE (COLEOPTERA:CURCULIONIDAE)

S. M Rodriguez¹, V. M Frigidi¹, S. Delfino³ & A E.Pelicano⁴, ¹Cátedra de Zoología Agrícola,² Cátedra de Estadística. Fac. de Agronomía, Univ. de Buenos Aires. Av. San Martín 4453 (1417). Bs. As. Argtentina. E-mail: silro@mail.agro.uba.ar

Insecticide and sinergic effects of water and alcohol natural extracts of Chrysanthemum cinerariaefolium and Quassia amara were analized. Two concentrations (10% and 20%) for the first sample were considered. Seven treaments with four repetitions each were evaluated: T1: control: water, T2: Q .amara bark extract solution 10%; T3: C. evaluated: 11: control: water, 12: Q . amara bark exhat solution 10%, 13: C. cinerariaefolium flowers extract solution 10%: T4: the same quantity of C. cinerariaefolium and Q. amara 10%; T5: Q. amara bark extract solution 20%; T6: C. cinerariaefolium flowers extract solution 20%. For the second trial, only one concentration (20%) was considered. Four treaments with four repetitions each were evaluated: T1: control: alcohol. Filter paper humidified with 1 ml of different solutions and over each one of them 10 weevils were placed. Died weevils percentage was considered at 30°, 6, 24 and 48 hours. The analysis of the data was made throught an ANVA and Tukey comparation, applying a significance level of 5%. The water extracts at 20% had the higher insecticide power at 24 hours. A low weevils mortality was detected on T7. There were not differences between treaments at 30' to 24 hours. However, there was mortality to 48 hours (averages: to C. cinerariaefolium was 0,75; to Q. amara was 0,25 and to the mixture of Q. amara and C. cinerariaefolium was 0,25). Significant differences were not registered. Index terms: weevils, sinergic effect, water natural extract, alcohol natural extract.

[1392] THE EFFICACY OF SOME AROMATIC PLANTS AGAINST STORED PRODUCT INSECTS

V. Rozman¹ & I. Kalinovi¹, 'Facul. of Agriculture, Univ.J.J. Strossmayer in Osijek, P. O. Box 719, 31000 Osijek, Croatia, E-mail vrozman@suncokret.pfos.hr.

This research has been carried out to investigate insecticidal activity of some Mediterranean herbs in Croatia against stored product insects, in order to use them as Recological and natural insecticides. Mercantile and seed wheat was infested by adults of *Rhyzopertha dominica* and *Sitophilus granarius* which were treated by *Lavandula* officinalis, Laurus nobilis, Rosmarinus officinalis and Thymus vulgaris with application in two forma: essential oils and plant powder. The insecticidal effect was observed by exposition of time up to 100% mortality of adults. The efficiency of the plant materials was compared to chemical insecticide based on dichlorovos, and to control with no treatment. Complete research was carried out under laboratory and storage conditions treatment. Complete research was called our and in and instance M and M a efficacy against S. granarius showed T. vulgaris essential oils, while L. officinalis and L. nobilis had very good results in powder form. After completed analysis, the quality of mercantile and seed wheat was tested. Mercantile wheat was assayed by using ekstenzograph, farinograph and amilograph determining the quality of flour and it was not changed. The quality of seed wheat was tested by analyses of energy of germination and germination itself. No significant statistical differences were founded among the control semination user, to significant statistical unterences were founded among the control without application and treatments in both characteristics. In general, all investigated aromatic plants (*L. officinalis*, *L. nobilis*, *R. officinalis* and *T. vulgaris*) in forms of essential oils and plant powder showed insecticidal activity against *R. dominica* and *S.* granarius on mercantile and seed wheat under laboratory and storage conditions. In praxis, synthetic insecticides can be partly replaced by these plant products for less quantity of stored wheat and decrease contamination of food and environment.

Index terms: Rhyzopertha dominica, Sitophilus granarius, herbs, stored wheat, control.

[1393] MECHANISMS OF RESISTANCE TO THE INSECTICIDE METHIDATHION IN Amblyseius womersleyi (ACARI: PHYTOSEIIDAE)

M. E. Sato¹⁴, T. Miyata¹, A. Kawai³ & O. Nakano³, ¹Lab. of Applied Entomology, Graduate School of Bioagricultural Sciences, Nagoya Univ., Nagoya 464-8601, Japan; National Inst. of Vegetables, Ornamental Plants and Tea, Aki, Mie 514-2392, Japan; ²ESALQ, USP, CP 9, Piracicaba, SP, 13418-900, Brazil; ²Present address: Inst. Biológico, CP 70, Campinas, SP, 13001-970, Brazil, E-mail mesato@dgInet.com.br, Scholar of CNPa.

The predaceous mite Amblyseius womersleyi is an important natural enemy of Kanzawa spider mite *Tetranychus kanzawai*, which is considered a key pest of tea in Japan. In order to study the mechanisms of methidathion in this phytoseiid mite, a resistant strain of *A. womersleyi* was selected for resistance; and along with this selection, a susceptible strain was selected for susceptibility to methidathion. After four selections for resistance and three selections for susceptibility, the resistance ratio (R/S) at the LC₃₀ increased from 16 to 342 times. The effect of some synergists (PBO, DEM, and DEF) was investigated on the toxicity of methidathion in *A. womersleyi*. The highest synergistic ratio (SR: LC₃₀ without synergist/LC₃₀ with synergist) was observed for piperonyl butoxide (inhibitor of mfo, mixed function oxidases), which increased 12.3 times the toxicity of the insecticide in the resistant population. A second test was carried out using PBO and PTPE (inhibitor of mfo) as synergists. The highest SR was observed for PTPE. mite Tetranychus kanzawai, which is considered a key pest of tea in Japan. In order to study the PTPE, with 59.3 times in the R strain. The results suggest that an increase in oxidative metabolism is involved in this resistance. In another experiment, an insensitive acetylcholinesterase was observed to have some effect on this resistance, however this acetylcholinesterase was thought to be a minor factor for resistance. Cuticular penetration of acceptationintestriate was analyzed, and the results obtained indicate that the penetration is not a methidathion was also analyzed, and the results obtained indicate that the penetration is not a factor involved in this resistance. Another study was about "in vitro" metabolism of methidathion, using different subcellular fractions of the predaceous mile. The degradation of MADPH I"Cl-methidathion by the microsomal fraction of resistant mite, in the presence of NADPH, was 48% higher than that obtained for the susceptible strain, corroborating observations that was 4656 night than that obtained for the susceptible shain, corroborating observations that mfo are involved in this resistance. In a final experiment, the toxicity of eight pesticides was evaluated in the R and S strains of this phytoseiid mite. The R strain was more resistant to all compounds with the exception of bifenthrin. The highest resistance ratios were observed for the insecticides methidathion, acephate, and malathion, for which the R strain was respectively 311, 20.4, and 13.1 times more resistant than the S strain. In the case of the pyrethroid bifenthrin, no cross-resistance was observed for this chemical. Index terms: Predaceous mite, synergist, cross-resistance

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[1394] MECHANISMS OF AZINPHOS-METHYL RESISTANCE IN A STRAIN **OF CYDIA POMONELLA FROM SOUTHERN EUROPE**

B. Sauphanor¹, J.C. Bouvier¹, D. Beslay¹, D. Bosch² & J. Avilla², ¹Unite de Zoologie-Apidologie - INRA, Agroparc, F 84914 Avignon Cedex, France; ²Centro UdL - IRTA de R+D de Lleida. Rovira Roure 177, E-25198 Lleida

A population of Cydia pomonella (Re) was collected in 1997 at Torrefarrera (NE of Spain) from a pear orchard chemically sprayed with organophosphates (mainly azinphos-methyl). Damage at harvest that year was greater than 30%. This population was found to be resistant to several insecticides. The neonates of the F1 generation exhibited a 10-fold resistance to azinphos-methyl compared to a French laboratory susceptible strain (S). This population was kept without selection for four generations to ensure its acclimatization to the laboratory conditions. The resistance to azinphos-methyl reverted to 2.3 fold during this period. A selection pressure with this compound was then applied, which resulted in a This period. A selection pressure with this compound was then applied, which resulted in a 13-fold resistance in the F9 generation. The enzymatic detoxication systems were analysed in the neonates of Re strain and of two strains previously selected for resistance to diffubenzuron (Rt) or to deltamethrin (Rv), and compared with those of the S strain. A 7.8, 7.6 and 9.4 increase of the mixed function oxidase activity was measured in Rt, Rv and Re strains, respectively. The difference between Re and the two other resistant strains was significant. The Re strain also exhibited a significant increase in glutathion-transferase (2.7 fold) and non specific esterase (3.8-fold) activity, while Rt and Rv did not. Moreover, a 5-fold decrease of the sensitivity of acetylcholinesterase to azinphos-methyl oxon occured in Re strain. Further studies are required to determine the involvement of each mechanism in the resistance to azinphos-methyl. Selection with this compound was found to increase the activity of detoxication mechanisms, which could explain the cross resistances frequently observed between azinphos-methyl and insecticides of different classes in C. pomonella.

Key words: codling moth, insecticide, metabolism, acetylcholinesterase

[1396] POPULATION DYNAMICS OF ODONATES IN AGRICULTURAL LANDSCAPES: A LARGE-SCALE ECOTOXICOLOGICAL PERSPECTIVE

T.N. Sherratt, K.F. Conrad & C.J. Thomas, Dept. of Biological Sciences, Univ. of Durham, South Road, Durham, DH1 3LE, UK, E-mail T.N.Sherrati

There is now a general awareness amongst ecologists that many natural populations of insects are most appropriately viewed not as single homogenous units, but as more complex structures, consisting of local semi-autonomous populations, linked to each other by dispersal. This "metapopulation" perspective is particularly important when one has a specific interest in estimating the rate of recovery of a population following the local application of a pesticide. In this paper, we present the results of an extensive markrecapture study of seven species of odonate (dragonflies and damselflies) in a British agricultural landscape. The population densities of odonates recorded around certain ponds fell dramatically when posticides were applied in the surrounding fields. Furthermore, while odonate species differed significantly in their overall rates of dispersal, we found that the probability of individuals of all the species moving between ponds all declined in a simple exponential manner with the distance between ponds. On the basis of these results we quantified the attributes of every pond above 10 m² in the Counties of Cheshire and Durham, using a Geographical Information System (GIS) based on Ordnance Survey 1:2500 scale digital vector map data. By incorporating the observed dispersal characteristics of odonates into this GIS, we have developed a tool which is capable of estimating the rate of immigration of odonates into any pond within these counties. Furthermore, by combining this information with a simple stage-structured population model, we have been able to crudely predict the rate of recovery of any local odonate population, after a pesticide is applied around a given pond within a real landscape. The development of tools and approaches such as these are important if we are to find practical ways of integrating more ecology into the risk assessment process. Index terms: damselflies, dispersal, pesticide, recovery.

[1395] INJECTION OF INSECTICIDES INTO TREE TRUNK FOR CONTROL **OF CITRUS PESTS**

A. A. Seraj, Plant Protection Department, Shahid Chamran University, Ahvaz, I. I. Iran. E-mail: aseraj@ahvazuni.neda.net.ir

One experiment was undertaken to determine the effect of injection of metasystox into Inne tree trunk citrus aurantifolia in spring 1997. Mean percent of citrus leaf mined areas *Phyllocnistis citrella* (Lepidoptera: Gracillaridae) per leaf of 1, 5 and 20 year old trees respectively treatment: 45,43 and 35%. Mean number of citrus oriental mite Eutetranychus orientalis (Acarina: Tetranychidae) per leaf of 5 and 20 year old tree were as follows: Injected treatment were as follows (first week after injection): Injection treatment: 4, 3.5 and 6.2%. Control: 0, 0. And mean number of southern mealybag Nipaecoccus viridis (Homoptera: Diaspididae) were as follows: Injection treatment: 0, 0. Control treatment: 2.5, 1, and 1. The treatments showed little effect of phytotoxicity. The injection of insecticide was more effect on young trees than old ones. A technique for injecting water-soluble insecticides such as metasystox into citrus tree trunks to control citrus pest is described. Ordinary disposable plastic syringes, which can be used repeatly, are used. The advantages of this type of treatment compared to conventional spray techniques can be summarized as follows: 1- The application and absorption of the required dosage of insecticide for pest control takes only a few minutes per tree. 2- as the entire plant system is poisoned all insects, including those in the most concealed hiding places, can be reached. In this way it should be possible with selected chemicals to control special pests and diseases. 3- there is no reason why a tree should not be fully sterile after treatment. In the case of certain pests the chances of reinfestation after treatment should be reduced considerably as survival of some individuals after normal spraying is usually the enemics will be able to attack the pest unhindered as no insecticide residues will be present on the tree.

Index terms: Injection, lime, citrus leaf miner, Eutetranychus citrella

[1397] CONTROL OF "WHITE FLY", Bemisia argentifolii WITE THE INSECTICIDES THIACLOPRID 480 SC; IMIDACLOPRID 700 GRDA AND IMIDACLOPRID 200 SC, IN CUCUMBER PLANTATION.

A.C. Silva'; L. O'. Salgado; J. Gitirana Neto' & M. A. R. Alvarenga'1 - Agroteste Pesquisa e Consultoria Praça Leonardo Venerando, 284 C.P 201 Lavras/MG 37.200-000 Brazil E-mail agrotest@ufla.br; 2 Universidade Federal de Lavras/UFLA C.P 37 Lavras/MG 37.200-000 Brazil

The "White fly" this is the pest more important in Brazil actually. The trial was realized in Uberlândia/Minas Gerais State – Brazil. The cultivate utilized was "Hibrido Safira" planted in $1,0 \ge 0.75$ m spacing. The experimental design used was randomized blocks, with 9 treatments and 4 replications, each plot with 18 m^2 . The treatments were applied 3 times in 24/06/99; 01/07/99 and 08/07/99. The treatments were applied in spray method with volume of 800L/ha. The insecticides tested (Formulated Product/ha) were: 1.Thiacloprid 480 SC - 100 ml; 2. Thiacloprid 480 SC - 150 ml; 3. Thiacloprid 480 SC - 200 ml; 4. Imidacloprid 700 GRDA - 200g; 5. Imidacloprid 700 GRDA - 300 g; 6. Imidacloprid 200 SC - 700 ml; 7. Imidacloprid 200 SC - 1000 ml; 8. Methamidophos 600 CE - 1000 ml and 9. Check. Were realized 3 evaluations weekly at 01/07/99 - 11/08/99; and more 5 evaluations in 15/07/99; 18/07/99; 23/07/99; 29/07/99 and 07/08/99. Evaluated 10 leaves/plot established the number of nymphs and pupas living. The means Evaluated to iterate statistics the number of hymphs and pupas living. The means were separate with Tukey test (p<0,05) and the efficiency established with Abbott formula. The insecticide Thiacloprid 480 SC showed an efficiency between 71,52 and 100,00% until 14 DAA (Days after the last application). Imidacloprid 700 GRDA showed an efficiency between 70,55 and 100,00% until 21 DAA. Imidacloprid 200 SC showed an efficiency between 70,55 and 92,38% until 30 DAA. Index terms: *Remising argentifolii* white fly character cumumber area

Index terms: Bemisia argentifolii, white fly, chemical control, cucumber crop.

[1398] PATTERNS OF ANSWER OF THE ENTOMOFAUNA OF THE CANOPY OF THE BEAN PLANT TO THE IMIDACLOPRID APPLICATION

<u>F.M. Silva¹</u>, M. Picanço¹, R. N. C. Guedes¹, E.J.G. Pereira¹, L. Bacci¹, ¹ Dept. de Biol. Animal, Univ. Fed. de Viçosa, CEP 36571-000, Viçosa, MG, Brazil, E-mail: marquini@alunos.mail.ufv.br.

This research was carried out from december 1998 to February 1999 in Coimbra, Mina Gerais State, Brazil with the objective evaluating the spacial and temporal effect of the neonicotinoid insecticide imidacloprid on the insect comunity associated with bean plant canopy. The experiment was established in a 20 days old bean plantation. The cultivated area had 1.9 ha and it was divided in two parts. The first was sprayed with 147g i.a/ha with a 700 GrDA formulation of imidacloprid. The second part constituted the control treatment where insecticide was not applied. Three transects were marked crossing from one area no another and sampling points 10 m apart from each other were establish in each transect starting from the intersection among the areas treated and not treated. Before the application of the imidacloprid and 3, 8, 14, 22, 29, 37 and 44 days after wards, the densities of the herbivore insects, predators, parasitoids and Collembola were evaluated in the canopy of nine plants. The imidacloprid controlled until the 22^e day after your application the total number of arthropods, total of insects fitossuccivoros, numbers of *Thrips tabaci* (Thysanoptera: Thripidae). *Caliothrips brasiliensis* (Thysanoptera: Thripidae) and *Empoasca kraemeri* (Homoptera: Cicadellidae) until 22 days after the insecticide applications, besides impeding the increase in Collembola (Insecta) density. There were higher densities of *E kraemeri* in the extremes of the treated area which Noctuidae) and *Frankliniella* sp. (Thysanoptera: Thripidae), which present larger densities by mid and end of the cultivation period. Imidacloprid also did not show effect on the number of mines and adults of *Lirionyza* spp. (Diptera: Agromyzidae), total of chewing insects (Homoptera: Aleyrodidae), which present larger densities by mid and end of the cultivation period. Imidacloprid also did not show effect on the number of mines and adults of Lirionyza spp. (Diptera: Agromyzidae), total of chewing insects and *Bemisia tabaci* (Homoptera: Aleyrodid

Index terms: Impact of insecticide, neonicotinoid, Phaseolus vulgaris

[1400] EFFECT OF A NEW FORMULATION OF LAMBDA-CYHALOTHRIN FOR THE CONTROL OF THE BOLL WEEVIL, ANTHONOMUS GRANDIS (COLEOPTERA: CURCULIONIDAE), IN COTTON

<u>R. B. Silva¹, M. Rotundo¹ & G. Papa¹, ¹ Dept. of Biology</u>, Univ. Estadual Paulista, Av. Brasil 56, Zip 15.385-000 - Ilha Solteira/SP, Brazil, E-mail: gpapa@bio.feis.unesp.br

The cotton boll weevil was found in Brazil for the first time in 1982, and even since it is causing considerable losses to the crop. The increasing search for safer alternatives for pest control, which are less aggressive to the environment, has brought a significant development of new insecticide formulations, with possibilities of use in agricultural pest management and contributing to a safer and more efficient way of pest control. The objective of this work was to evaluate the performance of the microencapsulated formulation of lambda-cyhalothrin for the control of the boll weevil, which is one of the main cotton pests in Brazil. The experiment was established under field conditions, in Ilha Solteira/SP/Brazil, using the cultivar IAC-22. The design was of randomized blocks, with 6 treatments and 4 replicates. Each plot consisted of 8 rows of the crop. Each row 10m long, and spaced 1m among each other, and total of 80 m². Five spray operations were conducted for each treatment, at 7-day interval, using a knapsack sprayer at the volume of 300 l/ha. Spray operations were initiated when the infestation level reached 5% of attacked flowering buds. The treatments consisted of a microencapsulated formulation of lambda-cyhalothrin at the concentrations of 5 and 25% (Karate Zeon) and Lambda-cyhalothrin as an emulsifiable concentrate formulation (Karate 50 CE), at the dose of 15g a.i./ha, deltamethrin, as an emulsifiable concentrate (Decis 25 CE) and a concentrate suspension (Decis 50 SC) formulations, at the dose of 10g a.i./ha and control. Evaluations were conducted 7 days after each application, by counting the number of attacked bud flowers (feeding and/or laying) out of 50 randomly picked buds, in each plot. Results showed that the microencapsulated formulation of lambda-cyhalothrin was efficient in controlling the of boll weevil at the two concentrations tested, and that it was similar to the standard treatment with deltamethrin as a concentrate suspension formulation, and better than the treatments with the emulsifiable concentrate formulations. Index terms: microencapsulated, chemical control, pyrethroid

[1399] REPELLENCY OF VEGETABLE OILS ON ADULTS OF ZABROTES SUBFASCIATUS (COLEOPTERA: BRUCHIDAE) IN BEAN GRAINS

G.J. R. Silva¹, <u>I.V. Oliveira¹</u>, R.L.B.C. Coitinho¹ & P.R. Machado¹, ¹Fitossanidade, Univ. Fed. Rural de Pernambuco, Av. Dom Manoel de Medeiros s/n, Dois Irmãos, 52171-900, Recife, P.E. E-mail: jvolivei@elogica.com.br

In the present work it was studied the repellent effect of oils of floral buttons of clove Syzigium aromaticum, leaves of eucalyptus Eucaliptus citriodora, bark of cinnamon Cinnamonum zeylanicuum, and eugenol on adults of Z subfasciatus in bean grains. Arenas formed by three plastic circular recipients were used in the tests. The central recipient was symmetrically connected to the two lateral recipients by plastic tubes. Ten couples of Z subfasciatus with 0-24 hours of age were placed into the central recipient, and 20 g of bean, treated and non-treated with oil, was placed into each one of the lateral recipients. Each oil dose was tested, separately, in ten arenas. The repellency was calculated 24 hours after the confinement of the insects, through the formula: PR = (NC-NT) / (NC + NT) x 100, being PR, percentage of repellency; NC, total of insects attracted in the control; NT, total of insects attracted in each treatment with oil. The number of adults attracted was reduced, and the repellency percentages increased with the oil doses. The eugenol was the most efficient, causing repellency of 93.9 and 86.6%, followed for cinnamon 91.8 and 62.7%, eucalyptus 74.1 and 55.2%, and clove 71.4 and 67.3%, at the doses of 2.5 and 0.5 ml/kg of bean grains, respectively.

Index terms: Insecta, bean weevil, natural insecticide, stored bean pest.

[1401] CARTAP RESISTANCE AND SYNERGISM IN POPULATIONS OF TUTA ABSOLUTA (LEPIDOPTERA: GELECHIIDAE)

H. A. A. Siqueira¹, <u>R. N. C. Guedes¹</u>, <u>M. Picanço¹ & E. E. Oliveira¹</u>, 'Dept. of Animal Biology, Federal Univ. of Viçosa, Viçosa, MG 36571-000, Brazil, E-mail: guedes@mail.ufv.br.

Control failures of cartap used against the tomato leafminer *Tuta absoluta* in Brazil and a recent report of cartap resistance in Brazilian populations of this pest-species led to the investigation of the possible involvement of detoxification enzymes on this phenomenon using insecticide synergists. The insect populations were collected from seven different sites in the states of Minas Gerais, Rio de Janeiro and São Paulo. These populations were subjected to insecticide-impregnated filter paper assays. The concentration-mortality assays were carried out for cartap alone and in mixture (1 cartap: 10 synergist) with the synergists diethyl maleate, piperonyl butoxide and triphenylphosphate which respectively inhibit the enzymes glutathion-S-transferases, cytochrome P450-dependent monooxygenases and esterases. Resistance to cartap was observed in all populations when compared with the standard susceptible population, with resistance ratios ranging from 2.3- to 21.9-fold. Piperonyl butoxide was the most efficient synergist with cartap synergism ratios ranging from 1.3- to 21.0-fold and nearly completely suppressing the resistance to cartap in all populations studied suggesting a major involvement of cytochrome P450-dependent monooxygenases as a cartap resistance mechanism in these populations of *T. absoluta*. Diethyl maleate and triphenylphosphate also synergized cartap in nearly every population, and they still provided partial suppression of cartap resistance in the leafminer populations studied. Therefore, glutathion-S-transferases and esterases seem to play a secondary role on cartap resistance in Brazilian populations of *T. absoluta*. Index terms: Tomato leafminer, insecticide resistance, insecticide synergism, diethyl maleate, piperonyl butoxide, triphenylphosphate

[1402] INSECTICIDE RESISTANCE IN POPULATIONS OF TUTA ABSOLUTA (LEPIDOPTERA: GELECHIIDAE)

H. A. A. Siqueira¹, R. N. C. Guedes¹, M. Picanço¹ & L. C. Magalhães¹, Dept. of Animal Biology, Federal Univ. of Viçosa, Viçosa, MG 36571-000, Brazil, E-mail: guedes@mail.ufv.br.

Control failures of insecticides used against the tomato leafminer Tuta absoluta (Lepidoptera: Gelechiidae) in Brazil led to the investigation of the possible occurrence of resistance of this insect-pest to abamectin, cartap, methamidophos and permethrin. The insect populations were collected from seven sites in the states of Minas Gerais, Rio de Janeiro, and São Paulo. These populations were subjected to insecticide-impregnated filter paper method for concentration-mortality bioassays. We were unable to obtain a single population which provided a susceptibility standard for all insecticides tested. Therefore, the resistance levels were estimated in relation to the most susceptible population to each insecticide. Resistance to abamectin and cartap were observed in all populations when compared with the susceptible standard population, with resistance ratios ranging from 5.2- to 9.4-fold and from 2.2- to 21.9-fold for abameetin and cartap respectively. Resistance to permethrin was observed in five populations with resistance ratios ranging from 1.9- to 6.6-fold, while resistance to methamidophos was observed in four populations with resistance ratios ranging from 2.6- to 4.2-fold. The long period and high frequency of use of these insecticides against this insect-pest suggest that the evolution of insecticide resistance on them has been relatively slow. Alternatively, the phenomenon might be widespread among Brazilian populations of T. absoluta making the finding of suitable standard susceptible populations difficult and leading to an underestimation of the insecticide resistance levels in this pest. Higher levels of resistance to abamectin, cartap, and permethrin are correlated with greater use of these compounds by growers. This finding suggests that local variation in insecticide use was an important cause of variation in susceptibility.

Index terms: Tomato leafminer, abamectin, cartap, methamidophos, permethrin.

[1404] INSECTICIDAL ACTIVITY AND MOLECULAR TARGETS OF LEGUME LECTINS ON THE PEA APHID, ACYRTHOSIPHON PISUM

F. A. M. Sousa¹², G. Duport¹, T.B. Grangeiro², Y. Rahbé¹ & B. S. Cavada², ¹Biologie Fonctionnelle, Insectes et Interactions - UMR INRA/INSA de Lyon, INSA Bäliment 406, 69621 Villeurbanne cedex, France ; ²Dept. de Bioquímica, Univ. Federal do Ceará, Caixa Postal 6033, CEP 60.451-970, Fortaleza, Brasil. This work was supported by a CAPES-COFECUB project (261/98).

In recent years, the insecticidal activity of plant lectins against many insect species, including those in Coleoptera and Homoptera, has been widely reported. Together with advances in transgenic technology and the availability of lectin genes, genetically modified plants are becoming increasingly common in human food products. The mechanism of lectin toxicity seems to be mediated by lectin binding to glycoprotein receptors in the insect midgut epithelium or in the peritrophic matrix. However, little is known about the subcellular and molecular effects of plant lectins on insect physiological systems and their specific molecular targets. In order to study the effects of leguminous lectins on the pea aphid, in vitro toxicity tests against larvae were carried out using ten lectins from the Diocleinae subtribe. This subtribe comprises a group of homologous lectins with mannose/glucose specificity. Statistical comparisons of mortality and growth inhibition curves showed that all the lectins tested exerted concentration-dependent toxic effects on the normal development of the insect. Canavalia brasiliensis (Con Br), *C.bonariensis*, *C.sp.aff.bolivianna*, *Dioclea rostrata* and *D.virgata* lectins were among the more toxic, decreasing the weight of the adult aphid by 50 % at doses between 99 and 122 μ g/ml. Lectin Blot analysis with biotin-labeled Con Br, *Cratylia floribunda* and *D.violacea* lectins were performed on solubilized-protein extracts from the aphid digestive-tube: while all these lectins were shown to share with Con A and GNA many common membrane-protein targets, their binding affinities varied significantly. In order to isolate and characterize a common "receptor" for the Diocleinae subtribe, possibly involved in their toxic mechanism, Con Br-agarose affinity chromatography and other biochemical techniques were performed. Index terms: Lectin, toxicity, Con Br, midgut

[1403] SIGNIFICANCE OF UPTAKE AND BINDING IN LEPIDOPTERA AND COLEOPTERA ON TOXICITY OF DIBENZOYLHYDRAZINE ECDYSONE AGONISTS

G. Smagghe, B. Carton, A. Heirman, W. Wesemael, I., Decombel & L. Tirry, Lab. Of Agrozoology, Dept. Of Crop Protection, Faculty of Agricultural and Applied Biological Sciences, Ghent Univ., Coupure Links 653, B-9000 Ghent, Belgium.

Dibenzoylhydrazine ecdysone agonists are a new group of insect growth regulators (IGRs) causing specifically premature, lethal larval molting, especially in Lepidoptera and Coleoptera. Toxicity bioassays were performed with four agonists, RH-5849, tebufenozide (RH-5992), methoxyfenozide (RH-2485) and halofenozide (RH-0345) against last-instar larvae of the beet armyworm, Spodoptera exigua (Hubner), the cotton leafworm, Spodoptera littoralis (Boisduval), and the Colorado potato beetle, Leptinotarsa decemlineata (Say). Methoxyfenozide was the most toxic against both caterpillar pests, whereas halofenozide showed the lowest LC_{ss} s in the Colorado potato beetle. Subsequently, uptake and excretion of ["C]labeled compound were studied after ingestion together with the distribution pattern in the insect body. In addition, the activity of the ecdysone agonists in terms of their potency to induce evagination in cultured imaginal discs and to bind the target receptors in whole discs in competition with [3H]labeled ponasterone A as compared to the natural molting hormone 20-hydroxyecdysone, was determined. The results obtained discuss the pharmacokinetics and dynamics for binding in relation to the toxicity, especially the difference between both insect orders, for this new group of IGRs.

Index terms: Spodoptera exigua, Spodoptera littoralis, Leptinotarsa decemlineata

[1405] BIOCHEMICAL MECHANISMS OF RESISTANCE IN TETRANYCHUS URTICAE

N. Stumpf & R. Nauen, Bayer AG, Agrochemicals Division, Research Insecticides, D-51368 Leverkusen, Germany, E-mail: ralf.nauen.rn@bayer-ag.de

The two-spotted spider mite, Tetranychus urticae (Acarina: Tetranychidae), is a worldwide pest of a vast range of crop and ornamental plants. T. urticae has developed resistance to numerous acaricidal compounds, but due to its small size the underlying biochemical mechanisms conferring resistance are difficult to study in detail. investigated the toxicology of several acaricides with different modes of action on different developmental stages of several laboratory and field strains of T. urticae. The efficacy of these acaricides on laboratory selected and field strains was compared to a strain supposed to be susceptible to organophosphates and all other chemical groups of commercial acaricides. Biochemical mechanisms of resistance investigated include insensitive acetylcholinesterase, glutathione S-transferase, esterases and cytochrome P-450-dependent reactions. Virtually all field derived strains of T. urticae seem to be resistant to organophosphate insecticides. Therefore acetylcholinesterase polymorphism has been studies in detail in individual spider mite equivalents using a microtiter plate bioassay and fluorescence detection.

Index terms: acaricides, spider mites, acetylcholinesterase

[1406] NEEM DERIVATIVES AGAINST CRAWLERS AND ADULT COCCIDS

S. Suresh, K.Kumar, K.Geetha, Department of Agricultural Entomology, Tamilnadu Agricultural University, Coimbatore 641 003, Tamil Nadu, India.

Many of the insecticides recommended for the control of coccids were also found to be toxic to natural enemies. To over come this a serious of plant derivatives were tested against the crawlers and adult females of Saissetia oleae, Pulvinaria psidii, Ferrisia virgata and Planococcus citri both in the field and in the lab. In the field the insecticides were srayed @ Imil/litre and plant derivatives @1&2%. Pre and post treatment counts were taken on the number of live and dead insects in ten randomly selected trees (5flushes from each) 1,3 and 7days after treatment and arrived at a percentage. In the lab, a leaf /stem disc of 5cm diamater was taken and dipped in the respective concentrations of plant derivatives and standard insecticides for a minute and shade dried and then placed in petriplates with moistened filter paper in three replications. Observations on the mortality of coccids were made similar to field treatment. Results indicated that, Tamil Nadu Agricultural University (TNAU) neem formulations viz., TNAU NO(A) 60EC @ 2%,TNAU NO(C) 2%,TNAU NOPO (C)2% were equally effective in reducing the F. virgata , P. citri,S. oleae and P. psidii population within three days resulting in 90 per cent control 7 days after treatment as that of Neem oil 2%, Fish Oil Rosin Soap 20 & 25g/l and other organic insecticides

Index terms: Ferrisia virgata, Saissetia oleae, Planococcus, citri and Pulvinaria .psidii.

[1408] EFFICIENCY OF INSECTICIDES TO STERNECHUS SUBSIGNATUS ON SOYBEAN

G. L. Tonet, Embrapa – National Wheat Research Center, BR 285, km 174, 99001-970 Passo Fundo, RS, Brazil. E-mail: gabriela@ cnpt.embrapa.br.

Since 1973, Sternechus subsignatus (Col., Curculionidae) was found as a secondary pest on soybean in the State of Rio Grande do Sul, southern Brazil. The increase in extensively cropped areas and the monoculture system, together with no-tillage practices, benefited the insect population. Nowadays it reached the status of major pest. It is an insect that causes damages on seedlings and young soybean plants and moves to different cropping areas searching for host plants to feed on. Damages are caused both by adults and larvae. The adults feed on the branches, surrounding them with scares and scratches, frequently killing the plants, and larvae penetrate the branches. Population of the pest can be reduced by alternative hosts sprayed with insecticides on the border of the main cropping areas. Aiming to test new efficient insecticides to control the pest, an experiment was done at Embrapa-National Wheat Research Center, in Coxilha, RS, Brazil, in a farmer site in 1998/1999 crop season. Three doses of the insecticide thiamethoxam and two doses of thiamethoxam + profenophos were compared with one dose of metamidophos and one of The results showed that thiamethoxam 5 g a.i./ha and thiamethoxam + deltamethrin. profenophos 144 g a.i./ha were the most efficient treatments up to 8 days after treatment, with 84.2 % and 89.5 % of adult control, respectively, although there was no significant statistical difference from the other insecticides and doses tested, which reached up to 80 % of minimum level accepted. Reduction of the insect population resulted in lower number of damaged plants to 36.2 % and 35.2 %, respectively. The test plots showed a rate of 96.9 % damaged soybean plants, eight days after treatment. It is concluded that only thiamethoxam + profenophos showed a control rate higher than 80.0 %, at 11 days after treatment, and no insecticide dose tested reached that rate of control 17 days after treatment.

Index terms: Chemical control, thiamethoxam, metamidophos, deltamethrin, soybean pest

[1407] PERFORMANCE OF THE MICROENCAPSULATED FORMULATION OF LAMBDA-CYHALOTIIRIN FOR THE CONTROL OF THE WHITEFLY, BEMISIA TABACI (BIOTYPE B) (HEMIPTERA: ALEYRODIDAE), IN BEANS

G. V. Tomquelski, F. J. Celoto' & G. Papa', 'Dept. of Biology, Univ. Estadual Paulista, Av. Brasil 56, Zip 15.385-000 - Ilha Solteira/SP, Brazil, E-mail: gpapa@bio.feis.unesp.br

In Brazil, the problems with the new strain of whitefly began in 1991 when high infestations in beans, cotton and soybeans crop occurred, as well in cucurbitaceae and solanaceae. The increasing search for safer alternatives for pests control, which are less aggressive for the environment, has brought a significant development of new insecticide formulations, with possibilities of use in agricultural pest management and contributing to a safer and more efficient way of pest control. The objective of this work was to evaluate the performance of the microencapsulated formulation of lambda-cyhalothrin, at weekly applications and alternated with parathion methyl, for the control of one of the main beans pests in Brazil, B. tabaci. The experiment was established under field conditions, in Ilha Solteira/SP/Brazil, using the cultivar carioca. The design was of randomized blocks, with 14 treatments and 4 replicates. Each plot consisted of 10 rows of the crop, each row 10m long, and spaced 1m among each other, with a total of 50m². Four spray operations were conducted for each treatment, at 7-day intervals, using a knapsack sprayer at the volume of 200 L/ha. Spray operations were initiated as a preventive treatment. The treatments consisted of a microencapsulated formulation of lambda-cyhalothrin at the concentrations of 5 and 25% (Karate Zeon) and lambda-cyhalothrin as an emulsifiable concentrate formulation (Karate 50 CE), at the doses of 10, 20 and 30g a.i./ha, applied as a sequential treatment each 7 days and as alternate applications with parathion methyl (Tamaron BR), at the doses of 10 g a.i./ha of lambda-cyhalothrin and 750 g a.i./ha of parathion methyl and control. Evaluations were conducted 7 days after each application, by counting the number of ninphs and adults whitefly in 30 leaves per plot. To count the ninphs, the leaves were taken to the laboratory and the counts were conducted with an stereoscopy microscopy. The counts of adults were conducted in the field, during the first hours of the morning because at this time the flies do not use to fly, which makes counting easier. Results showed that all formulations and concentrations of lambda-cyhalothrin were efficient for the control of whitefly at the dose of 30g a.i./ha and at the dose of 10 g a.i./ha, in alternate applications with parathion methyl, at the dose of 750 g a.i./ha. Index terms: chemical control, pyrethroid, organophosphate

[1409] DELTAMETHRIN RESIDUES ON/INCORN AND POPCORN GRAINS AND IN SOME OF THEIR PROCESSED PRODUCTS DETERMINED BY GAS CHROMATOGRAPHY

L.R.P. Trevizan¹, <u>G.C. de Baptista</u>¹ & O. Bahia Filho¹, ¹ Departamento de Entomologia, Fitopatologia e Zoologia Agrícola, ESALQ/USP, Av. Pádua Dias, 11, 13418-900 Piracicaba, SP Brazil, E-mail gcbaptis@carpa.ciagri.usp.br.

This study had the objective of evaluating the degradation/persistence of the residues of the pyrethroid insecticide deltamethrin on/in corn and popcorn grains and in some of their processed products, such as: corn: grain, wranjica", "farelinho" and "biju" (corn flour); popcorn: grain and popcorn. The grains were treated with the recommended dose of 0.35 mg . kg^d (ppm) of a.i. deltamethrin for the control of the lesser grain borer (*Rhyzopertha dominica*) and weevils (*Sitophilus* spp.), with the use of K-Obiol 25 CE (25 g deltamethrin + 250 g PBO/L) commercial product, with three replicates. Samples were taken at zero, 15, 30, 60 and 90 days after treatment. The analytical method consisted of extraction of residues with a mixture of hexane + ethyl ether (1/1, v/v), clean-up by partition with acetonitrile/hexane and silica gel column chromatography eluted with a mixture of hexane + ethyl ether (9/1, v/v). Quantitative measurements were made by gas chromatography, equipped with an electron capture detector (μ - ECD, Ni⁴⁵). A total of 210 samples (60 grains and 150 processed products) was analyzed. The limits of the method quantitation were different for the various matrices ranging from 0.01 mg . kg⁻¹ to 0.05 mg . kg⁻¹. Deltamethrin residues were persistent and stable in both kind of grains during the entire storage period (90 days). In corn processed products they remained mostly in the bran (3.5 times higher than in grain); very low residues were found in the endosperm, from which "canjica", "farelinho" and "biju" are obtained; popcorn has a trend of residue concentration 50% higher than in grain).

Index terms: Rhyzopertha dominica, Sitophilus spp., lesser grain borer, weevil

[1410] PULVERIZATIONS WITH THIAMETHOXAM TO CONTROL ADULTS OF *DIABROTICA SPECIOSA* ON SMALL POTATO CROP

M.A. Valério¹, <u>I.C. Martins¹</u>, M. Nishimura³, ¹Fundação Faculdade de Agronomia "Luiz Meneghel", P.O. Box 261, Area Code 86360-000 – Bandeirantes – Paraná – Brazil, E-mail jcelso@ffalm.br; ²Novartis Biociências – São Paulo – São Paulo – Brazil.

Although small potato its not large cultivated, it has important place among agricultural regions in Brazil, sheltering pests as *Diabrotica speciosa* (Coleoptera – Crysomelidae) doing high economical losts. This trial was conducted in Guarapuava City – Paraaf State, during summer crop 98/99, with the purpose to check efficiency and agronomical use of thiamethoxam as insecticide, applied by pulverization, in order to control adults of *D. speciosa* on small potato crop, Atlantic cultivar. It were used following treatments and doses in g a.i./ha: thiamethoxam (Actara 25 WG – 10, 12,5 and 15); deltamethrin (Decis 25 CE – 8); methamidophos (Tamaron BR – 480) and control (with no insecticide). Experimental design was randomized blocks with 6 treatments and 4 replications, using Tukey's test for medium comparing and Abbott's formula to obtain efficiency percentage. For both insecticides applications it was used, with an interval of 7 days, a back manual sprayer with constant pression of 4,1 Bar, equiped with a plain jet 11002 and 200 l/ha of volume. At evaluations, doing at 7 d.a.a.¹ and 7 d.a.a.² it were taken 25 randomized leaves/plot and counting found perforations number done by the insect. Higher doses of thiamethoxam were very efficient, given more than 80% to control adults of *D. speciosa* at all evaluations.

Index terms: Diabrotica speciosa, chemical control, small potato.é

[1411] INSECTICIDE THIAMETHOXAM USED ON DIFFERENT FORMULATIONS TO CONTROL MYZUS PERSICAE ON SMALL POTATO CROP

M.A. Valério'; <u>J.C. Martins'</u> & G. Nakamura', 'Fundação Faculdade de Agronomia "Luiz Meneghel", P.O. Box 261, Area Code 86360-000 – Bandeirantes – Paraná – Brazil, E-mail jcelso@ffalm.br; 'Novartis Biociências – São Paulo – São Paulo – Brazil.

Aphids are responsable for economical damages on small potato crop, due by transmission of virotical diseases. This trial was conducted in Guarapuava City, Paraná State, during summer crop 98/99. With the purpose to check efficiency and agnomical use of thiamethoxam, on different formulations, applied on different periods, in order to control Myzus persicae on small potato crop, Monalisa cultivar, it were used following treatments and doses at g a.i./ha: thiamethoxam (Actara 25 WG – 150 – 200); thiamethoxam (Actara 10 G – 150 – 200); phorate and aldicarb (Granutox 5 G – 2000 and Temik 15 G – 2025); thiamethoxam (Actara 25 WG – 150 and Actara 25 WG – 150 and Actara 10 G – 150 and Actara 25 WG – 200) and control (with no insecticide). The experimental design was randomized blocks with 6 treatments and 4 replications, using Tukey's test for medium comparing and Abbott's formula to obtain efficiency percentage. Liquid insecticides were applied on planting furrow and on plants before heaping at treatments 1, 2 and 5 with a back sprayer equiped with a 11002 nozzle, pression of 4,1 Bar and 200 *l*/ha diveloume. Granulated insecticides were handly applied on treatments 2, 3, 4 and 5 on planting furrow and at soil, besides plants before heaping. At evaluations, at 15, 30 and 45 d.a.e., it was taken a single randomized leaf on 20 randomized plants/plot and counting alive found aphids. Insecticide thiamethoxam 25 WG applied on pulverization, was the most efficient, upper than 80% at all evaluations on aphids control. Index terms: *Myzus persicae*, chemical insecticides, small potato.

[1412] THE EFFECT OF AQUEOUS EXTRACT OF AZADIRACHTA INDICA LEAVES ON THE CONTROL OF SPODOPTERA FRUGIPERDA FED WITH CORN LEAVES

P. A. Viana¹, H. T. Prates¹, I. Cruz¹ & J. M. Waquil¹, ¹Embrapa Milho e Sorgo, Caixa Postal 151, Sete Lagoas, MG 35701-970, Brazil, E-mail: pviana@cnpms.embrapa.br.

The fall armyworm, Spodoptera frugiperda is considered one of the most important corn pests. The control of this insect has been accomplished with synthetic insecticides, generally of high cost and with unknown molecules for the farmers, increasing the risks of toxicity and environmental contamination. The use of plant extracts may reduce the use of synthetic insecticides. The neem plant (Azadirachta indica) has shown insecticide activity for several species of insects. Aqueous extract of neem leaves was evaluated for its insectidal action against newly hatched S. frugiperda larvae. Corn leaves were submerged in this extract (10.000 μ g mL⁻¹) in laboratory or sprayed in the field with a CO, sprayer (80.03 flat nozzle, 40 p.s.i.) and placed in 50 ml plastic cups with 25 larvae each. The corn leaves were changed every other day. Twenty-five cups were used for each treatment. One group of larvae placed into the cups was sprayed with the extract and other group was not sprayed. The control treatments were made of corn leaves without the neem extract and infested with larvae not sprayed. Three and ten days after the beginning of the experiment, the number of live larvae was evaluated in each cup. At the 12th day, the effect of the extract was evaluated on the development of the live larvae (larva length, weight and width of the head capsule). There was low control efficiency, varying from 6.2 to 13.9%, three days after the application of the neem extract. At ten days the control efficiency varied from 12.6 to 94.4%, where the submerged leaves and larvae sprayed with the extract had 94,4% control, submerged larvae and larvae without spraying had 87,3% control, leaves and larvae sprayed had 32,2% control, and leaves without extract and larvae not sprayed had 12,6% control. The larvae fed on leaves submerged in the extract of neem stopped feeding after the first food change, causing the death of the larvae. The surviving larvae suffered a strong negative effect on its development. Larvae fed with leaves submerged in the extract were 5,8 mm long, weighed 5,0 mg and had a head capsule width of 0,9 mm, whereas the larvae in the check treatment were 24,6 mm long, weighed 205,0 mg and had a head capsule width of 2,5 mm. It was observed that the spraying on the larvae did not show efficiency in controlling the larva and the uniform covering of the leaf with the extract was an essential condition for the effectiveness of control.

Index terms: fall armyworm, neem, natural insecticide, insecta, Zea mays

[1413] RECLAMAL[†] N OF SELENIUM-CONTAMINATED SITES: RESPONSE OF SPODOPTERA EXIGUA (LEPIDOPTERA: NOCTUIDAE) TO CONTAMINATED ALFALFA AND ATRIPLEX PLANTS

D. B. Vickerman & J. T. Trumble, Department of Entomology, University of California, Riverside, CA 92521, USA.

Selenium (Se) is a significant pollutant associated with irrigation in nearly every Pacific Rim country. Many organisms have been severely affected, including fish, birds, and The primary effect appears to be the replacement of sulfur with selenium in mammals. amino acids resulting in nonfunctional proteins and enzymes. Very little information is known about the impact of selenium on insects, or how insects might affect biomagnification and remediation of selenium. Alfalfa, Medicago sativa, and several Atriplex spp. have been proposed as suitable plants for reclamation of selenium-contaminated sites. Our previous studies using artificial diet demonstrated form and concentration of selenium (Se) significantly influence development and survival of Spodoptera exigua (Lepidoptera: Noctuidae) in no-choice tests. Choice tests demonstrated a preference for control diet over sodium selenate treatments and sodium selenite treatments, but no preference between selenocystine or selenomethionine and untreated controls. Since all forms of selenium tested are toxic to these insects, this differential detection has the potential to affect both the distribution and diversity of terrestrial herbivores in both agricultural and natural systems. Both feeding and oviposition preferences will be critical to the use of plants in reclamation. For nearby growers, there may be a tradeoff; these plants can become a potential winter harborage for the important pest, or a 'sink' in which oviposition occurs, but development is inhibited. Development, survival and behavioral response of S. exigua to Se treated plants will be discussed.

Index terms: sodium selenate, Medicago sativa, biomagnification

[1414] THIACLOPRID - FIRST EXPERIENCES WITH THE NOVEL INSECTICIDE IN BRAZIL

I.Wetcholowsky 1, J.A.Geraldes 2, P.Calegaro 2, J.Kühnhold 1, 1 BAYER AG, PF-E-BE, Landwirtschaftszentrum Monheim, Geb. 6100, 40789 Monheim, Germany, Email Ingo Wetcholowsky.IWI@bayer-ag.de; 2 BAYER S.A., Proteção das Plantas, Rua Domingos Jorge, 1100; B. Socorro, 04779-900, São Paulo, S.P., Brazil, Email Jose.Geraldes.JG@bayer.com.br

The novel insectide Thiacloprid, launched in Brazil under the commercial name "Calypso", belongs to the chemical group of the Chloronicotinyls. Due to its properties it shows an unique activity. Its action is based on an interference with the transmission of impulses in the nerve system of insects. The product's effect is due to a disorder of the nervous system and, as a consequence, in death of the treated insects. On account on this mechanism of action, it is effective against strains of pests which are resistant to conventional products. Thiacloprid acts as an acute contact and stomach poison. The systemic activity is excellent which is combined at comparable low rates of application. Thiacloprid has a broad spectrum of activity, particularily against sucking insects, but also some species of coleoptera and lepidoptera. The product is safe on bees and many beneficial insects and therefore fits well into the IPM-concept. At present Thiacloprid has registrations in 14 different crops in Brazil. With rates between 48 and 96 g/ha a.i. it performs excellent against aphids, whiteflies, bugs and some coleoptera. In several years of trials with various formulations in numerous crops, Thiacloprid showed excellent crop compatibility.

Index terms: Thiacloprid, Calypso, Chloronicotinyl, Aphids, Thrips, Bugs, Coleoptera, Lepidoptera, IPM

[1416] COMPARISON OF ROTENONE CONTENT AND INSECT BIOACTIVITY BETWEEN ROOTS AND CALLUS CULTURES OF DERRIS ELLIPTICA

X. N. Zeng¹, J. T. Coll², J. J. Xie¹, X. Q. Liu¹ & F. D. Camps², ¹Lab. of Insect Toxicology, South China Agric. Univ., Guangzhou 510642, P. R. China; ²Inst. for Chemical and Environmental Research of Barcelona, CSIC, Barcelona 08034, Spain. The financial support from The National Natural Sciences Foundation of China (No: 29672001) and The Natural Sciences Foundation of Guangdong Province (No: 970027) to the present research is greatly acknowledged.

The rotenone content and insect bioactivity between roots and callus cultures of D. elliptica were compared in the laboratory. Root samples (<0.8mm in diameter) were collected from fields and the callus cultures were obtained by sub-cultivation of callus initially induced from leaves on revised MS media (Zeng et al. 1998). Samples were extracted twice with 10 times (V/W) 9:1 CHCL/MeOH for 24 h. under room temperature, purified by gradient filtration of the C-18 reversed-phase column and analyzed by HPLC using 70:30 MeOH/H₂O as mobile phase. The results showed that the roots and callus contained 2721.1 and 559.7 μ g/g rotenone, respectively. Bioassays of acetone extracts were conducted against cabbage worm, *Pieris rapea*. At the same rate of rotenone might play some role in the bioactivity. However, no significant difference can be seen between the bioactivity of roots and callus. All samples did not show repellence of egg deposition. Index Terms: botanical insecticide, *Pieris rapea*, bioassay

[1415] INFLUENCE OF SPINOSAD ON SOME HYMENOPTEROUS NATURAL ENEMIES OF AVOCADO, CITRUS AND OTHER ORCHARD PESTS

<u>M. Wysoki</u>, S. Rene, M. Eliahu & D. Blumberg, Dept. of Entomology, Institute of Plant Protection, ARO, The Volcani Center, Bet Dagan, 50250 Israel; e -mail: manesw@netvision.net.il

Spinosad under the trade name Tracer® a mixture of spinosyn A & D, produced by Saccharopolyspora spinosa (Actinomycetes), is used in Israel against the recently introduced orchid thrips, Chaetanaphothrips orchidii (Moulton)(Thysanoptera :Thripidae). Since many parasitoids of citrus and avocado pests where introduced and well established in Israel, influence of this product on some of the local and introduced natural enemies was evaluated. Two concentrations of the commercial product: 0.02 % (the recommended) and 0.01% were tested in laboratory trials and in preliminary field trials. Trials were performed on the influence of Spinosad on natural enemies, of pseudococcid citrus pests: Anagyrus pseudococci Girault and Leptomastix dactylopii (Howard)(Hymenoptera : Encyrtidae), a parasitoids of citrus mealybug, Planococcus citri (Risso); L. algirica Triapitzin (Hymenoptera : Encyrtidae), a parasitoid of citriculus mealybug, Pseudococcus Cryptus Hempel and on Thripobius semiluteus Boucek (Hymenoptera: Eulophidae), a well established parasitoid successfully controlling the greenhouse thrips, Heliothrips haemorrhoidalis (Bouche') (Thysanoptera :Thripidae) and on Metaphycus stanleyi Compere (Hymenoptera: Encyrtidae) the most abundant parasitoid of the pyriform scale, Protopulvinaria pyriformis Cockerell (Homoptera: Coccidae). Additionally was evaluated the influence on Mastrus ridibundus (Gravenhorst) (Hymenoptera: Ichneumonidae) a parasitoid of an apple pest, the codling moth, Carpocapsa pomonella (L.)(Lepidoptera: Tortricidae). This product shows detrimental influence on hymenopterous parasitoid is both concentrations in laboratory trials and long persistence in preliminary field trials.

[1417] TRITROPHIC IMPACT OF HOST PLANT RESISTANCE - SOME POTENTIAL PITFALLS FOR GENETICALLY MODIFIED CROPS

H. F. van Emden, Dept. of Agriculture, Univ. of Reading, Earley Gate, Reading. RG6 6AT, UK, E-mail h.f.vanemden@reading.ac.uk

Of the various ways in which plants can influence the natural enemies of herbivorous insects, three are relevant to pest resistant crop varieties, whether produced by conventional or transgenic methods. One relates to the responses of beneficial insects, particularly parasitoids, to volatiles from the host plant. There may be problems if the odour of a new variety is greatly different from that of other widely grown varieties of the crop. Secondly, if toxic allelochemicals are the basis of the pest resistance, there is the potential for mortality or sterility of natural enemies. The transfer to a crop variety of a single insect-toxic allelochemical is exactly the approach used in genetic modification (GM). This is in contrast to more broadly-based plant resistance, which often shows valuable synergism with biological control. Explanations of this synergism (which may be crop-specific or very generally applicable) do not involve the presence of allelochemicals. Thirdly, host plant resistance can effect the susceptibility of the pest to insecticide, and through this the differential mortality of pests as compared with their natural enemies. The smaller, stressed pests on resistant varieties are usually more susceptible to insecticide. The reduced dose then possible is increasingly selective to the degree that natural enemies do not, or at least to a lesser extent, show a similar shift in susceptibility. There are even cases where natural enemies become more tolerant of insecticide on pest-resistant varieties. However, pests may also become more resistant to pesticide where there is an allelochemical basis of a plant resistance. Allelochemicals in plants can raise the level of detoxifying enzymes in pests and reduce their mortality when insecticides are applied. Such induced tolerance to insecticides can be expected with GM crops as well as with conventionally-bred varieties with enhanced levels of secondary compounds. Just as natural enemies have a zero or lower shift than pests to greater susceptibility on many resistant varieties, so they are unlikely to show a shift towards pesticide-tolerance when the resistance is allelochemically based. With raised concentrations of insecticide then required against the pests, damage to biological control will increase. These three interactions between plant resistance and the third trophic level make a comparison with conventionally-bred pest-resistant varieties unfavourable for GM crops. However, host plant resistance is not often the technology for controlling pests that GM is designed to replace; much more usually it is use of insecticides. Then GM crops compare very favourably.

Index terms: Allelochemicals, biological control, insecticides.

[1418] TRANSGENIC INSECT RESISTANT PLANTS AND NATURAL ENEMIES

T. H. Schuler, Dept. of Entomology & Nematology, IACR-Rothamsted, Harpenden, AL5 2JQ, UK, E-mail Tanja, Schuler@bbsrc.ac.uk.

All currently commercialized insect resistant transgenic plants express δ -endotoxin genes from Bacillus thuringiensis (Bt). Parasitoids and predators are important natural enemies of pest insects and potential side effects of Bt plants on these beneficial insects are being studied. Direct negative effects of Bt crops have so far only been observed with one predatory insect but Bt plants will have indirect (or host-mediated) effects on both groups of natural enemies when compared to unsprayed crops. Current commercial Bt crops will cause host depletion for natural enemies specializing in highly susceptible target pests since the Bt crops cause close to 100% mortality of first instar larvae of such pests (e.g. European cornborer, Colorado potato beetle). Local survival of populations of specialists natural enemies will depend on the availability of other suitable food plants for their hosts, either weeds or other crops, in the vicinity of the Bt crop. In addition to target pests, crops also support other herbivores (the non-target pests) which are not susceptible to the Bt toxins or only susceptible to a limited degree. The supply of hosts for more generalist natural enemies will therefore be less dramatically reduced. The farming system and the general crop management, by controlling the presence of alternative food plants, will strongly influence the presence and size of natural enemy populations. However, the side effects of Bt plants have to be seen in context. Current conventional farming relies largely on broad spectrum insecticides for pest control which not only reduce host availability to parasitoids and predators but in addition indiscriminately kill the natural enemies of both target and non-target herbivores via direct contact activity. Bt plants should be used as a component within Integrated Pest Management (IPM) programmes which take into account beneficial insects. Natural enemies present useful tools to control non-target pests in crops and potentially can also assist with delaying the buildup of resistant pest populations. There is a strong case to be made for managing Bt crops as to encourage natural enemy populations if the promise that Bt crops will result in a long term reduction in insecticide use is to be realized.

Index terms: Bacillus thuringiensis, Bt crops, environmental risk assessment, parasitoids, predators

[1419] PLANTS KNOW HOW TO BE SWEET: PATTERNS OF EXTRAFLORAL NECTAR PRODUCTION OPTIMIZE INDIRECT DEFENSE

F. L. Wäckers, Dept. of Entomology, PO Box 8031, 6700 EH Wageningen, the Netherlands. NIOO CTO, PO Box 40, 6666 ZG Heteren, the Netherlands. E-mail: waeckers@cto.nioo.knaw.nl.

Extrafloral nectaries are commonly found in a broad range of plant taxa. Rather than serving a role in pollination, these nectaries are believed to represent a type of indirect plant defense. It is believed that the secretion of extrafloral nectar enables plants to attract and retain predaceous insects (e.g. ants and parasitoids), which in turn can guard the plant against herbivore attacks. Here I will test this putative defensive function, by addressing whether the temporal and spatial distribution of extrafloral nectar production fits predictions from the optimal defense theory. Patterns of extrafloral nectar production in castor (*Ricinus communis*), cotton (*Gossypium herbaceum*), and faba bean (*Vicia faba*) are compared. It could be demonstrated that extrafloral nectar production can be both constitutive, and inducible. The mechanism of induction was elucidated and it will be discussed how this mechanism differs from induction mechanisms known from other plant defenses. Finally, the effect of nectar distribution on ant recruitment is elucidated. Index terms: *Gossypium herbaceum*, induction, *Spodoptera littoralis*, sugar, ant

[1420] PLANTS CRY FOR HELP: DO PLANT BREEDERS AND BIOCONTROL COMPANIES LISTEN?

Marcel Dicke, Olga Krips & Conny Schütte, Lab. of Entomology, Wageningen Univ., P.O. Box 8031, NL-6700 EH Wageningen, The Netherlands. E-mail: marcel.dicke@users.ento.wag-ur.nl.

Host-plant resistance and biological control are highly valuable components of environmentfriendly pest control. However, these two components are not a priori compatible. The biological control agents are active on the plant and are thus affected by a wide range of plant traits that can influence their effectiveness either directly or through interactions with the pest organism. In order to develop an integrated pest management program that incorporates both methods of pest control, we should consider how the crop affects the beneficial organisms. Ideally we should incorporate the impact of plants on beneficial organisms both in selection procedures that select for the best plant cultivar for agriculture and in selection procedures that select for beneficial organisms that are most suitable for biological control of pest organisms. This will be illustrated with the example of herbivore-induced plant volatiles. These chemicals are produced by plants in response to herbivory and attract carnivorous enemies of the herbivores and may be considered a chemical 'cry for help'. This plant trait has never been selected for during plant breeding. Yet, it is still present in a large number of crop species, although it may be that the trait is more pronounced in wild relatives. In this presentation I will show how plant breeders can select for crops that have maximal attraction of biocontrol agents and how biocontrol practitioners need to consider intraspecific variation in the ability of the biocontrol agent to respond to the volatiles. An integrated approach should increase the options for environmentally-friendly pest control.

Session 08 - ENTOMOPHAGOUS INSECTS AND BIOLOGICAL CONTROL

[1421] APHID-INDUCED PLANT VOLATILES INFLUENCING PARASITOID BEHAVIOUR

<u>G. M. Poppy</u>¹ W. Powell¹, E. Guerrieri² & F. Pennacchio³, ¹Dept Entomology & Nematology, IACR Rothamsted, Harpenden, AL5 2JQ, UK, Email: poppy@bbsrc.ac.uk; ²Centro CNR per lo Studio delle Tecniche di Lotta Biologica (CETELOBI), via Iuniversita, 100, 80055 Portici (NA), Italy; ³Dipartimento di Biologia, Difesa e Biotecnologie Agro_Forestali, Universita della Basilicata, via N. Sauro, 85, 85100, Potenza, Italy.

The braconid, Aphidius ervi, is an endophagous parasitoid of several aphid species of economic importance, and is a commercially available biological control agent. Research in our labs has focussed on the chemical and behavioural ecology of this important species in a model tritrophic system involving Vicia faba and Acyrthosiphon pisum. In a windtunnel we have shown that females undertake in-flight orientation towards bean plants, Vicia faba, infested with their host aphid Acyrthosiphon pisum. This response to a plant produced "signal" is induced systemically throughout the plant. We have also demonstrated a relationship between the attractiveness of infested plants and the number of aphids feeding, and the duration of the aphid infestation. The parasitoid can also differentiate between plants infested with A. pisum and plants infested with the non-host Aphis fabae. The lack of response to plants infested with A. fabae, may be due to a missing or different component in the "signal" or changes in the ratio of components. This talk will focus on recent developments in our understanding of aphid-induced plant signals. Current research involves attempts to elucidate the mechanisms of the production of the signal within the plant and the role of aphid feeding and/or saliva in this process. We have also expanded our studies into a glasshouse so as to add more spatial complexity to our bioassays. These experiments involve placing "baited" plants in a complex matrix of uninfested plants. Both "baited" plants are infested with a cohort of 50 A. pisum coming from the same clone. However, one of these plants has previously been infested for 72 hours by hundreds of aphids (removed just before the new infestation), whereas the other plant has never been previously infested with aphids. Thus the only difference between the "baited" plants is their previous history of infestation. Twenty mated parasitoids are released into the glasshouse, and the "baited" plants removed after 24 hours and the numbers of mummies recorded over the next two weeks. These experiments demostrate that female parasitoids utilise plant signals to locate aphids in a more spatially complex environment than a windtunnel and that the duration of the infestation is important is attracting parasitoids to attack aphids.

Index terms: Aphidius ervi, Tritrophic interactions, Plant signalling, Indirect defence

[1422] IS IT FEASIBLE TO INCREASE THE ATTRACTIVENESS OF CROP PLANTS TO PARASITOIDS?

T. Turlings, M. E. Fritzsche, S. Gouinguené, C. Tamò & T. Degen, Inst. of Zoology, Univ. of Neuchâtel, Case Postale 2, CH-2007, Neuchatel, Switzerland, Email: Ted.Turlings@zool.unine.ch

Herbivory causes many plants to emit specific volatiles. Parasitoids use the resulting odour to locate their herbivorous prey. We study ways to exploit this phenomenon in order to increase the attractiveness of crop plants to these beneficial insects. Our model plant is maize, which shows a particularly fast reaction to caterpillar attack. Within hours it emits a blend of volatiles consisting mainly of terpenoids. We have found considerable variation among maize genotypes, both in terms of total amounts and specific compounds that are emitted. This variation allows us to test the potential of "creating" maize varieties that are particularly efficient in attracting parasitoids. A complicating, but fascinating factor is the learning ability of parasitoids, which largely determines their responsiveness to specific odour blends. Results of laboratory and field tests are presented and discussed in the context of breeding crop plants to enhance pest control. Index terms: plant synomones, host location, biological control

ABSTRACT BOOK I – XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[1423] HERBIVORE AND NATURAL ENEMY ASSEMBLAGE STRUCTURE: INFLUENCE ON TRI-TROPHIC INTERACTIONS AND BIOLOGICAL CONTROL

<u>P. Barbosa¹</u> & A. Caldas¹, ¹Dept. of Entomology, Univ. of Maryland, Plant Sciences Bldg., College Park, MD, 20742, USA, E-mail pb5@umail.umd.edu and ac182@umail.umd.edu.

Larval free-feeding macrolepidoptera of two riparian trees Salix nigra (black willow) and Acer negundo (box elder) were sampled and sorted by species and abundance. Both relative and absolute sampling has provided insights into patterns of parasitism, and of abundance, diversity, and persistence of macrolepidopteran species. The species on these two trees constitute two macrolepidopteran assemblages in which one to three species were numerically dominant. Using a theoretical model to describe the abundance distribution of species in an assemblage is an effective tool for both describing these assemblages and allowing comparisons among them. The log-series and the log-normal distributions are among the most common theoretical distributions used in community studies. Theoretically, a log-normal distribution is expected to arise in most natural community studies because it is more likely that multiple factors are determining the distribution of that community or assemblage. A log-series distribution, on the other hand, suggests that one or a few factors determine the abundance distribution To verify the commonness of the log-series distribution among insects, we used 36 sampling datasets of different sizes to generate rank-abundance distribution curves. Our analysis indicated that the assemblages on box elder and black willow were best described by a log-series distribution, reflecting the fact that most species were scarce. To verify the commonness of the log-series distribution among insects, we used 36 sampling datasets of different sizes to generate rank-abundance distribution curves. These analyses suggest that the logseries distribution is widespread among Diptera, Lepidoptera, Coleoptera, and many other invertebrate groups. If indeed, the log-series distribution is widespread it should have a significant influence on the interactions among and between natural enemies and their herbivore prey. The implications of the structure of assemblages of herbivore prey/hosts and their natural enemies on the ecology and evolution of three trophic interactions are discussed. Further, potential outcomes of classical and conservation biological control given the assemblage structures noted above are discussed.

Index terms: Assemblage structure, parasitoids, predators, biological control

[1424] ADDING FLORAL RESOURCES TO AGRO-ECOSYSTEMS: MANAGING THE CONSEQUENCES FOR THIRD AND FOURTH TROPHIC LEVELS

<u>S. D. Wratten¹</u>, G. Gurr², L. Berndt¹ & N. Irvin¹, ¹Ecology & Entomology Group, Soil, Plant & Ecological Sciences Division, P.O. Box 84, Lincoln University, Canterbury, New Zealand: ²Orange Agricultural College, The University of Sydney, PO Box 883, Orange, NSW, Australia 2800.

Current debate in "classical" biological control includes concerns about non-target species being affected by released agents. In "conservation biological control", a similar potential exists for unpredicted and unwanted effects. Many predators and parasitoids, whether introduced as "classical" agents or as part of an existing natural enemy community, require pollen and nectar to enhance fecundity, longevity and general fitness. However, adding certain flowering plants to agro-ecosystems can lead to a suite of negative effects. For example, the targeted pest may feed on or shelter in the added resource. Secondly, other predators and parasitoids may benefit from the resource and this may lead to fourth trophic level effects whereby natural enemies of the targeted biological control agent or of other beneficial species in the system may be advantaged. The dynamics and complexity of these effects need to be understood and managed. Examples will be given of case studies that have begun to unravel the consequences of adding floral diversity to enhance biological control.

[1425] CASE STUDIES - TRITROPHIC ASPECTS OF INTEGRATED PEST MANAGEMENT FOR CRUCIFER PESTS IN THE FIELD

R. H. J. Verkerk & D. J. Wright, Imperial College of Science, Technology & Medicine, Biology Dept., Silwood Park, Ascot, Berkshire SL5 7PY, UK E-mail: d.wright@ic.ac.uk

Can an understanding of the complex and dynamic interactions between plants, insect pests and their natural enemies over the crop cycle provide the basis for robust pest management solutions? For example, host plant resistance is not always compatible with biological control and it can vary with growth stage and environmental conditions. In contrast, laboratory studies have shown that host plant quality or cultivar can have an effect on parasitism success, suggesting that cultivar manipulation could be a way of enhancing parasitism in the field. Using examples of crucifer-pest-natural enemy systems in South East Asia (diamondback moth-parasitoid), the United Kingdom and Kenya (cabbage aphid-syrphid/parasitoid), we consider various interventionist approaches. Field studies on cabbage aphid systems will be used to illustrate why modeling techniques can provide improved understanding of applied tritrophic systems compared with conventional methods of data analysis.

[1427] REARING HYMENOPTEROUS LARVAL PARASITOIDS OF APHIDS ON ARTIFICIAL DIETS

<u>F. Pennacchio¹</u>, **R. Farneti¹**, **M. C. Digilio¹**, **P. Fanti¹** & **M. de Eguileor²**, 1Dipartimento di Biologia, Difesa e Biotecnologie Agro-Forestali, Università della Basilicata, via N. Sauro, 85, 85100 Potenza, Italy, E-mail pennacchio@unibas.it; 2Dipartimento di Biologia Strutturale e Funzionale, Università dell'Insubria, via Dunant, 3, 21100 Varese, Italy.

Aphidiines (Hymenontera, Braconidae) are important biological control agents of aphids. The development of artificial diets to rear these parasitoids in vitro would reduce their production costs and would provide a new tool for studying their physiology outside of the host. Recent research work aimed at defining suitable media for the aphid parasitoid Aphidius ervi Haliday, a model species widely used also for behavioural and physiological studies, will be presented. The media formulated until now, on a simple empirical basis, were unable to support the complete development of the pre-imaginal stages of A. ervi. This failure and the general, even though unsupported, hypothesis that endophagous Hymenoptera may have peculiar nutritional and/or physiological requirements stimulated experimental work in vivo on A. ervi nutritional physiology. The pea aphid, Acyrthosiphon pisum (Harris) (Hemiptera, Aphididae), was used as a model host. Parasitism-induced biochemical changes in the host haemolymph were measured and the associated physiological and molecular regulations investigated. Functional morphology and anatomy of A. ervi larvae were studied to identify the major routes and mechanisms involved in nutrient absorption. Artificial diet refinement was carried out, based on these in vivo observations. The oviposition behaviour and the major cues regulating the egg release in aphid dummies were also considered, in order to develop protocols for continuous in vitro rearing of A. ervi.

[1426] ARTIFICIAL DIETS FOR REARING PREDATORS AND PARASITOIDS OF GREENHOUSE PEST INSECTS

<u>S. Grenier</u>¹, P. De Clercq², A. Ferran³, F. Pennacchio⁴, C. Castañe⁵ & F. Kabiri⁴, ¹Labo. Biologie Appliquée, UA INRA 203, INSA Bât. 406, 20 av. Einstein, 69621 Villeurbanne France, E-mail sgrenier@jouy.inra.fr; ²Lab. Agrozoology, Dept Crop Protection, Ghent Univ., Coupure Links 653, 9000 Ghent, Belgium; ³Entomologie Lutte Biologique, SPE, INRA BP 2078, 06606 Antibes, France; ⁴Univ. degli Studi della Basilicata, Dipt di Biologia, Difesa e Biotecnologie Agro-Forestali, Via Sauro 85, 85100 Potenza, Italy; ⁵IRTA, Unitat d'Entomologia Aplicada, Carretera de Cabrils, 08348 Cabrils, Spain; ⁶Biotop, Rte de Biot, 06560 Valbonne, France.

In Europe, biological control is fairly developed in greenhouses. Some predators (the coccinellid Harmonia axyridis, and the heteropterans Orius laevigatus and Dicyphus tamaninii) and parasitoids (Aphidius ervi) are important biocontrol agents which are already used in various greenhouse crops against aphids, aleyrodids, and thrips. Efforts to shorten the production line have been performed by using alternative hosts/prey or artificial diets, but in many cases empirically established artificial diets, if any, are not suited for good quality production of entomophagous insects. Researches were developed to try to define artificial diets for the in vitro production of these natural enemies, based on an analytical and rational approach. The final objectives are different according to the species. We can expect, a diet for mass production for H. axyridis, diets that support the whole life cycle for O. laevigatus and D. tamaninii, and basic information for experimental diets for A. ervi. The predators feed on aphids as natural food and can be produced on Ephestia kuehniella eggs as substitution food. In a first step we analyzed the 2 kinds of food (biochemical analyses of the main nutrients, proteins, lipids, carbohydrates) to determine the nutritional needs. *E. kuehniella* eggs as well as young aphids are rich in amino acids (12% of the fresh weight), but E. kuehniella eggs are 3 times richer in lipids than aphids. Some other medium components such as feeding stimulants, consistency agents, preservative agents and other physiological needs will be defined. In a second step, according to available substrates, different diets suited to each species will be formulated partly by computation. Quality of entomophages obtained on newly developed diets or on adjustments of available diets will be compared with that of control entomophages reared on natural food by using different quality parameters, including biochemical, physiological, and behavioral traits. The differences between insects obtained on natural and artificial foods, will allow to further modify and improve the artificial diets. These researches are conducted in the framework and with the support of the European Commission via contract FAIR6 CT98- 4322. Index terms: Harmonia, Orius, Dicyphus, Aphidius, entomophage.

[1428] IN VITRO REARING OF PARASITOIDS IN BRAZIL: AN OVERVIEW

J. R. P. Parra¹, F. L. Cônsoli² & S. R. Magro¹, ¹Dep. Entomol., Fitop. e Zool. Agrícola, ESALQ-USP, 13418-900, Piracicaba-SP, Brasil, E-mail jrpparra@carpa.ciagri.usp.br; ²Dep. Entomology, Texas A&M University, College Station-TX, 77843-2457, USA.

Researches on *in vitro* rearing of parasitoids in Brazil began in the 1990s at the Department of Entomology of ESALQ/USP, in Piracicaba, SP, with species *Trichogramma pretiosum* Riley, 1879 (Hymenoptera: Trichogrammatidae). At the beginning, pupal viability was low and major deformation of adult abdomen and wings were observed with a diet based on Helicoverpa zea hemolymph (40%), egg yolk (40%), milk suspension (20%) and streptomycin (0.02%). Then, diet adjustments to rear T. pretiosum and T. galloi Zucchi were performed, with the latter never being reared under artificial diet. We made progress on rearing of the 2 species, obtaining the viabilities equal to those in countries which dominate the in vitro rearing technology, with 51% and 26%, respectively. The proportion of the components - hemolymph, egg yolk, bovine fetal serum and anticontaminants - is variable and dependable upon the species. Milk was not considered essential and H. zea hemolymph was very suitable for diets of both species. Although with the same size, the same longevity, the same host preference and having no deformation of the reproductive system, the insects produced in vitro were less fecund than those produced in vivo. Quantitative differences of free amino acids in the components of the diets interfere with the biological behavior of *Trichogramma* spp. Studies on chorion, volume of host egg and behavioral characteristics have improved the in vitro rearing techniques. High-density plastic polyethylene films of 7-8 and 9-10 µm thickness were suitable for making artificial eggs and the texture of the egg by the technical process of deformation was efficient to promote parasitization. Artificial 5 mmdiameter eggs and the proportion of 6 parasitoid females per artificial egg were the best combination for in vitro rearing of two species presenting distinct nutritional requirements. However, these proportions vary according to the strain of the Trichogramma. The diets with pupal holotissues of Diatraea saccharalis (65%), egg yolk (18%), bovine fetal serum (8.5%) or yeast extract solution (8.5%) lactalbumin hydrolysate (8.5%) and anticontaminants (0.3%) provided the best development of *T. pretiosum* and *T. galloi*. Adults obtained from this diet presented behavior and biological characteristics similar to the insects reared in vivo. For the past 2 years, the parasitoid Bracon hebetor (Hymenoptera: Braconidae) has been reared under artificial diet set on parafilm, with a diet similar to that used for T. galloi and T. pretiosum. The viabilities were high for the diet mentioned, although lower than those reared on Anagasta kuehniella host. The spinning of cocoons showed some differences among the diets. Index terms: biological control, artificial diets

[1429] WILL ARTIFIAL REARING SYSTEMS CAUSE A REAL BREAKTHROUGH IN BIOLOGICAL CONTROL? NA INDUSTRY VIEWPOINT

Bolckmans, K,

[1431] IN VITRO REARING OF TRICHOGRAMMA OSTRINIAE PANG ET CHEN

Shichou Han, Wenhui Liu, <u>Living Li</u>, Qiaoxian Chen & Bingkun Zeng, Guangdong Entomological Institute, Xingang West Road 105, Guangzhou 510260, China. E-mail gzgeii@publicl.guangzhou.gd.cn

Asian corn borer, Ostrinia furnacalis (Guenee), is the main insect pest of corn in China. Trichogramma is used widely for biological control of O. furnacalis in North China with about 0.6 million hectare annually. Usually, T. dendrolimi was the species for mass production and releases. But. laboratory experiments showed that T. ostriniae was more effective than T. dendrolimi for parasitizing the eggs of O. furnacalis. In some provinces, T. ostriniae is the dominant trichogrammatid species in the corn fields. The difficulty in mass rearing T. ostrinias with the eggs of Antheraea pernyi limits its wide use in controlling O. furnacalis. In 1985-1986, some species of Trichogramma, including T. ostriniae, were reared in laboratory with in vitro rearing method. But, because it was difficult to attract T. ostriniae to lay eggs into the artificial "host-eggs" (with artificial medium, composed of pupal hemolymph of A. pernyi 40%, 10% malt solution 30%, chicken yolk 20%, Neisenheimer's salt solution 10%400 unit.ml of penicillium & streptomycin) through polypropylene "chorion", the parasitism of artificial "host-eggs" was low. Laboratory experiments showed significant stimulating function of polyvinyl alcohol. The percentages of artificial "host-eggs" (with a 85.79% respectively, while in control (without stimulant) they were 28.18%, 18.56% and 23.60% respectively. Recently, a newly improved machine for automatically making artificial "host-eggs" was designed and manufactured by the Guangdong Entomological Institute and Guangzhou Electronic Research Institute. The productivity of this machine is 1.3 million wasps per hour.

Index terns: Ostrinia furnacalis (Guenee), Trichogramma ostriniae Pang et Chen, in vitro rearing, ovipositional stimulant, polyvinyl alcohol.

[1432] RECENT ADVANCES IN THE DEVELOPMENT OF ARTIFICIAL DIET

D. A. Nordlund¹ & Z. X. Wu², ¹USDA, REE, ARS, MSA, Biological Control and Mass Rearing Research Unit, P. O. Box 5367, Mississippi State, MS 39762-5367, USA, E-mail

donn@ra.msstate.edu; ²Dept. of Entomology and Plant Patholgy, Mississippi State University, P. O. Box 9775, Mississippi State, MS 39762-9775, USA, E-mail

Egg parasitoids are, potentially, among our most valuable biological control agents, in part because they kill the insect pest before it causes any damage. However, egg parasitoids tend to be small, live a relatively short time, and require releases of very large numbers to be effective. Thus, an ability to produce very large numbers of high-quality parasitoids at a low cost is essential to their practical use. Considerable progress has been made in the development of artificial diet based systems for rearing *Trichogramma* spp. More recently, there has been progress in the development an artificial diet based system for *Anaphes iole*. From these two models, we are begining to develop an understanding of what is required to develop both artificial diets and practical artificial diet based mass rearing systems for egg parasitoids. For example, in addition to a high-quality diet, there must exist systems/procedures for collecting large numbers of parasitoid eggs, mixing those eggs with the artificial diet, holding the diet/egg mixture for development, and for harvesting/releasing the adults. In a rearing system capable of producing billions or trillions on insects, most of these steps will require high levels of automation and sanitation. Recent findings, and their implications for system development, will be reviewed and discussed. The development of automated artificial diet based systems for mass rearing of egg parasitoids will have a significant impact on augmentative biological

[1433] PRODUCTION OF PREDATORY BUGS ON ARTIFICIAL AND FACTITIOUS FOODS AND THEIR USE IN GREENHOUSE PEST MANAGEMENT

P. De Clerca, Y. Arijs, S. Walgraef, F. Merlevede & V. R. Chocorosqui, Lab. of Agrozoology, Dept. of Crop Protection, Ghent University, Coupure Links 653, B-9000 Ghent, Belgium, E-mail: Patrick.DeClercq@rug.ac.be.

Several heteropteran predators are commercially available for biological control of a variety of insect pests in European greenhouses. The anthocorid Orius laevigatus has been routinely used for the control of western flower thrips, Frankliniella occidentalis, since the early nincties. Because mass rearing of this anthocorid on eggs of Ephestia kuehniella is relatively expensive, the suitability of different factitious and artificial foods was assessed. Successful development and reproduction of O. laevigatus was noted on hydrated cysts of the brine shrimp, Artemia spp. Also, the predator could be reared on meat-based artificial diets with similar developmental and reproductive success as on E. kuehniella eggs. Podisus maculiventris is a pentatomid predator that is commercially available in The Netherlands since 1997 as an additional asset to suppress outbreaks of noctuid caterpillars in greenhouse vegetables and ornamentals. This pentatomid is easily reared on several factitious hosts, including Tenebrio molitor and Galleria mellonella. Although development is similar on both of these prey types, fecundity on T. molitor is only about half of that on G. mellonella. Mass production of these relatively large predators is hampered by their voracity, necessitating large cultures of prey and forcing up labour costs. Artificial diets based on bovine meat proved to be suitable for the production of Podisus bugs, although development is slightly prolonged and achieved body weights and fecundity are lower. Perillus bioculatus is a pentatomid predator of mainly chrysomelid prey that has potential for the biological control the Colorado potato beetle, Leptinotarsa decemlineata. P. bioculatus was able to develop on bovine meat diets, but the results were inferior to those obtained on larvae of the cotton leafworm, Spodoptera littoralis.

[1434] LABORATORY PRODUCTION AND FIELD EVALUATION OF HYMEMOPTEROUS ECTOPARASITOIDS REARED ON ARTIFICIAL DIETS

J. E. Carptenter¹, P. D. Greany², S. M. Ferkovich³, & D. B. Gelman⁴, ¹USDA-ARS, Crop Protection Management Research Unit, P.O. Box 738, Tifton, GA 31793; ²USDA-ARS (retired), Tallassee, FL; ³USDA-ARS, CMAVE, Gainesville, FL 32604; ⁴USDA-ARS, Insect Biocontrol Laboratory, Beltsville, MD 20705.

Diapetimorpha introita (Hymenoptera: Ichneumonidae), a native ectoparasitoid of Spodoptera spp. pupae was reared in the laboratory on an artificial diet devoid of any insect host components. Diet-reared wasps demonstrated a propensity to search for and parasitize natural hosts in a field cage trial. Longevity of the diet-reared wasps was comparable with the longevity of wasps reared on host pupae. Survival rate of D. introita was 67.3% when reared on diet and 76.3% when reared on host pupae. Developmental time was significantly longer for wasps reared on the artificial diet than for wasps reared on host pupae. Reduced fecundity and reduced wasp weight were characteristics of dietreared D. introita. Efforts to improve wasp weight, developmental time, fecundity and longevity have included the use of culture media conditioned by insect cell lines, additional nutrients in the diet, and diets supplemented with lipid extracts from host pupae. These efforts resulted in some improvement in wasp weight and fecundity. Other studies comparing molting hormone titers of diet-reared and host-reared D. introita were undertaken to elucidate factors responsible for the reduced emergence of diet-reared wasps. After the initiation of cocooning, there were six stages of development in which hemolymph ecdysteroid titers were significantly higher in host-reared than diet-reared wasps. Thus, insufficient ecdysteroid in the hemolymph during metamorphosis may contribute to the higher percentage mortality that occurred in wasps reared on the artificial diet. Because the wasps can be reared on the artificial diet without any exposure to host kairomones, we investigated the role of preimaginal and imaginal exposure to host kairomones on the acceptance and preference of different host species. We found that rearing D. introita on artificial diet (in the absence of host kairomones) did not significantly influence female oviposition response in choosing a preferred host. Also, our results indicate that there is limited opportunity to manipulate the host preference of D. introita by preimaginal or imaginal exposure to host or non-host kairomones.

(1435) SCIENTIFIC, SOCIAL, POLITICAL AND ETHICAL ISSUES FOR CLASSICAL BIOLOGICAL CONTROL IN THE COMING MILLENNIUM

Mariorie A. Hov1, 1Dept. of Entomology and Nematology, University of Florida, P.O. Box 110620, Gainesville, FL 32611-0620 USA

Since 1992, three serious pests of citrus have invaded Florida. The first was the citrus leafminer (CLM), Phyllocnistis citrella. The CLM rapidly colonized all of Florida and caused significant damage, especially in nurseries. A classical biological control program was initiated and, with the assistance of scientists in Australia, Thailand and Taiwan, two populations of the encyrtid parasitoid Ageniaspis citricola were imported and released. A. citricola established and spread, colonizing all of Florida's citrus. This parasitoid, in combination with native natural enemies, has reduced CLM populations to the point that few groves are treated for the CLM. Unfortunately, this parasitoid appears to do best in humid tropical and subtropical climates and has failed to perform well in Mediterranean climates. The second invader was the brown citrus aphid (BCA), Toxoptera citricida. This pest caused direct damage to flushes and also is an efficient vector of citrus tristeza virus. During 1999, we obtained a colony of Lipolexis scutellaris (Aphidiidae) with the assistance of Ross Miller in Guam. L. scutellaris has been evaluated in quarantine and we hope to release it in Florida during the 2000 growing season. The third pest was the Asian citrus psylla, Diaphorina citri, which is a direct pest and also a vector of citrus greening disease. Two parasitoids were imported from Taiwan and Vietnam, Tamarixia radiata (Eulophidae) and Diaphorencyrtus aligarhensis Encyrtidae). T. radiata was released during the 1999 growing season and we hope to release D. aligarhensis during the 2000 growing season. Risk assessments conducted for these releases will be discussed, and some thoughts presented regarding the social, political and ethical issues facing classsical biological control workers.

[1436] PARASITOIDS OF CITRUS PESTS IN REUNION ISLAND (INDIAN OCEAN)

S. Ouilici, CIRAD-FLHOR Réunion, Laboratoire d'Entomologie, BP180, 97455, Saint-Pierre Cedex, France. E-mail quilici@cirad.fr

Reunion Island is a French overseas department in the west of the Indian Ocean. Citrus crops, which have been developped there since the last thirty years, are attacked by a variety of pests. The Citrus Greening Disease (CGD) has long been a major limiting factor of citrus growing. Until the 1980's, it was transmitted by the african psylla Trioza erytreae and the asian psylla Diaphorina citri. Among major pests are aphids transmitting the CTV (Citrus Tristeza Virus), particularly Toxoptera citricidus and Aphis gossypii, different species of fruit flies (Ceratitis rosa and C. capitata), the Citrus Rust Mite (Phyllocoptruta oleivora), the South African Citrus Thrips (Scirtothrips aurantii), the Citrus Flower Moth (Prays citri), and various species of scale insects. More recently, the Citrus Leafminer (Phyllocnistis citrella), has been recorded in the island. The Wooly Whitefly, Aleurothrixus floccosus, for a long time a major pest, has been successfully controlled biologically. During the last thirty years, parasitoids have been used in classical biological control programs conducted by CIRAD scientists against citrus pests. The programme against the vectors of CGD can be considered a case-study of successful biocontrol in an island. While the introduction of the eulophid Tamarixia dryi (1974) allowed the eradication of T. erytreae at the beginning of the 80's, the introduction of Tamarixia radiata (1978) led to a drastic reduction in the populations of the asian psylla. A very favorable biological equilibrium also followed the introduction of Cales noacki against the Wooly Whitefly in 1976. More recently, the successful introduction of Ageniaspis citricola in 1997 enabled us to improve the natural control of the Citrus Leafminer. Indigenous parasitoids may play a prominent role in the natural control of various citrus pests, as in the case of the large parasitoid complexes associated with lecanid or diaspid scales. The Margarodidae Icerya seychellarum is under very good control by the combined action of the ladybird Rodolia chermesina and the dipteran parasitoid Cryptochetum sp... Five indigenous parasitoids play a major role in the control of the Citrus Leafminer. Aphids are also attacked by various species of Aphidiidae and Aphelinidae, with a variable degree of control. In other cases, the contribution of parasitoids to the natural control of the pest seems much less effective, like for fruit flies, for which parasitoids contribute as a minor mortality factor on wild host-plants. The possible side-effects of classical biocontrol must be thoroughly considered before any operation, particularly in the case of fragile island ecosystems. Current and future programmes will only consider the possibility of using parasitoids with the narrowest possible host-range. In the meantime, the knowledge of the local entomofauna has considerably progressed, allowing a better prevision of possible side-effects.

ABSTRACT BOOK I - XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[1437] AUGMENTATION OF PARASITOIDS FOR CONTROL OF CITRUS PESTS IN SOUTHERN AFRICA

<u>S. D. Moore¹</u>, V. Hattingh², B. A. Tate² & A. B. Ware², ¹Capespan, P.O. Box 12531, Centrahil 6006, South Africa, E-mail: sean_moore@capespan.co.za; ²Outspan Citrus Centre, P.O. Box 28, Nelspruit 1200, South Africa, E-mail: vaughan_hattingh@capespan.co.za

The southern African citrus industry is committed to an approach of bio-intensive integrated pest management (IPM). In an effort to reduce the use of chemical insecticides, augmentation of natural enemies of certain key pests has been investigated over several years. This involves the mass production and inundative release of large numbers of parasitoids, resulting in an earlier peak in parasitism levels, an earlier decline in pest levels, and hopefully a lower pest presence at harvest. Intensive trials have indicated the value of this approach, particularly with Coccidoxenoides peregrinus, a parasitoid of citrus mealybug, Planococcus citri. In cases of low to moderate P. citri infestation, releases of 100 000 C. peregrinus per hectare per season over a five month period, have proved adequate. Greater release intensities were necessary against high levels of mealybug. Higher levels of parasitism of mealybug were recorded in release orchards than in adjacent control orchards, up to nine weeks after release. This showed that C. peregrinus disperses at a rate of approximately 100m per month. Mealybug came under commercial control biologically in well over 90% of 250ha in which semi-commercial releases were conducted. Lack of control could be blamed on injudicious use of pesticides and ant activity. A similar programme has been adopted with California red scale, Aonidiella aurantii, using Aphytis lingnanensis. The aim is to release 120 000 A. lingnanensis per hectare per season. This is however more difficult to implement than the mealybug biocontrol programme, due to problems with mass production, disruption by thripicides and ants, a low export tolerance for red scale, and uncertainty whether A. lingnanensis is the best species for certain areas. Currently, augmentation of the egg parasitoid, Trichogrammatoidea cryptophlebiae, is also being investigated, for control of lepidopteran pests. Initially a total of only 20 000 parasitoids were released per hectare per season. In one case, level of parasitism was increased by 40% and consequently fruit loss was reduced by 41%, compared to an adjoining non-release orchard. During a second season, 150 000 parasitoids were released per hectare. Early season evaluations indicate a higher level of parasitism and a lower level of fruit damage since parasitoids have been released, than in adjoining non-release orchards. As a consequence of the positive results achieved with these augmentation initiatives, a total of nine insectaries have been established in citrus producing regions throughout South Africa.

Index terms: Coccidoxenoides peregrinus, Aphytis lingnanensis, Trichogrammatoidea cryptophlebiae, Planococcus citri, Aonidiella aurantii.

[1438] MYMARID PARASITOIDS OF THE GLASSY-WINGED SHARPSHOOTER IN SOUTHERN CALIFORNIA CITRUS

<u>P. A. Phillips</u>, Cooperative Extension, Univ. of California, 669 County Square Dr. #100, Ventura, CA 93003, USA, E-mail paphillips@ucdavis.edu.

The glassy-winged sharpshooter (GWSS), Homalodisca coagulata, was introduced into Southern California from the southeastern US around 1990. Increasing populations of this bacterial plant pathogen vector pose a significant threat to several of California's valuable agricultural industries, including citrus, grapes, stone fruits, and almonds. Endemic species of parasitoids (family; Mymaridae; genus, Gonatocerus) have been consistently recovered during field biology studies of the GWSS in commercial citrus orchards in Ventura County. Of the four species recovered (G. ashmeadi, G. morilli, G. incomptu, and G. novifasciatus), G. ashmeadi has accounted for more than 95% of all recorded parasitism. Annual fluctuations in parasitoid activity, as measured by yellow sticky traps and GWSS egg collections, are synchronized with the two periods of GWSS oviposition each year. Parasitism of first generation GWSS egg masses, occurring in the late winter through spring, is very low compared to second generation egg mass parasitism occurring from late summer through early fall. First generation GWSS egg mass parasitism was higher in 1999 than in the previous two years. Despite parasitism rates averaging 40% and ranging from 10 to 85% on second generation GWSS egg masses, GWSS populations continue to increase in Ventura County citrus orchards. In April 1999, a foreign exploration trip was conducted into NE Mexico in search of a more effective parasitoid of first generation GWSS egg masses. Another Mymarid, G. triguttatus was recovered from GWSS eggs in both lemon and peach foliage. Current plans are to import this species through UC quarantine facilities for release into California citrus.

Index terms: Gonatocerus ashmeadi, Gonatocerus triguttatus, parasitism, lemon, vector

[1439] INFLUENCE OF *SPINOSAD* ON SOME HYMENOPTEROUS NATURAL ENEMIES OF AVOCADO, CITRUS AND OTHER ORCHARD PESTS

M. Wysoki, S. Rene, M. Eliahu & D. Blumberg, Dept. of Entomology, Institute of Plant Protection, ARO, The Volcani Center, Bet Dagan, 50250 Israel; e -mail: manesw@netvision.net.il

Spinosad under the trade name Tracer® a mixture of spinosyn A & D, produced by Saccharopolyspora spinosa (Actinomycetes), is used in Israel against the recently introduced orchid thrips, Chaetanaphothrips orchidii (Moulton)(Thysanoptera :Thripidae). Since many parasitoids of citrus and avocado pests where introduced and well established in Israel, influence of this product on some of the local and introduced natural enemies was evaluated. Two concentrations of the commercial product: 0.02 % (the recommended) and 0.01% were tested in laboratory trials and in preliminary field trials. Trials were performed on the influence of Spinosad on natural enemies, of pseudococcid citrus pests: Anagyrus pseudococci Girault and Leptomastix dactylopii (Howard)(Hymenoptera : Encyrtidae), a parasitoids of citrus mealybug, Planococcus citri (Risso); L. algirica Triapitzin (Hymenoptera : Encyrtidae), a parasitoid of citriculus mealybug, Pseudococcus cryptus Hempel and on Thripobius semiluteus Boucek (Hymenoptera: Eulophidae), a well established parasitoid successfully controlling the greenhouse thrips, Heliothrips haemorrhoidalis (Bouche') (Thysanoptera :Thripidae) and on Metaphycus stanleyi Compere (Hymenoptera: Encyrtidae) the most abundant parasitoid of the pyriform scale, Protopulvinaria pyriformis Cockerell (Homoptera: Coccidae). Additionally was evaluated the influence on Mastrus ridibundus (Gravenhorst) (Hymenoptera: Ichneumonidae) a parasitoid of an apple pest, the codling moth, Carpocapsa pomonella (L.)(Lepidoptera: Tortricidae). This product shows detrimental influence on hymenopterous parasitoids in both concentrations in laboratory trials and long persistence in preliminary field trials.

[1440] AUTOMATION IN MASS REARING - MAKING THINGS POSSIBLE

D. A. Nordlund, USDA, REE, ARS, MSA, Biological Control and Mass Rearing Research Unit, P. O. Box 5367, Mississippi State, MS 39762-5367, USA, E-mail donn@ra.msstate.edu.

Insect rearing is essential to much entomological research and for certain pest management approaches. Rearing systems range from research level cultures, producing a few hundred insect per generation cycle, to systems for sterile insect technique or augmentative biological control programs that may require billions/trillions of insects per day. As production capacity increases, the need for automation increases. Mass rearing, defined by Mackauer as "the rearing, per generation cycle, of one million times the mean number of offspring per female," though possible, is not generally practical without a significant level of automation in the system. Automation is use of, more or less, automatically Benefits of automation controlled mechanical devices to perform rearing operations. Benefits of automation include: a reduction in the labor required to perform an operation, performance of an operation at a higher rate, performance of multiple operations at one time, performance of an operation for long periods without interruption, and increased uniformity with which operations are performed; resulting in increased production capacity, improved quality, and reduced production costs. Pest management techniques, such as the sterile insect technique and augmentative biological control, even at the research stage, may require the production of millions of high-quality insects, or more, per day. From the implementation stand point, it is essential that these insects be produced at a low cost, or the technique will not be competitive with alternative management practices. Automation of insect rearing systems makes such pest management approaches possible.

Index terms: insects, biological control, sterile insect technique

Symposium and Poster Session

[1441] RESULTS OF THE DEVELOPMENT AND INTRODUCTION OF ENGENEERING TECHNOLOGIES FOR THE MASS REARING OF ENTOMOPHAGES AND ACARIPHAGES IN THE EASTERN PALEARCTIC REAGION

I. P. Starchevsky¹ & <u>E. A. Sadomov²</u>, ¹Engineering-Technological Institute «Biotechnica», Odessa, 65012, Ukraine, E-mail: biotech@te.net.ua; ² IOBC/EPRS Secretariat, Moscow 107807 Russia, 095 915-7212.

Per 90 years the agriculture and plants protection of the countries by East Palearctic is experienced by deep changes. The economic and legal conditions have changed. Last years the new strategy of organization of an agriculture is created, switching and plant protection. In these countries are available agroregions, differing on ecological and economic conditions requiring for different technologies of protection. By their development we should adhere to principles of steady development, first of all of biological method with preferable use of the natural factors of suppression harmful organisms, organization-economical and agrotechnical methods, steady grades and biological means. It is provided three-stage the decision of a task on a substantiation of prospects of development of a biomethod in conditions of market economy. The special role in biological protection against the wreckers in an open ground is removed Trichogramma and Bracon, which manufacture is mastered practically in all countries by East Palearctic. Taking into account high efficiency of application and rather low cost of these insects the special attention is given to modernization of technological lines on an operating time in view of last engineering development. In practice of biological protection of the closed ground the greatest distribution has received application of predators and parasites greenhouse whitefly, web ticks and decay. In hothouses and seedbeds use of a biological method decides a practical task of cultivation of ecologically clean production in hothouse facilities of Russia, Ukraine, Hungary, Poland, Moldova, Bulgaria etc. In biolaboratories hothouse combines produce necessary volumes encarsia, phitoseiulus, ambliseius, dall-fly, aphidius and others entomo-acariphages, which in conditions of the closed ground, work more effectively in comparison with chemical means of protection of plants. In institute "Biotechnica" (Ukraine) is developed the universal equipment for an operating time entomo-acariphages of the closed ground. The biological laboratory by the industrial area about 90 M² is capable to let out of production for protection 3 ha of hothouses. At the same time it is necessary to note also that the major factor is the reconsideration and possible change of all factors of protection of plants and even plantwork, that the planned purpose, that is restoration and preservation of a biovariety ecosistems could be carried out. Index terms: biometod, plant protection.

[1442] THE ENTOMOLOGICAL INDUSTRY IN THE UKRAINE: CONDITIONS AND PROSPECTS FOR DEVELOPMENT

<u>I.P. Starchevsky</u>, Y.C. Samoilov & LN. Bespalov, Engineering-Technological Institute «Biotechnica», Odessa, 65012, Ukraine, E-mail biotech@te.net.ua

The ecological and economic situation which has been usual in Ukraine has defined formation at a qualitatively new level of official state scientific and technical and industrial politics in the field of biotechnologies as priority strategic direction of scientific and technical progress and its integral component - biologization of agriculture. Thus the task of achievement by Ukraine scientifically - is proved of level of replacement chemical pesticides on biological pesticides much earlier is put, than it will be achieved in the conducting agrarian states of the world. In area entomological of methods of plant protection the basic attention is given to restoration and development on a qualitatively new basis of volumes of manufactures and application trichogramma. The original complex of the equipment ensuring necessary conditions for the contents and an operating time of parties maternal cultures of local races trichogramma is created that has basic importance for maintenance of appropriate quality commodity trichogramma. Besides the idea about creation of new generation of a technological line for mass cultivation Sitotroga, mechanization, distinguished by a high level, of labour-consuming technological operations is realized. Represent also practical interest results of researches on development of technologies and creation of the equipment for mass cultivation Brakon, Dibrahis, Metaseiulus (Institute "Biotechnica", Ukrainian Research station of plant quarantine, Research station of quarantine of a grapes and fruit cultures of institute of plant protection, institute of plant protection Republic Moldova). The complete set of the unified equipment for mass cultivation of a complex entomoacariphages of the protected ground is created. The technology of complex biological protection of hothouse cultures is developed resource saving. Its basic difference consists in maintenance during all vegetation period of dynamic balance of community entomoacariphages and phitophages, that provides essential reduction of need in means of plant protection (institute "Biotechnica").

Index terms: biological pesticide, plant protection, technological line.

[1443] UNIFICATION OF INDUSTRIAL LINES OPERATING TIME ENTOMOPHAGES

K.A. Asanov¹, A.I.Goncharuk² & V.M. Belchenko², ¹Uzbecian Research Institute Plant Protection, Tashkent, 700017, Uzbekistan; ²Engineering-Technological Institute «Biotechnica», Odessa, 65012, Ukraine, E-mail: biotech@te.net.ua.

Task of industrial cultivation entomophages is the operating time of the certain assortment is artificial reproduced parasitoids for suppression harming phitophages. A question on development of criteria of selection of kinds, general principles of their cultivation and designing of lines of flexible manufacture in this connection is lifted. According to a task, criterion of a selection entomophages is accepted a ecological-biological generality of kinds given in one type location, owners, connected to determined ecological group, in certain ontogenetical to a phase consuming a resource by one way. The ecologicalbiological generality assumes the similar ecological standard of kinds, and it means that the life-support in technogenic environment at their artificial cultivation submits to the general technological circuit with the amendments on ecological features of kinds, them trophical specialization. Stated is a basis for offered classification of types of the technological circuits. So, we distinguish 2 such as industrial complexes. In one case focused on the owners, which reproduced on rough forages, in second - on juicy. The industrial complexes include a line of lines differentiated on concrete ecological-biological group of the owners. Each line on cultivation of the owner or their group includes technologies of cultivation egg's egg-larva's, larva's, vimph's the parasites. And, the technology of cultivation egg's, egg's-larva's of the parasites is under construction in view of features eggs laging by the owner. Same concerns to features of technology of cultivation larva's parazitoides freely and the latently lived the owners. Offered criteria of selection of kinds and, system, connected to it, of technological lines allows to hope for exception of long research by a trial and error method, and assortment entomophages is provided not with a casual set of kinds, but purposeful methodical selection. Index terms: selection of kinds, cultivation, reproduction.

[1444] REDUCTION OF PARAMETRICAL SPACE DIMENSION AS A BASIS OF INSECT'S REPRODUCTION AUTOMATIC SYSTEMS CONSTRUCTION

A.V.Chernikov, Engineering-Technological Institute (ITI) "Biotechnica", Odessa, 65012, Ukraine, E-mail: biotech@te.net.ua

The reproduction cycle of an artificial insect's population can be view as object of control. Input parameter at that is the an "quality" of initial generation Q_0 , and output parameter – an "quality" of posterity Q1. The deflective of meaning Q1 factors we shall share into two groups - constant of cycle k and variable of cycle W. A constant of cycle k unites the some deflective factors, which meanings should not appreciably change during a cycle (including Q₀). To not taken into account by a component of a constant of cycle ξ_k carry petty and unknown factors. A variable of cycle W unites deflective of artificial environment (AE), which can be operated. To not taken into account by a component of a variable of cycle Ew carry petty and unknown AE components. Current informative parameters of a cycle can be, for example, meanings of a gas exchange: consumption of oxygen ΔO_2 and allocation of carbon dioxide ΔCO_2 . The basic formula of a cycle is $Q_1 =$ $(k + \xi_k)$ f (W + ξ_w) It is known, that the final "quality" of insect's artificial culture Q₁ can be expressed by one number (Greenberg, 1990). Then the basic task becomes development of a method integrated estimation of the current meaning of a variable of cycle W by the real non-negative number, which will be understood as "AE quality". At numerical control this task has discrete character. For its decision such sequence of actions is propose: physical measurements - normalization - convolution - metrization - cluster analysis classification - resultant number from a range [0;1]. Mathematical modeling very simple AE with dimension n=5 for 3 meanings of each parameter (243 alternative condition) have shown, that there is at least 5 close to optimum by criterion "metabolism level" state of insect's vital functions. Also begins possible to construct usual bivariate diagram of dependence, for example, metabolism level of an artificial insect's population in technocenosis conditions from set of the taken into account factors of a variable of cycle W. Such approach to a problem can be a basis of construction of automatic control systems for biotechnical systems of insect's mass rearing.

Index terms: quality, artificial environment, mass rearing, deflective factors

[1445] DEVELOPMENT AND ORGANIZATION OF MANUFACTURE VIRUS PREPARATION VIRIN

Y.C. Samoilov¹ & V.B. Mitrophanov², ¹Engineering-Technological Institute (ITI) "Biotechnica", Odessa, 65043, Ukraine, E-mail biotech@te.net.ua; ²All-Russia institute of plant protection (UIPP), St.-Petersburg, 189620, Russia

The large-scale application of granulosis viruses for struggle with codling moth restrains by difficulties arising at mechanization and automation of mass cultivation of insects for an operating time of plenties of virus bioweight. There are some alternative ways of real increase of release of a biopreparation on the same industrial areas and at identical expenses for its manufacturing: a) Increase of an output of virus bioweight from one nimph by influence of the various factors on growth of an insect in a stage caterpillar and selection of lines codling moth with higher weight caterpillars; b) Selection virulence strains of a granulosis virus, giving raised output of virus bioweight. On these directions the positive results in ITI "Biotechnica" and UIPP are received. Together with URPP ITI "Biotechnica" has developed and has tested a complete set of the equipment for trial For the equipment of the equipment of a line of manufacture virin $-\Gamma SIII$. The development of the equipment of a line of manufacture virin $-\Gamma SIII$ was conducted in view of the technological rules describing all stages and operation of an operating time of a preparation at each stage. Each of operations of an operating time larva of bioweight is important and requires implicit observance of the technological rules. Especially important the requirement on observance of ecological parameters (temperature and humidity of air, air exchange, mobility of air, duration of light day, light exposure etc.) is. It is especially important for a line maternal of culture. The board of management of all system includes (individual) systems of maintenance of light exposure, sterility of air given temperature and humidity varying within day, and allows distation operate the listed parameters. The system provides regulation of parameters during all cycle of development of insects. The developed system of regulation of ecological parameters can be used by development of lines of mass cultivation of various insects, which untroduce on an artificial medium. The received preparation was applied to struggle with polyvoltine (2-3 and more generations for a season) populations codling moth in Crimea. The technical efficiency virin - ГЯП has made from 70 up to 94 % depending on climatic conditions. Also it is necessary to note, that these preparations are not toxic and are not produced in organism thorough-bred and in cultures of crates. Epidemical danger do not represent. Index terms: granuloses virus, codling moth, larva.

[1446] TECHNOLOGY TRANSFER IN AUGMENTATIVE BIOLOGICAL CONTROL: AUTOMATION FOR COMMERCIAL PRODUCTION AND APPLICATION OF NATURAL ENEMIES

N. C. Leppla⁴, E. S. Delfosse² & F. Ferrer³, ¹Dept. of Entomology and Nematology, Univ. of Florida, P. O. Box 110630, Gainesville, FL 32611-0630, USA, E-mail ncl@gnv.ifas.ufl.edu; ²USDA, ARS, Room 218, Bldg. 005, BARC-WEST, 10300 Baltimore Boulevard, Beltsville, MD 20705-2350, USA, E-mail esd@ars.usda.gov; ³Servicio Biologico, Carrera 5 N0 4-76 Urbanizacion del Este, Barquisimeto - Estado Lara, Venezuela, E-mail fferrer@telcel.net.ve.

Basic principles exist for moving an invention or discovery from research to implementation as a new technology. Inventions or discoveries may include useful machinery, manufactured articles, chemical compositions, processes and organisms. In augmentation biological control, these respective categories encompass rearing and handling equipment, materials for manipulating the organisms, diets and processing chemicals, rearing and application methods, and certain natural enemies. These technologies may be new or significant improvements that can be patented in individual countries, disseminated through the scientific literature or kept secret. Patents disclose the details of a technology but protect the owner from illegal infringement, requiring payment of licensing fees for access. Technology is often provided free of charge by government researchers but most commercial biological control producers do not reveal their advancements. An interesting example of these technology transfer principles is the entomopathogenic nematode, Steinernema scapterisci, originally collected in Uruguay for importation into the United States and patented by the University of Florida. A company patented processes and equipment for mass producing this nematode in liquid culture, storing infective juveniles for long periods, and shipping and releasing them for mole cricket control. This company independently collected and imported S. scapterisci from South America but was not allowed to sell it in the United States without a licensing agreement with the University of Florida. Historically, however, methods for large-scale production and application of natural enemies have been developed by public sector researchers and freely contributed for the advancement of biological control. Notable examples are production of Trichogramma spp., Chrysoperla carnea, Phytoseiulus spp., Muscidifurax spp. and Catolaccus grandis. A recent innovation is to combine patented artificial diets with industrial food processing technology and produce packaged rearing and delivery systems for predators. This kind of system is being tested for Geocoris spp., Orius spp., Cryptolaemus montrouzieri, Hippodamia convergens, Harmonia axyridis and other commercially produced species.

Index terms: Steinernema scapterisci, insect rearing, biological control, patenting and licensing, mass production of natural enemies

[1447] DEVELOPMENT AND IMPLEMENTATION OF AN AUTOMATED SYSTEM FOR MASS REARING PINK BOLLWORM (PECTINOPHORA GOSSYPIELLA)

<u>E. Miller¹</u>, F. Stewart², J. Ploski² & R. Edwards³, ¹USDA-APHIS PPQ PPPC 3645 E Wier Av., Phoenix, Az, USA² USDA-APHIS-PPQ PBWRF 3645 E Chipman Av., Phoenix, Az, USA³USDA ARS Western Region Research Center, Albany Ca.,USA

Since 1995 significant changes have been made in the methodology used to mass rear Pink Bollworm Pectinophora gossypiella (PBW) as the use of sterile PBW release shifts from a 29 year old exclusion program in the San Joaquin valley of California to an Area Wide Management Program for PBW. Production demands for the Pink Bollworm Rearing Facility (PBWRF) will increase from 5 million moths per day to 32 million moths per day in the expanded program. The 32 million per day production schedule is tentatively scheduled for the year 2002. In 1991 work on developing new technology for mass rearing PBW began. Actual implementation of this technology into PBW mass rearing was initiated in 1995. The objective of this change was to reduce labor costs through automation of labor intensive rearing tasks, improve utilization of rearing space and improve rearing efficiency through higher yields per unit of diet. These goals were accomplished with the following developments and implementations: 1) A thermoformed on site rearing container made of PVC plastic film replaced the 32 oz paper convocan. 2) A Twin-Screw Extruder (TSE) continuous diet processing system with ancillary support equipment that employ technology adopted from the food processing industry replaced the steam kettle diet batch making system. 3) The original diet formula was modified 4) The method of disinfecting eggs prior to implant in the diet was changed. These combined changes in the PBWRF have resulted in a 1999 pupal production yield of 9.4 pupae per gram of diet. This is a 42.4 % increase in yield (9.4 versus 6.6 pupae per gram of diet) when compared to the highest production yield (1994) obtained from the old mass rearing methodology. Implementation of the new technology has reduced labor costs by 20%. Total production costs have been reduced from \$3.00 per 1000 moths to \$ 1.85 per 1000 moths in a 1X facility. These savings will increase appreciably as production increases in the facility.

[1448] QUALITY CONTROL IN AUTOMATED MASS REARING

S. M. Greenberg¹ & D. A. Nordlund², ¹Integrated Farming & Natural Resources Research Unit, Kika de la Garza Subtropical Agricultural Research Center, USDA-ARS, Weslaco, TX 78596, USA, E-mail: sgreenbe@weslaco.ars.usda.gov; ²Biological Control & Mass Rearing Research Unit, USDA-ARS, P. O. Box 5367, Mississippi State, MS 39762, USA, E-mail: donn@ra.msstate.edu.

Insect mass rearing systems involve selection of the target population, strain development, establishment of an initial culture, mass production, short- and long term storage, shipment to users, and release in the field. All these steps are mediated by process and product Mass rearing should be preceded by the development of quality control procedures. control methods. This allows pursuit of promising avenues of research related to mass rearing techniques, as well as allows producers to undertake an organized effort to improve the quality of the insects. According to modern notions of quality, the quality index of mass reared insects must be based on their ability to perform the function for which they are produced. Thus, criteria for evaluating the quality of mass reared insects may best be based on vitality and productivity. The development of global indices is preferable. Quality control assessment methods must also be quick and reliable. Original methods for standardized assessment of quality classes of Trichogramma spp. and methods for standardized assessment of quality classes of *Trenogramma* spin and *Catolaccus grandis*, and a device for determining a global index for *Trichogramma*, as related to field efficacy, will be discussed. The methodology for determining related to field efficacy, will be discussed. The methodology for determining Trichogramma release rates, and prediction of generalized criteria of effectiveness based on pest density, the quality of released wasps, weather conditions, and plant phenology also will be presented.

Index terms: Trichogramma spp., Catolaccus grandis, global indices.

[1449] BRAZILIAN LEGISLATION IN THE EXCHANGE BENEFICIAL ORGANISM/CONVENTION ON BIOLOGICAL DIVERSITY

Dias, B. F. S.

[1451] HOST SELECTION STRATEGIES BY THE APHID PARASITOID APHIDIUS ERVI

<u>F. Pennacchio</u>¹, D. Battaglia¹, E. Guerrieri², G. Poppy³, W. Powell³, A. Romano¹ & A. Tranfaglia¹, ¹Dipartimento di Biologia, Difesa e Biotecnologie Agro-Forestali, Università della Basilicata, via N. Sauro, 85, 85100, Potenza, Italy, E-mail pennacchio@unibas.it; ²Centro C.N.R. per lo Studio delle Tecniche di Lotta Biologica (CETELOBI), via Università, 100, 80055 Portici (NA), Italy; ³IACR Rothamsted Experimental Station, AL5 2JQ Harpenden, UK.

The braconid Aphidius ervi Haliday (Hymenoptera, Braconidae) is an endophagous parasitoid of several aphid species of economic importance. This parasitoid has been widely used as a model species for both behavioural and physiological studies. The present contribution summarizes the most recent findings on chemical ecology and behavioural physiology aspects that play a key role in the regulation of host location and recognition in the experimental system A. ervi – Acyrthosiphon pisum (Harris) (Hemiptera, Aphididae). The roles played by plant-derived synomones and by host associated cues, both chemical and physical, are taken into consideration. Broad bean (Vicia faba L.) plants infested by the pea aphid produce and release synomones used by A. ervi females for inflight orientation. These plant volatiles are aphid specific and systemically inducible by aphid feeding, when a minimal threshold of infestation level is exceeded. Plant attractiveness to the female parasitoids can be significantly enhanced in uninfested broad bean plants by their hydroponic co-culture with pea aphid infested plants. This would suggest the occurrence of helicitors that can be translocated throughout the plant, which may affect its secondary metabolism. A considerable degree of plant genetic variation in the attractiveness to parasitoids of aphid-infested plants has been detected among different broad bean cultivars. These have been characterized from a behavioural, chemical and genetical point of view. Short range and contact cues regulating the final steps of the host selection process are both physical and chemical. Colour vision plays a pivotal role in stimulating an oviposition attack. The rate of attack of physically suitable aphid dummics can be enhanced when experimental females are also exposed to host cuticular kairomones. The final egg laying is controlled by internal host cues detected via the ovipositor. The purification and characterization of both external and internal kairomones has been undertaken. A. ervi behavioural plasticity, as a result of learning, is also considered and its influence on host selection is discussed.

[1450] FOREIGN EXPLORATION FOR NATURAL ENEMIES OF THE WEEVIL DIAPREPES ABBREVIATUS (COLEOPTERA: CURCULIONIDAE) A SERIOUS PEST OF CITRUS IN FLORIDA

<u>J. E. Pena</u>, University of Florida, IFAS Tropical Research and Education Center, Homestead, FL 33031 USA

The west Indian sugarcane roostalk borer weevil, Diaprepes abbreviatus (L.), originated in the Caribbean region, is an important pest of several crops (i. e., citrus, sugarcane, vegetables, ornamentals) in Florida for over 30 years. However, until today, very little effort has been made to include the use of entonophagous insects in the whole management program for Diaprepes abbreviatus. An exploratory program for egg parasitoids of this species, has been initiated in the Caribbean and Colombia. Several egg parasitoids of this species, has been initiated in the Caribbean and Colombia. Several egg parasitoids (Ceratogramma etiennei, Quadrastichus haltiensis, Aprostocetus vaquilarum,) have been introduced from the Caribbean Region, in cooperation with entomologists and authorities of each country. The taxonomical position of some of the parasitoids have been re-evaluated and determined by systematists from USDA, Beltsville, MNH, UK, and UC, Riverside. One of the introduced, parasitoids, Ceratogramma etiennei (Hymenoptera: Trichogrammatidae) from Guadeloupe was tested for specificity, against lepidopteran eggs of native butterfly species, weevils released for biological control of weeds and close related weevils (i.e., Pachnaeus sp.). All other introduced species, are been screened for specificity and potential as hyperparasitoids. The important aspect in all these introductions will not only be to make available pertinent information to researchers from the country where exploration takes place, but also to share the results of different studies on augmentation and mass production of the introduced species. [1452] POST-EMERGENCE HOST MANIPULATION BEHAVIOR BY LARVAE OF THE SOLITARY ENDOPARASITOID COTESIA MARGINIVENTRIS (HYMENOPTERA: BRACONIDAE)

M. E. Fritzsche-Hoballah & T. C. J. Turlings, Institute of Zoology, University of Neuchatel, Rue Emile-Argand 11, CH-2007, Neuchatel, Switzerland. Email ted.turlings@zool.unine.ch.

Cotesia marginiventris (Hymenoptera: Braconidae) is a solitary endoparasitoid of many lepidopteran larvae. We observed a unique behavior of the parasitoid larva during emergence, which we think is typical for this Cotesia species and has not been described before. The larva emerges when it has completed its third and final instar. As soon as it has exited the host halfway, the parasitoid larva begins to spin the bottom half of its cocoon. Interestingly, the parasitoid not only employs the silk to spin the bottom half of its cocoon. Interestingly, the parasitoid not only employs the silk to spin the bottom half of the social tach itself and the host to the surface of the leaf. Once the first half of the cocoon is built, the parasitoid larva emerges completely from the host, and it positions itself firmly in the coccoon. At this time the larva first uses its mouth parts to detach the host from the leaf surface and then its head to push the host until it falls to the ground, where it dies within 24 hours. The parasitoid larva, free of its host, then finishes to spin its coccon and pupates. This post-emergence behavior was not observed in other solitary endoparasitoids that we study. Several hypotheses concerning the function of this unique behavior were tested and the results are discussed.

[1453] ORIENTATION BY SELF-PRODUCED VIBRATIONS: HOW PUPAL PARASITOIDS HUNT FOR HIDING HOSTS

F. L. Wäckers, Dept. of Entomology, PO Box 8031, 6700 EH Wageningen, the Netherlands. NIOO CTO, PO Box 40, 6666 ZG Heteren, the Netherlands. E-mail: waeckers@cto.nioo.knaw.nl.

Parasitoids which lay their eggs in insect pupae face the problem that their hosts do not feed or move. In comparison to parasitoids of larval stages this constrains the range of stimuli by which the parasitoid can locate their hosts. We were able to demonstrate that the pupal parasitoid *Pimpla turionellae* can circumvent this problem by using self generated vibrations to investigate potential oviposition sites. During this vibrational sounding the parasitoid creates vibrations in the substrate and uses the resonance of the reverberating substrate to decide where to insert its ovipositor. Here I will address the following aspects of this unique host location mechanism:

- The method of vibration production.

- The mechanism of vibration transmission, in particular the description of specific antennal structures which could facilitate this process.

- Description of the subgenual organ (mechanoreceptor) and behavioral evidence for its involvement in vibrational sounding.

- The effect of parasitoid size on the efficacy of vibrational sounding

Index terms: *Pimpla turionellae*, vibrational sounding, echolocation, sensory orientation, mechanoreceptor

[1455] LOCAL ADAPTATION OF PARASITOID POPULATIONS: WHAT DOES LEARNING HAVE TO DO WITH IT?

K.M. Kester¹ & H. R. Royaltey², 1. Department of Biology, Virginia Commonwealth University, 816 Park Ave., Richmond, Va . 23284-2012.2. Dept. Biology, Univ. California-Santa Cruz, CA 95064. Email kmkester@saturn.vcu.edu

Foraging behavior of parasitoids is modified by both post-emergence and ovipositional experiences with plants. Post-emergence experience induces positive responses to the plant experienced at emergence and generalized responses, either positive or inhibitory, to other plants. Ovipositional experience induces a positive response to the plant on which oviposition occurs. In a series of laboratory experiments with *Cotesia congregata* (Say) [Hymenoptera: Braconidae], a gregarious endoparasitoid of *Manduca sexta* L. [Lepidoptera: Sphingidae], we tested the effects of post-emergence experience followed by ovipositional experience with both typical and novel host foodplants on searching responses, offspring allocation and sex ratios of resulting offspring. Implications of these responses for local adaptation of parasitoid populations to host food plants were explored using an individual-based simulation model.

[1454] FINDING HOSTS IN A COMPLEX ENVIRONMENT: THE ROLE OF PLANT COMMUNICATION

C.M. De Moraes & J.H. Tumlinson, USDA-ARS-CMAVE, P. O. Box 14565, Gainesville, FL 32604, USA Email: CDeMoraes@gainesville.usda.ufl.edu

tritrophic plant-herbivore-parasitoid interactions are often complex and tightly interwoven, chemical signaling by plants has profound implications for parasitoid foraging efficiency and plant defense. plant-derived chemical cues are the dominant long-range cues used by parasitoids to locate cryptic, highly dispersed hosts within a complex physical and chemical environment. it is well documented that volatile chemical signals produced and released by plants specifically in response to herbivore feeding play an important roll in parasitoid foraging. these volatile semiochemicals are produced by several biosynthetic pathways. although some volatile compounds are released from storage when damage occurs, others are synthesized *de novo* in response to herbivore attack. plants release these induced compounds from undamaged as well as damaged leaves. new evidence suggests that in addition to being easily detectable and reliable indicators of herbivore presence, herbivore-induced plant volatiles may convey herbivore-specific information that allows parasitoids to discriminate even closely related herbivore species at long range. in this presentation we discuss recent developments in the investigation of plant-parasitoid interactions and the potential significance of these developments.

index terms: tritrophic interactions, parasitoids, plant chemicals, host location.

1456] SPIRACULAR GLANDS OF *DROSOPHILA MELANOGASTER* PUPARIA ELICIT RECOGNITION RESPONSE IN *TRICHOPRIA DROSOPHILAE*

N. Isidoro¹, R. Romani¹, S. B. Vinson² and <u>F. Bin¹</u>, ¹Department of Arboriculture and Plant Protection – Entomology, University of Perugia, Borgo XX Giugno, Perugia 06121, Italy, E-mail: fbin@unipg.it; ²Department of Entomology, Texas A&M University, College Station, Texas, 77843-2475.

The recognition process takes place usually mediated by physical and chemical stimuli perceived on contact by antennal sensory structures. The diapriid *Trichopria drosophilae* recognizes *Drosophila melanogaster* pupae using two types of multiporous gustatory sensilla (MGS). MGS type I are about 60 arranged in patches on the last two antennomeres. MGS type II consist of 5-6 basiconic sensilla with porous shaft located in a pit on the apical antennomere. Bioassays are carried out using altered females (one or two apical antennomeres removed) with intact puparia or intact females with host horned spiracles of both ends covered with wax or removed. Host recognition does not occur if the apical antennomere is removed or when intact female cannot antennate spiracular horns. The tips of these are covered with an oily secretion which oozes from associated glands. Morphological and behavioural data indicate that MGS type I and II are likely used to detect kairomone/s from different sources, i.e. the puparium body and the respiratory horns, respectively. However, while the former sensilla type may not be relevant, the latter always triggers the recognition response. Some more examples of MGS type I and II are shown in other diapriids

Index terms: antennal gustatory sensilla, oily secretion, recognition kairomone

Symposium and Poster Session

[1457] EGG PARASITOIDS ATTACKING HOMOLOGOUS HOSTS: EQUIVALENCES AND DIFFERENCES BETWEEN TWO ALLOPATRIC CABBAGE BUGS

E. Conti¹, <u>F. Bin¹</u>, S. B. Vinson² & H. J. Williams³, ¹Department of Arboriculture and Plant Protection – Entomology, University of Perugia, Borgo XX Giugno, Perugia 06121, Italy, E-mail: fbin@unipg.it; ²Department of Entomology, Texas A&M University, College Station, Texas, 77843-2475; ³Department of Chemistry, Texas A&M University, College Station, Texas, 77843-2475.

Two allopatric pentatomids, the European Harlequin Bug (EHB), Eurydema ventrale Klt., and the American Harlequin Bug (AHB), Murgantia histrionica (Hahn) (Heteroptera: Pentatomidae), present several similarities. These include using the same host plants (Cruciferae and Capparidaceae, both rich in mustard oil glycosides), having similar life cycles, adult size, warning coloration, oviposition sites, and clustered eggs (12 eggs in two rows). In addition, their eggs are attacked, respectively, by the European Trissolcus simoni (Mayr) and the American Trissolcus brochymenae (Ashm.). (Hymenoptera: Scelionidae). Because of such similarities, it could be expected that these parasitoids would easily switch hosts and, as a result, produce a new association sheding light on specificity and having potential in biological control. Possible host switches were therefore evaluated in terms of host location, recognition and suitability in laboratory conditions. However, host switches are non-reciprocal as T. simoni attacks and develops in AHB while T. brochymenae does not recognize EHB. In order to fully understand the mechanism, studies on the other aspects of the host selection process are in progress. Results are discussed in terms of ecological and physiological equivalences or differences in order to gain further insight into the attributes that determine host range of parasitoids used in biological control.

Index terms: Eurydema ventrale, Murgantia histrionica, Trissolcus simoni, Trissolcus brochymenae, host switch

[1459] SPECIES INTERACTIONS IN MULTI-SPECIES BIOLOGICAL PEST MANAGEMENT SYSTEMS: DO THEY ENHANCE OR DETER BIOLOGICAL CONTROL?

M. P. Parrella, Department of Entomology; University of California, Davis, California 95616, USA. E-mail: mpparrella@ucdavis.edu

Biological control developed in glasshouses around the world with repetitive releases of a single species of natural enemy. While this methodology has been a model for success, particularly with Encarsia formosa whitefly control and Phytoseiulus persimilis for control of two-spotted spider mites, it is being replaced by an approach which utilizes multiple natural enemies for the same target pest. This evolution has occurrred because of the advent of new polyphagous pests in the glasshouse (eg., Frankliniella occidentalis and Bemisia argentifolii) and because of the very low aesthetic thresholds inherent in many crops (particularly floriculture). Multiple tactics must be used in the floriculture greenhouse if IPM and biological control are to become an integral part of grower practices. Toward that end, my laboratory has been examining the use of two or more natural enemies together for control of key pests and this has cut across different guilds of natural enemies. For example studies have been completed or are ongoing in the following areas; the use of a fungus (Beauveria bassiana) and an aphid parasitoid (Lysiphlebus) for control of melon aphids on Asiatic lilies; the utility of a predatory coccinelid (Delphastus) in conjunction with a whitefly parasitoid (Eretmocerus) for control of whiteflies in poinsettia; and a nematode (Neoaplectana) in conjunction with a leafminer parasitoid (Diglyphus) for control of leafminers on chrysanthemums and gerbera. These studies involve detailed laboratory investigations to examine potential compatibility which focuses on ecological interactions and intraguild predation. If promising, the next step involves small greenhouse trials on campus, and then larger trials with commercial growers.

Key Words: Biological Control, Intraquild Predation, predators, parasitoids, pathogens

[1458] DIFFERENTIAL HOST EXPLOITATION STRATEGIES BY MORPHOTYPES OF *MELITTOBIA DIGITATA* (HYMENOPTERA, EULOPHIDAE)

F. L. Cônsoli & S. B. Vinson, Dept. of Entomology, Texas A&M University, College Station, TX 77843-2475, USA, E-mail f-consoli@tamu.edu.

Melittobia digitata is an ectoparasitic wasp of mud-tauber wasps and many other species of bees. This parasitoid can develop in three different wing-types depending on how long they are able to feed on the hemolymph before they start digesting the host's tissues. Morphotypes differentiation will also dictate their ability to disperse and lay eggs. Shortwing wasps do not disperse, using the same host they developed to lay their eggs. They are provigenic, laying their eggs as soon as the host is found. On the contrary, the long-wing wasps are synovigenic and they must disperse, find and feed on a new host before they start laying their eggs. These morphotypes seems to use different cues to elicit host recognition. Long-wing wasps use physical cues to recognize the host and they also need an oviposition stimulant to lay their eggs. However, chemical cues are used for host recognition by the short-wing wasps.

Index terms: host location, host recognition, reproduction

[1460] INTRINSIC & EXTRINSIC FACTORS INFLUENCING BIOLOGICAL CONTROL OF BEMISIA ARGENTIFOLII IN GREENHOUSES

M. S. Hoddle, Department of Entomology, Univ. of California, Riverside CA 92521, USA. E-mail: mark.hoddle@ucr.edu.

Bemisia argentifolii is a serious foliar pest of greenhouse grown poinsettias. Evaluations of parasitoids in small experimental greenhouses and commercial greenhouses using paired life tables and concurrent functional response assays have revealed important intrinsic factors that affect successful biological control in the Greenhouse-Bemisia-Poinsettia-Parasitoid system. The most important intrinsic factors that affect successful biological control that we have identified are related to the speed at which parasitoids find whitefly patches, levels of parasitoid induced mortality of Bemisia argentifolii, in particular non-parasitism types of mortality (e.g., host feeding), and plant growth. An important extrinsic factor that can enhance the cost competitiveness of biological control of Bemisia argentifolii with conventional insecticide programs is the incorporation of a parasitoid compatible insect growth regulator (IGR) into an integrated Bemisia argentifolii control on poinsettias can produce colored poinsettia at a cost compatible to imidacloprid applications and similar low levels of whitefly infestation.

Index terms: Eretmocerus eremicus, Encarsia formosa, poinsettias, buprofezin

[1461] AUGMENTATION OF PARASITOIDS FOR CONTROL OF CITRUS PESTS IN SOUTHERN AFRICA

<u>S. D. Moore¹</u>, V. Hattingh², B. A. Tate² & A. B. Ware², ¹Capespan, P.O. Box 12531, Centrahil 6006, South Africa, E-mail: sean_moore@capespan.co.za; ²Outspan Citrus Centre, P.O. Box 28, Nelspruit 1200, South Africa, E-mail: vaughan_hattingh@capespan.co.za

The southern African citrus industry is committed to an approach of bio-intensive integrated pest management (IPM). In an effort to reduce the use of chemical insecticides, augmentation of natural enemies of certain key pests has been investigated over several years. This involves the mass production and inundative release of large numbers of parasitoids, resulting in an earlier peak in parasitism levels, an earlier decline in pest levels, and hopefully a lower pest presence at harvest. Intensive trials have indicated the value of this approach, particularly with Coccidoxenoides peregrinus, a parasitoid of citrus mealybug, Planococcus citri. In cases of low to moderate P. citri infestation, releases of 100 000 C. peregrinus per hectare per season over a five month period, have proved adequate. Greater release intensities were necessary against high levels of mealybug. Higher levels of parasitism of mealybug were recorded in release orchards than in adjacent control orchards, up to nine weeks after release. This showed that C. peregrinus disperses at a rate of approximately 100m per month. Mealybug came under commercial control biologically in well over 90% of 250ha in which semi-commercial releases were conducted. Lack of control could be blamed on injudicious use of pesticides and ant activity. A similar programme has been adopted with California red scale, Aonidiella aurantii, using Aphytis lingnanensis. The aim is to release 120 000 A. lingnanensis per hectare per season. This is however more difficult to implement than the mealybug biocontrol programme, due to problems with mass production, disruption by thripicides and ants, a low export tolerance for red scale, and uncertainty whether A. lingnanensis is the best species for certain areas. Currently, augmentation of the egg parasitoid, Trichogrammatoidea cryptophlebiae, is also being investigated, for control of lepidopteran pests. Initially a total of only 20 000 parasitoids were released per hectare per season. In one case, level of parasitism was increased by 40% and consequently fruit loss was reduced by 41%, compared to an adjoining non-release orchard. During a second season, 150 000 parasitoids were released per hectare. Early season evaluations indicate a higher level of parasitism and a lower level of fruit damage since parasitoids have been released, than in adjoining non-release orchards. As a consequence of the positive results achieved with these augmentation initiatives, a total of nine insectaries have been established in citrus producing regions throughout South Africa.

Index terms: Coccidoxenoides peregrinus, Aphytis lingnanensis, Trichogrammatoidea cryptophlebiae, Planococcus citri, Aonidiella aurantii.

[1462] THE INFLUENCES OF SPATIAL AND TEMPORAL DYNAMICS OF HOST-PARASITOID INTERACTIONS ON APHID BIOLOGICAL CONTROL

K.M. Heinz, Department of Entomology; Biological Control Laboratory; Texas A&M University; College Station, Texas 77843-2475. USA. E-mail KMHeinz@tamu.edu

During the early stages of an outbreak, aphids form small clumps on individual plants within chrysanthemum greenhouses. These initial outbreaks quickly become serious problems because aphid populations quadruple in size daily when occurring on healthy plants. Aphid population growth on a newly infested pot is greatest aphid densities are low and decreased when aphid infestations became more dense. In addition, Myzus persicae and Aphis gossypii can spread over an area of 13.5 m² per day after infesting an single potted chrysanthemum. Hence, aphids may be present for a long time within a greenhouse and have the opportunity to reproduce and spread throughout the crop before being noticed. For predators and parasitoids to provide successful aphid biological, these natural enemies must locate and consume aphid patches when they are relatively scarce and before the aphids infest the entire greenhouse. After completing a set of intensive studies, results demonstrated the limitations to obtaining biological aphid control by releasing predators and parasitoids. Chrysoperla rufilabris larvae, used as a model predator, were found to be incapable of navigating between potted chrysanthemums placed Although lacewing larvae voraciously consume aphids once atop solid benches. discovered, successful biological control requires placement of lacewing larvae onto each individual plant infested with aphids. By comparison, studies with the parasitoid wasp A. colemani demonstrated that it could spread over an area of 16 m² per day after being released from a single potted chrysanthemum. From these results, it was determined that the most effective biological aphid control could be obtained by releasing A. colemani from points no greater than 4-m apart within a potted chrysanthemum greenhouse. Results from these predictions were verified in field studies. Use of the optimal release distances (every 4-m) resulted in significantly better aphid biological control than the 16-m treatment and in comparison to plots not receiving any wasps.

Key Words: Biological Control, Dispersal; Aphid, Chrysoperla, Aphidius

[1463] AUGMENTATION BIOLOGICAL CONTROL AS APPLIED IN LATIN AMERICA

<u>V.II.P. Bueno¹</u> & J.C. van Lenteren², ¹Detp. de Entomologia, Univ. Fed. de Lavras, Caixa Postal 37, Lavras, MG, 37200-000, Brasil, E-mail vhpbueno@ufla.br, ² Laboratory of Entomology, Wageningen University, P.O. Box 8031, 6700EH, Wageningen, The Netherlands.

Inundative and seasonal inoculative biological control, where natural enemies are periodically introduced, is commercially applied over large areas in various cropping systems worldwide. Internationally, more than 125 species of natural enemies are commercially available for augmentative biological control. Up to date, reliable figures on current use of inundative and seasonal inoculative biological control are very hard to obtain and the estimates about application in Latin America are incomplete. The best known examples of inundative and seasonal inoculative biological control in Latin America are use of the egg parasitoid Trichogramma for management of Lepidoptera in various crops. More than 100 species of Trichogramma occur in agroecosystems throughout the world. However, only 10 species are used in biological control programmes and most trials have envolved only five species against two pests. Most of the commercially used species have a low host specificity, which makes it possible to mass rear them relatively easily on different host species, and to release then against various pest species. This low host specificity may, however, involve the risk of parasitisation of non-target species, a much-debated issue in biological control today. The former USSR ranked first in application of Trichogramma (10 milion hectares), followed by China (2.1 milion hectares) and Mexico (2 milion hectares). Application in South America is limited for economic reasons (high labour costs involved in mass production of Trichogramma) and more intensive use of pesticides that have a negative effect on natural enemies. In Brazil, in an area of 2590 hectares of tomato crop, was released T. pretiosum against Tuta absoluta (Meyrick). Estimations of applications with Trichogramma in all countries with the exception of former USSR, China and Mexico, are in the order of 300,000 to 400,000 hectares. Of egg parasitoids other than Trichogramma used in commercial releases, the main species is Trissolcus basalis (Wollaston) against the heteropteran Nezara viridula (L.) in soybean in Brazil, and Telenomus remus Nixon against Spodoptera frugiperda Smith in corn in Venezuela. Natural enemies attacking larval and pupal stages are not use to a large extent in augmentative biological control in field crops. An example is the use of Cotesia parasitoids against sugarcane borers in China and Brazil. Data from 1996, in Brazil, showed the release in the field (area of 200,000 hectares of sugar cane) of 23,6 milion cocoon masses of C. flavipes and 1.5 milion of tachinid fly Paratheresia claripalpis Wulf. adults. A recent development is the use of biological control in protected cutivation in Latin America, for example, Colombia, Brazil and Peru. Index terms: inundative biological control, seasonal inoculative biological control.

[1464] USING GREENHOUSE ENVIRONMENT TO AUGMENT BIOLOGICAL CONTROL

J. L. Shipp, Y. Zhang and K. Wang, Agriculture and Agri-Food Canada, Greenhouse and Processing Crops Research Centre, Harrow, ON NOR 1G0, CAN.

Greenhouse environment or more specifically greenhouse climate has a dominant impact on greenhouse production yield and fruit quality. Greenhouse climate also has an important influence on insect and mite population dynamics, ecology, damage caused by these pests and the effectiveness of different control strategies against greenhouse pests. In greenhouse production, the climate in the greenhouse is monitored with highly accurate sensors and computer system that can maintain the temperature and humidity within narrow limits. At the GPCRC, a model (PSCLIMATE) has been developed to predict the microclimate (temperature and humidity) within the plant canopy and at the leaf surface. Greenhouse climate can influence the dispersal of pests and their biological control agents. Studies have also found that temperature and humidity will influence the predation rate of mites on western flower thrips and the survival of predatory mite life stages. The effectiveness of control agents, such as entomopathogens, can be substantially affected by humidity conditions in the greenhouse. Manipulation of greenhouse climate can be used as a control measure itself during greenhouse clean-up depending on the time of the year. More accurate prediction of pest outbreaks and the interactions between predators/parasitoids and their prey/hosts would result in improved effectiveness of biological control. A decision-support system (DSS) for pest management of greenhouse vegetable pests has been developed at the GPCRC and software communication protocol is currently being developed so that climate control systems can transfer the climate information that they are monitoring to the DSS. Access to this information will result in the development of models that can accurately predict pest population dynamics and assist in determining the induction rates of biological control agents for more effective and costefficient biological control of greenhouse pests.

Index terms: greenhouse pests, biological control, greenhouse climate

[1465] DO ECONOMICS AND BIOLOGY POSSESS SIMILAR GOALS?

J. van Schelt, Koppert B.V., P.O. Box 155, 2650 AD Berkel en Rodenrijs, The Netherlands

Biology and economics in biological pest control can be viewed from many sides. There is the grower who decides to start with an IPM program, but the grower-organisation, auction, supermarket, consumer and legislation will influence him. Because large growers are dependent on the export of their products, these factors can differ depending on the country. Economics and biology are also playing a daily role in the rearing of the beneficials at the producer site. For already more than 30 years the main market for Koppert, a producer of beneficial insects, mites and microbials, has been mainly in protected crops. This seems obvious, because the turnover per square meter is considerable higher compared to outdoor crops. But there are also less clear reasons. Beneficials have a very short shelf life so it is very expensive to raise a natural enemy for a release period of only a few weeks per year. For most parasites the rearing costs are still relatively high because they are generally propagated on their natural hosts on a plant. For many predators however, the development of artificial diets and alternative food sources, as lepidopteran eggs, will economise the cost in the future. For Koppert around 70% of the turn over comes from products used in tomatoes. Bumblebees for pollination; Encarsia formosa, Phytoseiulus persimilis, Diglyphus isaea are used to control whiteflies, spidermites and leafminers. More recently Aphidius ervi against aphids and the mirid Macrolophus caliginosus has been added. M. caliginosus has proven to be a very efficient "stabiliser" during the season. Because the mirids can survive periods of food scarcity by feeding on plant juices the population can stay at a high level and immediately suppress whitefly outbreaks. An interesting side effect is its potential to prey on lepidopteran eggs and even on leaf miner larvae. E. formosa is recently "upgraded" by developing a new release card and scaling up a new strain which does better under cold as well as warm circumstances. Also the introduction of Eretmocerus eremicus helped to optimise the whitefly control. This parasite is more resistant to chemicals and contributes to the whitefly control by a very high level of host feeding. Many growers use both species. For the Mediterranean area the control of Bemisia at high temperatures is very important. At the moment the specific parasite Eretmocerus mundus is scaled up. For the US an indigenous mirid: Dicyphus hesperus is commercialised. In general polyphagous predators are very interesting because it is not very economic to develop a specific biocontrol agent for every new pest in every country. For pests like whitefly, aphids and caterpillars a biological solution with only one natural enemy is impossible. A shield with different parasites and predators will be the solution for the coming years.

Index terms: Macrolophus caliginosus, Dicyphus hesperus, Eretmocerus eremicus, Encarsia formosa, Phytoseiulus persimilis, Diglyphus isaea biological control, tomatoes

[1466] THE BIOLOGY OF RAPHIDIOPTERA: A REVIEW OF PRESENT KNOWLEDGE WITH A CRITICAL VALUATION OF THE POSSIBLE USE OF SNAKE-FLIES IN INTEGRATED PEST CONTROL

H. Aspöck, Dept. of Med. Parasitology, Clinical Institute of Hygiene of the University, Kinderspitalg. 15, A-1095 Vienna, Austria, E-mail horst.aspoeck@univie.ac.at.

Up to 1960 Raphidioptera were among the most poorly investigated insects and there was only little knowledge on the biology of snake-flies. During the past 40 years, however, both families of the order - Raphidiidae and Inocelliidae - have been the subjects of intensive research in all major parts of the world where snake-flies occur. Nowadays about 185 (valid species of) Raphidiidae and 21 Inocelliidae are known (the total of extant species may be around 250). The distribution of the order is restricted to certain arboreal parts of the Holarctic where there are sufficiently low temperatures during winter. Temperatures around or below 0°C are apparently an indispensable prerequisite for the development. The larvae of all species of both families (so far described or at least known of about 130 species) are predacious feeding on a great variety of preferably soft-bodied arthropods including many pests (aphids, coccids, larvae of Lepidoptera, Coleoptera, Hymenoptera). They live under the bark of trees or in the soil. Also the adults of Raphidiidae are predators mainly feeding on aphids and other Sternorrhyncha, while the food of Inocelliidae is unknown (possibly pollen). There are large regions in all continents, particularly in the Southern hemisphere, but also in North America, which offer excellent ecological conditions for snake-flies but which lack them for historical-biogeographical reasons. Thus, an introduction of certain species with a high potential as predators seems very promising. We have reared about 120 species (many of them from the egg stage) from all four continents where snake-flies occur so that a lot of information on various biological parameters (preferred habitats, associations with certain plants, developmental periods and life-spans, mating behaviour, optimal breeding conditions, food and parasites) has accumulated which represents a reasonable basis for a realistic estimation of the possible use of snake-flies in integrated pest control.

Index terms: Neuropterida, ecology, predators, intercontinental transfer.

[1467] LIFE HISTORY OF *PARASITUS CONSANGUINEUS* FED ON THREE SPECIES OF PESTS OCCURRING IN MUSHROOM HOUSES

<u>E. Szlendak</u> & M. Lewandowski, Dept. of Applied Entomology, Warsaw Agricultural Univ., ul. Nowoursynowska 166, 02-787 Warsaw, Poland. E-mail szlendak@alpha.sggw.waw.pl

Parasitus consanguineus is a non-parasitic mite, new for Polish fauna, which occurs in various habitats including mushroom houses. P. consanguineus feeds on small arthropods, nematodes, and eggs of both these groups. The objective of our study was to clarify whether P. consanguineus can complete its life cycle feeding on common pests occurring in Polish mushroom houses: the nematode Rhabditis cucumeris, or first- and second-instar larvae of the phorid Megaselia halterata and the sciarid Lycoriella solani. Life tables were constructed for P. consanguineus fed on these three species. The developmental time of immature stages of P. consanguineus was longest (8.33 days) on sciarid larvae and shortest (7.06 days) on nematodes. Young P. consanguineus fed on phorid larvae emerged into adults after 7.91 days. Survival of P. consanguineus up to the adult stage was low on all offered diets, reaching 53, 49, and 63% on R. cucumeris, M. halterata and L. solani, respectively. The total fecundity of P. consanguineus females reared on the various diets was also very low, averaging 11.2, 12.4 and 17.7 eggs/female on the above-mentioned diets, respectively. Population parameters computed for *P. consanguineus* indicated that sciarid larvae were the best of the three species of pests tested as food for the predator. On this diet all parameters reached higher values than for other species and were as follows: (rm) 0.16; (Ro) 5.61; (T) 10.96; (lambda) 1.17. The lowest population parameter values were obtained when nematodes were provided as food: (rm) 0.10; (Ro) 2.84; (T) 9.34; (lambda) 1.10. P. consanguineus fed on phorid larvae had the following population parameters: (r_m) 0.10; (Ro) 3.02; (T) 10.49; (lambda) 1.11. Low values for the net reproductive rate of increase (Ro) in all tests suggested that *P. consanguineus* populations can increase only 3- to 6-fold during one generation when fed on the selected species of pests. This result is significantly different from data recorded for other soil-associated predators of Gamasida, and indicates that our selected test species of mushroom pests are unfavourable as food for P. consanguineus.

Index terms: Parasitus consanguineus, population parameters

[1468] CRITICAL ISSUES IN EGG PARASITOIDS

F. Bin & E. Conti, Department of Arboriculture and Plant Protection – Entomology, University of Perugia, Borgo XX Giugno, Perugia 06121, Italy, E-mail: fbin@unipg.it

Three families of egg parasitoids (Scelionidae, Mymaridae and Trichogrammatidae) and species belonging to nine other families of Hymenoptera are associated worldwide with hosts belonging to eight orders of insects, including many pest species. However, the research on egg parasitoids and their utilization in biological control has been focused mainly on *Trichogramma* species while, in spite of their recognized ecological and economic importance, the other groups have been poorly studied. The host-parasitoid associations described in the literature (CAB Database, Current Contents and several other papers) and from unpublished observations are analyzed and the effort applied for each group is discussed in relation to the results obtained in biological control. Efficacy and limits of *Trichogramma* spp., that represent more than half of all the efforts on egg parasitoids, are evaluated and compared to the efficacy and limits of the other species. Indications are given with the aim of increasing the utilization of species other than *Trichogramma* spp. for the control of crop and forest pests. Some aspects that should be considered in order to predict egg parasitoid efficacy and prevent the risks of biological control are discussed.

Index terms: Scelionidae, Mymaridae, Trichogrammatidae

[1469] THE RELATIONSHIP BETWEEN EGG LOAD AND FECUNDITY AMONG TRICHOGRAMMA PARASITOIDS

N. J. Mills¹ & U. Kuhlmann², ¹Insect Biology, Wellman Hall, Univ. of California, Berkeley, CA 94720-3112, USA, E-mail nmills@nature.berekeley.edu; ²CABI Bioscience Centre, Rue des Grillons 1, CH-2800 Delémont, Switzerland.

The relationships between parasitoid egg load, size, and age (3-72h) for Trichogramma minutum, T. platneri, and T. pretiosum, reared from two factitious hosts, Ephestia kuchniella and Sitotroga cerealella, were evaluated to test the hypothesis that 24h egg load can be used to estimate the fecundity of Trichogramma parasitoids. Egg load increased in relation to female age over the first 3 days of adult life for all three Trichogramma species to a mean egg storage capacity of 46.7 eggs for T. minutum, 41.1 for T. pretiosum, and 35.7 for T. platneri. At 24 h of age, T. minutum had matured enough eggs to fill 67% of its storage capacity, in comparison to 74% for T. pretiosum and 91% for T. platneri. There was a positive relationship between egg load and parasitoid size for all ages of the three Trichogramma species reared from both hosts, accounting for 14-69% of the variance in egg load. The potential fecundity, estimated realized (3 day cumulative) fecundity, and oviposition rate (potential fecundity/longevity) of T. platneri were all related linearly to size-dependent variation in 24h egg load. However, only the realized fecundity of T. pretiosum, and none of the reproductive characteristics of T. minutum, were related to 24h egg load. It is suggested that 24h egg load may not be an accurate measure of egg storage capacity in parasitoids and should be used cautiously to represent fecundity. The potential fecundity of seven Trichogramma species reared from E. kuehniella varied from 55 to 150, but neither potential fecundity nor oviposition rate was related significantly to egg load. Selection to avoid egg depletion in the attack of gregarious hosts appears most likely to account for the variation in potential fecundity among Trichogramma species.

Index terms: Trichogramma minutum, Trichogramma platneri, Trichogramma pretiosum, age, oviposition rate, size

[1471] EFFECT OF ALTERNATING TEMPERATURES ON THE DEVELOPMENT, LONGEVITY AND REPRODUCTION OF *TRISSOLCUS BASALIS* (HYMENOPTERA: SCELIONIDAE)

L. A. Foerster¹ & P. A. Nakama¹, ¹Dept. of Zoology, Universidade Federal do Paraná, P. O. Box 19.020 (81531-990) Curitiba, PR, Brazil. E-mail: foerster@bio.ufpr.br

Scelionid egg parasitoids are effective in reducing populations of stink bugs in soybeans. In warmer areas of Northern Paraná State, these parasitoids remain active throughout the year due to the availability of host eggs laid on alternative plants during autumn and winter. Under colder conditions, these parasitoids must have other strategies to survive in the absence of hosts during adverse climatic conditions. In colder areas of Southern Brazil, the green stink bug Nezara viridula overwinters in the adult stage and it is not known if its egg parasitoid Trissolcus basalis is able to survive winter temperatures using alternative host eggs. To assess the development, longevity and reproduction of T. basalis at temperatures similar those prevailing during winter in Southern Paraná State, the immature stages of the parasitoid were submitted to 15°C for different periods. Parasitized eggs of N. viridula were transferred from 25°C either in the egg, first instar or pupal stage of T. basalis and remained at 15°C from 7 to 90 days. Part of the parasitized eggs was dissected after each interval at 15°C to determine the developmental stage of the parasitoids, and part returned to 25°C to assess their development and emergence. Parasitoids transferred to 15°C either in the egg or in the first instar completed larval development and pupated after 35 and 30 days respectively, but the adults failed to emerge at this temperature. Storage of T. basalis in the pupal stage at 15°C after egg and larval development at 25°C during seven days, did not affect adult emergence, but delayed the pupal stage by 10 days in comparison to the time required at 25°C. Adults emerged at 15°C obtained from parasitoids reared at 25°C until one day before emergence survived for five months at the lower temperature. However, female fertility was sharply reduced, and only 3.1% of the eggs exposed to the females at 15°C were parasitized. It is concluded that the immature stages of T. basalis do not complete their development at winter temperatures in Southern Paraná and that the adults are able to survive throughout the winter in a state of hibernation. During this period, reproduction of the parasitoids is significantly reduced. Index terms: Biological control, egg parasitoid, Nezara viridula, stink bug, soybean.

[1470] EFFECT OF DENSITY OF DIATRAEA SACCHARALIS EGGS IN THE PARASITISM OF TRICHOGRAMMA GALLOI IN SUGARCANE

A. de S. Pinto¹, J. R. P. Parra², H. N. de Oliveira² & E. de B. Arrigoni³, ¹C. U. Moura Lacerda, Ribeirão Preto-SP, Brazil, E-mail aspinn@uol.com.br; ²Dep. Entomol., Fitop. e Zool. Agrícola, ESALQ-USP, 13418-900, Piracicaba-SP, Brasil; Copersucar, Piracicaba-SP.

The performance of *Trichogramma galloi* Zucchi, 1988 in different egg densities per point of artificial infestation of *Diatraea saccharalis* (Fabr., 1794) in sugarcane was studied. The trials were conducted in commercial sugarcane fields in Piracicaba, SP, Brazil in 1998. An inverse proportional relationship between the number of eggs per infestation point and the percentage of parasitism starting with 50 eggs per infestation site was observed. The results indicated that the egg density is fundamental for studies on *T. galloi* parasitism under field conditions. The studies on parasitism by *T. galloi* must use areas with infestation points with low egg density, which can be achieved by using older females in the cages attached to the plants in which they lay fewer egg masses. Index terms: biological control, egg parasitoid, sugarcane borer

[1472] THE ROLE OF INDUCED PLANT VOLATILES FOR EGG PARASITOIDS AND THEIR POTENTIAL FOR SEMIOCHEMICAL CONTROL

T. Meiners & M. Hilker, Institut für Biologie, Freie Universität Berlin, Haderslebener Str. 9, D-12169 Berlin, Germany, e-mail meito@zedat.fu-berlin.de

Parasitoids of herbivorous hosts face the problem that they have to utilize reliable and detectable cues during host location. It has been shown that larval parasitoids can solve this problem by orientating towards plant odors that are released after herbivore feeding damage. The role of induced plant volatiles for egg parasitoids is almost unknown. Its elucidation, however, may contribute to the enhancement of performance of egg parasitoids utilized as biological control agents. The egg parasitoid Oomyzus gallerucae (Hymenoptera, Eulophidae) attacks eggs of the elm leaf beetle Xanthogaleruca luteola (Coleoptera, Chrysomelidae), which is a serious defoliator of different elm species in Southern Europe, North America and Australia. O. gallerucae has been repeatedly introduced into the United States for biological control of the elm leaf beetle. In Southern France 30 -70 % of elm leaf beetle egg masses sampled on different locations and during different years were parasitized by O, gallerucae. These high discovery efficiencies of female egg parasitoids might be mediated by volatile synomones. Our olfactory studies on host location of O. gallerucae proved that these egg parasitoids are attracted to the odor of field elm (Ulmus minor) leaves that are carrying eggs of the elm leaf beetle. Oviposition of X. luteola induces a change of the volatile pattern emitted by the field elm leaves resulting in the attraction of the egg parasitoids. The plant's reaction to oviposition is systemic; the leaves without eggs adjacent to those with eggs also emit attractants. Females O. gallerucae also react to odor of elm leaves treated with jasmonic acid. Jasmonic acid is known as mediator of plant responses induced by feeding of herbivorous arthropods. Plants that are able to respond to oviposition of herbivores may defend themselves by emission of volatiles which "call" for egg parasitoids. This potential might be used to enhance the performance of egg parasitoids for semiochemical control of herbivores. Index terms: Oomyzus gallerucae, elm leaf beetle, egg parasitoid, synomone induction, biological control

[1473] EFFECT OF DIATRAEA SACCHARALIS SCALES ON MASS PRODUCTION OF TRICHOGRAMMA GALLOI ZUCCHI REARED ON ANAGASTA KUEHNIELLA EGGS

M. Lima Filho¹ & J. O. G. de Lima², ¹Campus Dr. Leonel Miranda-UFRRJ, Estr. do Açúcar, Km5, Penha, CEP 28020-560, Campos dos Goytacazes, RJ, E-mail: clmufrj@rol.com.br; ²LPP/CCTA/UENF, Av. Alberto Lamego, 2000, CEP 28015-620, Campos dos Goytacazes, RJ, E-mail: joscar@uenf.br.

The parasitoid Trichogramma galloi is a potential agent for biological control of the sugar cane borer, Diatraea saccharalis. However, eggs of Anagasta kuehniella are the most appropriate substitute hosts for mass production of this parasitoid. Virgin female lepidopterans release pheromones through their scales which may function as kairomones. In order to test the effect of virgen females D. saccharalis scales on parastism of A. kuehniella eggs by T. galloi, the following experiments were carried out. Eggs were exposed to female parasitoids for 24 and 48 h, at 25 ± 1 °C, 70 ± 10 % RH and 13 h photoperiod. The presence of the scales was found not to increase parasitism. Independently of treatment with scales, an average of 30 and 45 eggs were parasitised by each female parasitoid during 24 and 48 h exposure, respectively. One adult parasitoid was generated per parasitized egg. Although reared for approximatelly 60 generations in eggs of A. kueniella, T. galloi was able to parasitise an average of 19 and 26 eggs of D. saccharalis during 24 and 48 h, respectively, from which emerged an average of 1.6 adult per parasitised egg. The number of adult offspring and adult sex ratio (r = 0.9) produced by each female T. galloi on eggs of both hosts was not significantly different (P< 0.05) (41 adults on eggs of D. saccharalis, 51 and 46 on eggs of A. kuehniella, treated and not treated with scales, respectively).

Index terms: Insecta, biological control, parasitoid, kairomone, sugar cane borer

[1475] BIOLOGICAL DATA ON *MEGAPHRAGMA AMALPHITANUM* VIGGIANI AND *MEGAPHRAGMA MYMARIPENNE* TIMBERLAKE (HYMENOPTERA: TRICHOGRAMMATIDAE), EGG-PARASITOIDS OF *HELIOTHRIPS HAEMORRHOIDALIS* (THYSANOPTERA: THRIPIDAE) IN SOUTHERN ITALY

U. Bernardo¹, <u>G. Viggiani²</u>, Centro di Studio CNR sulle Tecniche di Lotta Biologica, Via Università 133, 80055 Portici, Italia. E-mail: G.Viggiani@iabbam.na.cnr.it; Univ. di Napoli "Federico II", Dept. Entomologia e Zoologia Agraria, Via Università, 100, 80055 Portici, Italia. E-mail: genviggi@unina.it.

Megaphragma amalphitanum Viggiani, an anfigonic species, and Megaphragma mymaripenne Timberlake, a normally thelitokous species, (Hymenoptera: Trichogrammatidae) are egg-parasitoids of the greenhouse thrips, Heliothrips haemorrhoidalis (Bouché) (Thysanoptera: Thripidae) in Campania (southern Italy) (Viggiani and Bernardo, 1997). Several biological parameters of the two species (longevity, mating, egg and preimaginal stage development, duration of the egg-adult cycle, fecundity, progeny, sex-ratio) have been comparatively studied in laboratory at different temperatures. M. amalphitanum showed higher fecundity and longevity, shorter egg - adult cycle than M. mymaripenne, but the preimaginal stages of latter species were more resistant to low temperature.

Index terms: longevity, fecundity, progeny, egg-adult cycle

[1474] PARASITISM RATE AND VIABILITY OF *TRICHOGRAMMA MAXACALII* (HYM.: TRICHOGRAMMATIDAE) ON EGGS OF THE *EUCALYPTUS* DEFOLIATOR *EUSELASIA APISAON* (LEP.: RIODINIDAE)

H. N. de Oliveira¹, J. C. Zanuncio¹, D. Pratissoli² & L Cruz³, ¹Dep. de Biologia Animal, Univ. Federal de Viçosa, 36.571-000 Viçosa, MG, BRAZIL. E.mail: zanuncio@mail.ufv.br; ² Dep. de Filossanidade, Univ. Federal do Espírito Santo, 29.500-000 Alegre, ES, BRAZIL; ³ CNPMS/EMBRAPA, C. Postal 151, 35.701-970, Sete Lagoas, MG, BRAZIL.

Parasitism rates and viability of individuals of two populations of Trichogramma maxacalii (Voegelé and Pointel, 1980) (Hymenoptera: Trichogrammatidae) were evaluated in two Eucalyptus plantations in the Counts of Ribeirão Preto, State of São Paulo and Nova Era, State of Minas Gerais, Brazil. These parasitoids were reared on eggs of the host Anagasta kuehniella (Zeller 1879) (Lepidoptera: Pyralidae) with or without honey and were exposed to eggs of the host after 0, 6, 12, 24, 36, 48 and 60 hours after emergence. Each recently emerged parasitoid female was placed in a 4.0 x 0.7 cm glass tube with a blue 3.5 x 0.5 cm cartoon with 40 glued non viable eggs of A. kuehniella and parasitism was permitted during 24 hours. Viability of T. maxacalii (above 96.0%) was not affected by the presence of food, by the origin of the parasitoid population, or by the period in which it was kept without eggs of the host. However, parasitism rate was higher than 75.0% and lower than 65.0%, for parasitoids with or without honey, respectively. Individuals of the population from São Paulo showed higher parasitism rates when they received eggs of the host at longer periods after its emergence. Parasitism was higher for the population from Minas Gerais when eggs of the host were provided soon after emergence. Parasitism behaviour in these two populations shows that they can be combined to obtain a better efficiency of T. maxacalli in programs of mass release against Euselasia apisaon (Dalman) (Lepidoptera: Riodinidae) in Eucalyptus plantations. Intex terms: Trichogrammatidae; parasitoids; Eucalyptus

[1476] HOST ACCESSIBILITY IMPACTS ON BIOLOGICAL CONTROL OF LYGUS HESPERUS WITH ANAPHES IOLE: THE STRAWBERRY EXPERIENCE

S. Udavagiri¹ & S. C. Welter², ¹Univ. of California Cooperative Extension, 1432 Freedom Blvd., Watsonville CA 95076, USA, E-mail sujaya@ucdavis.edu; ²Div. of Insect Biology, Univ. of California, 201 Wellman Hall, Berkeley, CA 94720, USA.

Lygus hesperus Knight (Heteroptera: Miridae) is native to western parts of the US and is a major pest in strawberries on the central coast in California. Adults migrate from overwintering weed sites in spring when the rains cease, and two generations develop in strawberries. Nymphs and adults feed on the fruits, and as a result, the fruits are distorted or 'cat-faced', and are not acceptable in the fresh market. We evaluated the potential for inundative biological control of L. hesperus with the native Anaphes iole Girault (Hymenoptera: Mymaridae). Being a high cash value crop, inputs into strawberry production are high, and an expensive control strategy such as inundative biological control has a high likelihood of being adopted if the program is effective. We released 15,000 A. iole in acre (0.4 ha) sized plots every week at three sites, and observed a 64 % suppression of L. hesperus. We doubled the release frequency the following year but obtained only a marginal increase in Lygus hesperus suppression. On several weed species, high levels of parasitism of L. hesperus by A. iole have been observed. To determine whether plant-related factors affect parasitoid performance in strawberries, we examined L. hesperus egg distribution in individual strawberry plants, and parasitism by A. iole of eggs in different strawberry plant structures. We observed that L. hesperus laid more eggs (46.5% of all eggs laid) in the fruit (between the achenes [seeds] in the fleshy receptacle), compared to the petiole (23.3%), leaflet (20.3%), peduncle (6.2%) or calyx (3.7%). In a no-choice test, parasitism by A. iole was higher in the petiole (96.7%), calyx (91.9%) and leaflet (85.2%) compared to the fruit (51.8%), where the achenes appeared to hinder parasitoid access to host eggs. In young fruits where the inter-achene distance was minimum, parasitism was considerably lower (25.4%) than in fruits where receptacle swelling had resulted in inter-achene distances that were medium (65.7% parasitism) or large (77.1% parasitism). Our results suggest that strawberry fruits can provide refugia from parasitism by A. iole, and that maximum protection occurs when the achenes are contiguous. The relevance of these findings to inundative biological control of L. hesperus with A. iole, and options for integration with other strategies will be discussed. Index terms: Lygus hesperus, Anaphes iole, refugia, inundative biological control.

[1477] MULTIPLICATION OF TELENOMUS PODISI AND TRISSOLCUS BASALIS (HYMENOPTERA: SCELIONIDAE) ON EUSCHISTUS HEROS (HEMIPTERA: PENTATOMIDAE) EGGS FOR SOYBEAN STINK BUGS CONTROL

W.A.A. Peres¹ & B. S. Corrêa-Ferreira², ¹Universidade Federal do Paraná, Departamento de Zoologia, Caixa Postal 19020, Curitiba, Paraná 81531-990, Brasil. Email: wilsimar@cnpso.embrapa.br., ²Embrapa-Soja, Caixa Postal 231, Londrina, PR, 86001-970, Brasil, E-mail: beatriz@cnpso.embrapa.br.

The biological control of soybean stink bugs in Brazil is based on mass rearing in the laboratory and field release of the egg parasitoid *Trissolcus basalis*. Today the brown stink bug *Euschistus heros* is the most abundant pentatomid onsoybean crop, besides, Telenomus podisi has been considered as an important egg parasitoid of soybean stink bug. Laboratory studies were conducted to test the suitability of E. heros eggs to mass rearing T. podisi and T. basalis, compared to the standard methodology (T. basalis multiplied in N. viridula eggs). The eggs of E. heros were exposed to parasitoids by different ways. When individualized eggs were exposed, the parasitism was high (> 96%) but adult emergence rates were low (51.2 and 26.1%, respectively), showing that this egg distribution was inadequate to parasitoid multiplication. When egg masses were exposed to parasitism with eggs on the normal position, obtained emergence rates of 83.1% for T. podisi and 50.6% for T. basalis compared to values of 79.9% and 63.1% with eggs exposed on other positions, did not differed significantly, and showing that the egg mass pulverization methodology was adequate. On cardboard tickets, 162 egg masses or 1193 eggs of E, heros were laid, being 38%, 36.6% and 25.4% of the eggs on lateral, normal and inverted positions, respectively. Parasitism rates of T. podisi and T. basalis (ca. 99%) were similar to that observed with the standard methodology (99.7%). Nevertheless, the emergence rates (50.5% for T. podisi and 60.4% for T. basalis) were significantly lower, probably due a high number of eggs with lateral shrinking, in which there was no development of the parasitoid.

Index terms: biological control, egg parasitoid, mass rearing.

[1478] DIAPAUSE INDUCTION AND COLD STORAGE IN TRICHOGRAMMA NERUDAI

A. A. Tezze & E. N. Botto, Insectario de Investigaciones para Lucha Biológica. IMYZA-CNIA-INTA Castelar. C. C. 25 (1712), Buenos Aires, Argentina. E-mail: atezze@cnia.inta.gov.ar

Diapause induction in egg parasitoids can be used as a storage technique. In this study it was evaluated the effect of different cold storage periods (treatments) on previously diapause induced Trichogramma nerudai pupae. Developmental time from pupa to adult emergence (emergence time), birth proportion (born adults / parasitized eggs) and survival at 72 h. and sexual proportion (females / females + males) of emerged adults, were used to evaluate the effect of treatments. Diapause induction and breaking were obtained following the methodology developed in the Soviet Union for T. evanescens and T. pintoi. The experimental sequence followed in the treatments was: diapause induction - cold storage - diapause breaking - standard conditions. Cold storage times were 60, 120 and 150 days. Non diapause induced pupae (control group) and emerged adults after breaking the diapause were maintained at rearing standard conditions (temperature: $25 \pm 1^{\circ}$ C; humidity: 80 ± 5 %; and photoperiod of L14:D10). Time to adult emergence increased with increasing cold storage times whereas pupa survival (birth proportion) decreased in the 120 and 150 cold storage days. Adult survival and sexual proportion were no significantly different between treatments. Up to 60 days cold storage did not affect the emergence of adults but longer times reduced it by nearly 25%. The obtained results support the idea that diapause induction and cold storage techniques could be successfully applied to this novel species and used in its mass production.

[1479] HOST SPECIES AND AGE SELECTION BY TRICHOGRAMMA PRETIOSUM IN GREEN LACEWING SPECIES

N. M. M. S. de Albergaria¹, H. O. S. Dória², G. Bissolli³, R. J. Ferreira⁴ & S. A. De Bortoli¹, ^{1,2,3}Dept. de Fitossanidade, Fac. Ciências Agrárias e Veterinárias, UNESP, Via de Accesso Prof. Paulo Donato Castellane, s/n, 14884-900, Jaboticabal, SP, Brasil, (¹FAPESP Fellowship), (²CNPq Fellowship), ⁴Dept. de Biologia, Fac. Filosofia, Ciências e Letras de Ribeirão Preto, Univ. de São Paulo, Av. dos Bandeirantes, 3900, 14040-901, Ribeirão Preto, SP, Brasil (FAPESP – Fellowship). E-mail: nntendes@zaz.com.br.

The green lacewings are frequently parasited by *Trichogramma pretiosum* Riley, 1879, in several crop fields systems. This work was carried out to investigate *T. pretiosum* preference to the eggs of five different green lacewing species that belongs to 5 genders. Among the species was investigated the preference eggs age too. The trials was conducted using eggs of *Chrysoperla externa*, *Ceraeochrysa cincta*, *Chrysopa paraquaya*, *Nodita* sp and *Ceraeochrysa cubana* in four classes of age (0-24, 24-48, 48-72 and 72-96 hours). The eggs were submitted to the *T. pretiosum* females up to 24 hours of age. According to the results was observed difference among the parasitism to the five species of crisopids and there was preference to the eggs 0-24 hours age.

Index Terms: Crisopid, biological control, preference, Neuroptera

[1480] TETRASTICHUS PHYTOMYZAE (HYMENOPTERA: EULOPHIDAE), AN INTERNAL PARASITOID ON THE BROOMRAPE FLY, PHYTOMYZA OROBANCHIA (DIPTERA : AGROMYZIDAE)

Al-Eryan , M. A. S., Gadelhak, G. G. & Rezk, H. A, Dept. of Economic Entomology, fac. Agric. (Elshatby), Alexandria Univ., Egypt. Email: m_a_aleryan@yahoo.com

The broomrape, Orobanche crenata is one of the most important parasitic weeds on the legume plants causing considerable damage in yield. One of the most important biological control agents used against this weed is the monophagous dipteran fly, Phytomyza orobanchia. The use of this fly has been promising in many countries. The larvae of this fly feed only upon the immature seeds of Orobanche spp. destroying most seeds in the fruit capsule. The natural capacity of Phytomyza in reducing the Orobanche population is limited by many factors, such as low temperature, cultural practices, insecticide applications and natural enemies. Tetrastichus phytomyza is one of the encountered parasitoid of P. orobanchia in Egypt. This parasitoid lays its eggs in Phytomyza pupae where larvae live as gregarious endoparasites causing death of their hosts. This study aims to develop an understanding of its parasitization rats on P. orobanchia in three districts in northern Egypt. Infested Orobanche spikes with Phytomyza were collected in April of 1996, 1997 and 1998 seasons. At that time, larvae migrate into the underground parts of Orobanche to undergo pupation and start diapause for the next seasons. Stems were dissected to collect the fly pupae. Pupa was placed in glass veils covered with muslin till the next season. Percentage of Phytomyza adult emergence was calculated in each year, separately. Based on the above study, the season of 1998 was chosen for the investigation of the parasitoid on the pupae of *Phytomyza* at three districts in the west Nile Delta. Percentages of *Phytomyza* adult emergence were 87.32%, 32.13% and 18.72% in 1996, 1997 and 1998, respectively. Meanwhile, percentages of parasitized pupae with Tetrastichus were 0.0%, 27.87 and 64.25% in the three consecutive years at respect. The remains pupae enter prolonged diapause and represented 12.68%, 40.0% and 17.04% in the abovmentioned three years, respectively. Percentages of parasitism in 1998 season in Kafr El-Dawar, Housh Issa and Alexandria districts were 16.0%, 63.16% and 67.77%, respectively. According to high parasitism in over-summering generation of Phytomyza, the expected Phytomyza population synchronized with new emerged Orobanche will be decreased. As a matter of fact, this factor should be considered during the planning of Phytomyza release programs.

Key words: Biological control, Orobanche crenata, Egypt

[1481] PHYSIOLOGICAL FACTORS DETERMINING SUITABILITY OF BRACONID ENDOPARASITOIDS (COTESIA FLAVIPES COMPLEX) FOR DEVELOPMENT IN NOVEL-ASSOCIATION LEPIDOPTERAN STEMBORERS (DIATRAEA SPECIES AND OSTRINIA NUBILALIS)

<u>M. Allevne</u>¹ & R. N. Wiedenmann², ¹Univ. of Illinois at Urbana-Champaign, Department of Entomology, 320 Morrill Hall, Urbana, IL 61801, USA, E-mail: vanlaarh@uiuc.edu; ²Illinois Natural History Survey, Center for Enconomic Entomology, 607 Peabody Drive, Champaign, IL 61820, USA.

Extensive study of insect immune systems has yielded a better understanding of the interplay between behavioral, cellular, molecular and genetic mechanisms used by insects to defend against invaders. This knowledge should be used to predict how parasitoids (novel and coevolved) utilize potential hosts, which will help us plan the safe deployment of these natural enemies for biological control. Our experimental system consists of two New World pyralid stemborers, Diatraea saccharalis and D. grandiosella: one Old World pyralid, Ostrinia nubilalis; and three Old World braconid parasitoids, Cotesia chilonis, C. sesamiae, and C. flavipes. Experiments on host suitability, chronology of encapsulation, host hemocytes, etc., indicate that parasitoids that are taxonomically, behaviorally, and ecologically very similar may differ in utilization of a host of the same species. For instance, O. nubilalis is unsuitable for parasitoid development whereas D. saccharalis supports development of all three parasitoid species. D. grandiosella shows a mixed response. Those host species that encapsulate parasitoid progeny are only capable of doing so three to four days post-parasitization. These patterns of encapsulation do not correspond with differences in total hemocyte numbers. Parasitoids may use different methods at different times after parasitization to counter the immune response (i.e. egg and larval surface features, polydnavirus, parasitism specific proteins, teratocytes, etc.). The short-term immunosuppressive methods used by the parasitoids studied here are ineffective in O. nubilalis. In Diatraea hosts this short-term method does work, however, for some host-parasitoid combinations this effectiveness is lost or longer-term factors are not capable to evade the host's immune response. Patterns suggest that the host range of the parasitoids studied here will be narrow -- due to physiological factors -- thus limiting effects on non-targets. However, the lack of consistent patterns indicates that explicit testing will be needed to determine host ranges.

Index Items: biological control, encapsulation, host range, immune response.

[1482] INFLUENCE OF HOST DENSITY ON ATTACK RATES OF TACHINAEPHAGUS ZEALANDICUS ASHMEAD (IIYMENOPTERA: ENCYRTIDAE) ON MUSCA DOMESTICA (DIPTERA: MUSCIDAE) AND CHRYSOMYA PUTORIA (DIPTERA: CALLIPHORIDAE)

M.A.F. de Almeida¹, A.P. do Prado¹ & C.J. Geden², ¹Dep. de Parasitologia, IB, Universidade Estadual de Campinas, CP 6109, Campinas, São Paulo, Brasil, CEP 13083-970, E-mail: cmfa@lancernet.com.br, ² USDA, ARS, CMAVE, PO Box 14565, Gainesville, FL 32604, USA, E-mail: cgeden@nervm.nerdc.ufl.edu. This study was supported by FAPESP and CAPES.

Tachinaephagus zealandicus is a gregarious parasitoid that attacks muscoid flies in the larval stage; at 25°C adult parasitoids emerge from fly pupae ca. 25 days after oviposition. Certain evidences indicate that this species is endemic to the Southern Hemisphere and has been collected in carcasses and from poultry farms in Brazil. A colony of T. zealandicus was established in the Laboratory of Entomology, UNICAMP, Brazil from a sample collected in a poultry house in Santa Cruz da Conceição, São Paulo, Brazil. We evaluated the potential of females for killing pupae of M. domestica and C. putoria in different densities of hosts considering that these species of flies, mainly M. domestica are very noxious in these kinds of environments. We used five different densities (2, 4, 8, 16, 32) of larvae for each species of flies, and for each density we used 20 females of T. zealandicus (N = 100) that were isolated in 30ml clear plastic cups covered by snap-on plastic lids with screened openings, and the period of exposure to oviposition was 24 hours. The females used were 2d old and were removed from the colony where they were only fed with honey and water and had no contact with any kind of host. The results showed that the mean no. of M. domestica larvae killed by T. zealandicus was 1.9, 3.8, 7.0, 11.9 and 21.7 for the densities of 2, 4, 8, 16, 32; respectively. For C. putoria was 1.4, 1.8, 3.4, 5.3, 9.5 and 13.5 for the densities of 2, 4, 8, 16, 32, respectively. The number of killed pupae, either for C. putoria or M. domestica was affected by the host density and species (overall ANOVA F=52.00 **). Rates of host attacks were significantly affected by host species (F=14.41**), density (F=104.41**) and by the interaction of density*species (F=7.10**). This shows that T. zealandicus was able to kill large number of immatures of these two species of flies. Considering that these flies are the primary dipteran pest species found in poultry houses in Brazil, these results indicate that T. zealandicus may be an important biological control agent for use in poultry facilities.

Index terms: parasitoids, flies, biological control, density, gregarious

[1483] ECONOMICALLY IMPORTANT PESTS OF THE COSAVE REGION AND THE AVAILABLE TECHNOLOGIES FOR THEIR BIOLOGICAL CONTROL

¹<u>M.I. Ares</u>, Dirección del Servicio deProtección Agrícola Ministerio de Agricultura, Ganadería y Pesca Montevideo,Uruguay. Email: miares@netscape.net; ²E. Caceres, Paraguay.

In the Southern South America countries biological control activities have increased rapidly. The South Cone Plant Protection Committee (Comité de Sanidad Vegetal del Cono Sur - COSAVE) is a Regional Plant Protection Organization (RPPO) established in1989, through an agreement among the governments of Argentina , Brazil , Chile , Paraguay and Uruguay. COSAVE is in charge of developing Regional Standards to harmonize the phytosanitary regulations and procedures to facilitate the regional and international trade of agriculture products. Cosave has different Permanent Work Group (PWG) each one addresses specific issues related to Plant Protection. The Biological Control Permanent Work Group (BC-PWG) has established a list of biological control agents used within the countries of the region to determine which pests should be commonly targeted in order to speed the development of the biological control technologies. In this way, research was done in order to establish the main pest of each Cosave country and the biological control technologies available for each of these pests, including the stage in which these technologies have been developed. It was considered 4 stages of development: 0=no technology or research available.1= technology in the beginning stages of research.2=technology in advanced stages of development.3=technology available commercially.4=This technology was used in the past, but not in the present because the pest is no longer a problem in the country or because other technologies have replaced it. As a result of this work, a technical report was made and can be accessed at <htpp://www.cosave.org.py>.It was organized in a series of tables, each one addressing one crop that is important in at least three countries in the region. As of now, only insects, mites, and fungi are considered. Other pests, such as bacterias, nematodes, viruses, and insect vectors. will be included in further revisions of the report. This list is not static, and will be updated periodically as new pests or technologies are available in the region.

[1484] BIOLOGICAL ASPECTS OF CHRYSOPERLA EXTERNA AND CERAEOCHRYSA CINCTA IMMATURE STAGES FED EGGS AND NYMPHS OF BIOTYPE "B" BEMISIA TABACI

A. M. Auad¹, L. C. Toscano¹, A. L. B. Junior¹ & S. Freitas¹, ¹Universidade Estadual Paulista (UNESP), Faculdade de Ciências Agrárias e Veterinárias (FCAV), Departamento de Fitossanidade, Via de Acesso Paulo Donato Castellani, s/n°, 14870-000, Jaboticabal, SP, E-mail: amauad@fcav.unesp.br.

It was evaluated the biological aspects of *Chrysoperla externa* (Hagen) and *Ceraeochrysa* cincta (Schneider) immature stages, fed eggs and nymphs of biotype "B" *Bemisia tabaci* (Genn.). After the larval eclosion, they were fed 2 cm diameter leaves discs, containing eggs and nymphs of whiteflies native of tomato and cabbage plants, respectively. The evaluated parameters were: duration (days) and viability (%) of each instar and pupal phase, for each specie of predator fed different prey stages. It was verified that for *C. externa* 1" instar larval there was influence of offered prey stage on development period, the same did not occur for *C. cincta*. The 1st instar larval development of both species of predators did not differ when they were fed eggs, however *C. cincta* showed a longer period (5.4 days) in relation to *C. externa* (4.0 days) when fed nymphs. For 2^{sd} instar larval and larval phase there was no influence of offered prey stage (egg or nymph) on development period, however the 2^{sd} instar duration was longer for *C. cincta* than *C. externa* (4.75 and 4.00 days, respectively). For 3^{sd} instar larval and larval phase there was a longer development period for *C. externa* (4.75 and 16.30 days, respectively) compared to *C. cincta* (4.0 and 15.3 days, respectively). The larval instars viability was up to 90% for both species, nevertheless, lower viability of pupal phase were recorded for *C. cincta* when fed eggs (30%) or nymphs (55.6%).

[1485] FIELD SCALE RESPONSES OF APHIDS AND THEIR NATURAL ENEMIES TO ELEVATED CO_2 AND O_3

C.S.Awmack & R.L.Lindroth, Dept. of Entomology, University of Wisconsin-Madison, 1630 Linden Drive, Madison, WI 53706 U.S.A. E-mail: awmack@entomology.wisc.edu.

A key question in climate change research is the effects of environmental change on the population dynamics of insect pests and their natural enemies. Data collected so far suggest that chewing insects may be adversely affected by changes in plant quality caused by atmospheric pollutants while populations of sap-feeding insects may increase and cause more damage to their host plants. These studies have, however, been carried out using plants grown in pots in controlled environments, making it difficult to predict the probable effects of changes in atmospheric composition on populations of herbivores and their natural enemies. This talk will present data collected at the USDA FACTS II project in Rhinelander Wisconsin showing that there are effects of both CO2 and O3 on the performance of individual aphids, aphid populations and the natural enemy complexes associated with these aphids. Some aspects of individual aphid performance (development time, fecundity and intrinsic rate of increase) were not affected by elevated CO2 or O3 while adult weight and embryo number differed significantly between treatment. This uncoupling of fitness parameters has implications both for the effects of environmental change on aphid population dynamics and the ability of natural enemies such as ladybeetles and lacewings to control these populations. When populations of natural enemies were surveyed there were significant differences between the treatments., with more natural enemies at elevated CO2 and fewer at elevated O3. Index terms: Chaitophorus stevensis, Populus tremuloides, climate change, CO2, O3.

[1487] STATUS OF BIOLOGICAL CONTROL OF THE CITRUS LEAFMINER (PHYLLOCNISTIS CITRELLA) IN ITALY

<u>S. Barbagallo</u>, S. Longo, G. Siscaro, P. Reina, L. Zappalà, Dip. di Scienze e Tecnologie Fitosanitarie, Sez. Entomologia agraria, Univ. of Catania – Via Valdisavoia, 5 – 95123 Catania, Italy, E-mail sebarbag@mbox.unict.it.

In Italy, as well as in other Mediterranean citrus areas, several species of indigenous eulophid wasps (mainly belonging to the genera Cirrospilus and Pnigalio) have been detected on Phyllocnistis citrella Stainton (Lep. Gracillariidae) since its first appearance in 1994. Because of the low efficiency of these indigenous entomophagous, a classical biological control program of the leafminer has been started in Southern Italy by means of the introduction of exotic parasitoids. Ageniaspis citricola Logvinovskaya (Hym. Encyrtidae), Quadrastichus sp. and Citrostichus phyllocnistoides (Narayanan) (Hym. Eulophidae) have been introduced and reared. Among these entomophagous, only A. citricola and Quadrastichus sp. have been also released in field during spring 1996 and fall 1997. Up to the end of August 1996 about 3,000 Quadrastichus sp. specimens have been distributed in more than 30 sites in Sicily. A. citricola was released, in the same island, in the provinces of Messina, Catania, Enna, Siracusa, Caltanissetta and Ragusa during May-July 1997; nearly 6,000 specimens of the encyrtid have been distributed in 44 sites from May to July 1997. Periodical observations have been carried out to verify the establishment of the parasitoids and detect some bio-ecological aspects of the introduced species. The eulophid Quadrastichus sp. reached parasitization levels near to 40% but it has not overwintered in any release site. A. citricola was recovered in some lemon orchards of the provinces of Catania and Messina, lying in more temperate climatic areas. During summer-fall 1997, in these biotopes the parasitization rates varied from 60% to 90%. A. citricola has overwintered in these sites and the strain recovered in 1998 is presently maintained in rearing. Further studies are still in progress to evaluate its permanent establishment in the area. In addition, during the same year (1998) the Australasian specific parasitoid Semielacher petiolatus (Girault) (Hym. Eulophidae) has been recovered for the first time in many biotopes in Sicily and Calabria. This ecesis case has a particular ecological relevance, since the natural spreading of such an ectophagous wasp in the Mediterranean basin may efficiently improve the biological control of citrus leafminer. Index terms: indigenous eulophids, Ageniaspis citricola, Quadrastichus sp., Semielacher petiolatus, parasitoids.

[1486] PREDATION OF *DOCIOSTAURUS MAROCCANUS* BY ZOOPHAGOUS DIPTERA AND COLEOPTERA (SOUTHERN ITALY)

F. Baldacchino & T. Moleas, Dip. di Biologia e Chimica Agro-Forestale ed Ambientale, Università di Bari, v. Amendola 165/a, 70126 Bari, Italia.

The recent acrididae infestations reported from Apulia (Southern Italy), in some protected areas of 'Parco Nazionale del Gargano', have revived studies on the natural enemies of Dociostaurus maroccanus (Orthoptera, Caelifera). For carefully monitoring the infestations by this orthopteran, an environment-friendly control programme has been initiated, also including observations on ootheca predator insects. This preliminary work is aimed at reporting results obtained in the four-year period 1996-1999. In the first year of observations (1996), the presence of predators has not been reported. Conversely, since 1997, a few adults of the coleopteran Mylabris variabilis (Coleoptera, Meloidae) have been observed in some areas in May-July. In 1998, the presence and spread of this coleopteran increased. At the same time, the Diptera Systoechus ctenopterus and Cytherea obscura (Diptera, Bombyliidae) have been reported since June. Observations carried out the same year have highlighted the progressive spread, even in new areas, of Meloidae and to a larger extent of the above Bombyliidae. The soil samples have revealed the presence of Meloidae larvae and in particular, those of Bombyliidae until May, in the empty oothecas of D. maroccanus. In 1999, it was observed that the Bombyliidae flight is longer although it starts later compared to Meloidae; indeed, Diptera adults were reported until late September. The effectiveness of these predators has proved to be very high also for the year 1999, in that they considerably destroy oothcas. In general, Bombylidae larvae prevail (60% to 100%). This leads to assume a harmful effect of the chemical control, carried out to combat D. maroccanus from April to May, on the first adults of M. variabilis, which emerge since mid-May. In contrast, Bombyliidae would escape this effect because they emerge later.

Index terms: Dociostaurus maroccanus, predators, Mylabris variabilis, Bombyliidae.

[1488] DATA ON THE NATURAL CONTROL OF THE OLIVE MOTH, *PRAYS OLEAE*, BY PARASITOIDS IN TRÁS-OS-MONTES REGION (NORTHEASTERN PORTUGAL)

A. A. Bento¹; L. M. Torres² & J. A Pereira¹, ¹ Escola Superior Agrária de Bragança. Quinta de Sta Apolónia. Apartado 172. 5 301 - 855 Bragança. bento@ipb.pt. ² Universidade de Trás-os-Montes e Alto Douro. Apartado 202. 5 000 - 911 Vila Real. Itorres@utad.pt. This work was supported by the Project PAMAF IE&D 6117

A study was carried out over the period of 1996 to 1999 in unsprayed olive groves at Trásos-Montes region (northeastern Portugal) in order to identify the parasitoid complex of the olive moth, Prays oleae (Bern.) and to evaluate its role to control the pest. The study fell upon the last imature stage of development, of each of the three generations of P.oleae, that is phyllophagous, antophagous and carpophagous. Eight species of hymenoptera parasitoids were identified, namely: Ageniaspis fuscicollis Dalm. var. praysincola Silv. (Encyrtidae), Chelonus eleaphilus Silv. (Braconidae), Apanteles xanthostigmus Hal. (Braconidae), Habrocon crassicornis Thoms (Braconidae), Elasmus flabelatus Fonse. (Elasmidae), Angitia armilata Grav. (Icneumonidae), Pnigalio mediterraneus Ferr. & Del. (Eulophidae) and Dicladocerus westwoodi West. (Eulophidae). The level of parasitism recorded varied from 7.4% to 46.7% in the phyllophagous generation, from 25.4% to 56.5% in the anthophagous generation, and from 21.3% to 61.9% in the carpophagous generation. A. fuscicollis var. praysincola, C. eleaphilus and A xanthostigmus were the most frequent species observed, being present in all the samples. These species were also, in general, the ones which presented the highest levels of parasitism, with numbers between 5.5% and 55.2% for A. fuscicollis var. praysincola, between 0.2% and 14.2% for C. eleaphilus, and between 1.4% and 11.6% for A xanthostigmus.

Key-words: olive; integrated pest management; Prays oleae (Bern.); natural control; Ageniaspis fuscicollis Dalm.

[1489] BEHAVIOR OF TRICHOGRAMMA PRETIOSUM (HYMENOPTERA: TRICHOGRAMMATIDAE) IN SPODOPTERA FRUGIPERDA (LEPIDOPTERA: NOCTUIDAE) EGG-MASSES

E.B. Beserra^{1,2}, T.S. Dias³, J.R.P. Parra⁴, ¹Dept. Farmácia e Biologia, Univ. Estadual da Paraíba, cx 781/791, 58100-000, Campina Grande PB. ²Doutorando em entomologia ESALQ/USP, E-mail ebbeserr@carpa.ciagri.usp.br, ³Dept. de Ciências Exatas, ESALQ/USP, cx 09, 13418-900, E-mail etsdias@carpa.ciagr.usp.br, ⁴Dept. de Entomologia, Fitopatologia e Zoologia Agrícola, ESALQ/USP, cx 09, 13418-900, E-mail jrpparra.@carpa.ciagri.usp.br.

The fall armyworm, Spodoptera frugiperda, is potentially controlled by the egg parasitoids of the genus Trichogramma. The fall armyworm egg-masses is characterized by layered egg distribution covered by the female scales that may affect the action of the egg parasitoid. The paper deals with the impact of such physical barriers on the behavior of T. pretiosum. Daily egg-masses of S. frugiperda with different physical characteristics was used as follows: one layer with no scales, two layers with no scales, and one layer with scales. In the latter the scale density was discriminated as high and low density. For each egg-mass of 20-30 type *T. preliosum* females were set in glass tubes (7.0x1.2cm) with up to 24-hour emergence and filmed for 20min by means of a stereoscopic microscope coupled to a video camera system. The duration of drumming, drilling, oviposition, time over egg- mass and gap elapsed between parasitized eggs was timed, and the number of parasitized eggs recorded. The presence of scales in the egg-masses was observed to significantly increase the time spent by the parasitoid in every behavior stage, also increasing the gap elapsed between the parasitized eggs, decreasing the permanence time over egg- mass and the number of parasitized eggs. The growth in the number of layers decreased significantly the number of eggs parasitized in relation with the egg- masses with one layer and with no scales. A positive correlation was observed to occur between the time spent on the egg- mass and the number of eggs parasitized (r=0.85523) and an inverse correlation between the gap elapsed between parasitized eggs and the number of parasitized eggs (r=-0.75441). It was observed that the physical barriers in S. frugiperda egg-masses did change the behavior of T. pretiosum, affecting the parasitization capacity.

Index terms: egg parasitoid, fall armyworm, parasitization, mechanical defense

[1490] LONGEVITY AND REPRODUCTION OF *DIACHASMIMORPHA* LONGICAUDATA (HYMENOPTERA: BRACONIDAE) BRED IN LARVAE OF CERATITIS CAPITATA (DIPTERA: TEPHRITIDAE)

S. W. P. Bispo¹ & <u>A. S. Nascimento², ¹</u> UFBA-EMBRAPA, Rua Raul Leite, 921, apt. 304, Vila Laura, 40270-180, Salvador, BA,BR.²EMBRAPA Mandioca e Fruticultura, Caixa Postal 007, 44380-000, Cruz das Almas, BA, E-mail antnasc@cnpmf.embrapa.br

In order to understand the reproductive behavior of the Diachasmimorpha longicaudata (Ashmead, 1905) (Hymenoptera: Braconidae) fruit flies parasitoid, aiming at optimizing its laboratory breeding, studies were carried out about the longevity of its virgin and fertilized females, its periods of oviposition, and number and sexual rate of its descendants. These data were collected from insects specially bred with an artificial diet, under controlled conditions of temperature (25° C), humidity (60 – 80%) and hours of exposure to light (12 hours). As the oviposition substratum, 3^{rd} stadium larvae of *Ceratitis capitata* (Wiedemann, 1824) (Diptera: Tephritidae), also bred in laboratory, were used. The findings of these studies lead to the conclusion that virgin females of *D. longicaudata* live, on the average, 22,25% more than the fertilized ones, although they produce only male descendants. The fertilized females generate both male and female descendants, at a sexual rate of around 1:1. It was found that the females of that braconid, whether fertilized or not, are able to produce, on the average, approximately 170 parasitoids throughout their entire adult phase, concentrating around 90% of that offspring on the first 20 days of the cycle.

Index terms: behavior, fruit fly, parasitoid, biolgy

[1491] DEVELOPMENT OF IMMATURE STAGES OF PALMISTICHUS ELAEISIS (HYM.: EULOPHIDAE) ON LEPIDOPTERA PUPAE

M.A.L. Bittencourt¹ & E. Berti Filho², ¹Depto. de Ciências Agrárias e Ambientais (UESC), Rod. Ilhéus-Itabuna, Km 16, 45.650-000, Ilhéus, BA. E-mail¹: malbitte@ jacaranda.uescba.com.br. ²Depto. de Entomologia (ESALQ/USP) C. Postal, 9, 13.418-900, Piracicaba, SP. E-mail: eberti@carpa.ciagri.usp.br.

Palmistichus elaeisis Delvare & LaSalle, 1993 is an endoparasitoid collected from pupae of Sabulodes sp. (Lep.: Geometridae). The immature stages of this parasitoid were studied in laboratory ($25 \pm 1^{\circ}$ C; $70 \pm 10 \%$ RH; 14-hour photoperiod) on the following Lepidoptera pupae: Diatraea saccharalis (Fabricius, 1794) (Crambidae), Anticarsia gemmatalis Hübner, 1818, Heliothis virescens (Fabricius, 1781), Spodoptera frugiperda (J.E. Smith, 1797) (Noctuidae) and Thyrinteina arnobia (Stoll, 1782) (Geometridae). It was observed that the eggs and the 1st instar larvae are hyaline and hymenopteriform; 2nd, 3rd and 4th instars larvae are whitish and 12-segmented; the pupa is of the exarate type. The host species did not influence the number of instars.

Key words: biological control, forest entomology, parasitoids.

[1492] BIOLOGICAL CYCLE, REPRODUCTION AND LONGEVITY OF PALMISTICHUS ELAEISIS (HYM.: EULOPHIDAE) IN LABORATORY

M.A.L. Bittencourt¹ & E. Berti Filho², ¹Depto de Ciências Agrárias e Ambientais (UESC), Rod. Ilhéus-Itabuna, Km 16, 45.650-000, Ilhéus, BA. E-mail1: malbitte@ jacaranda.uescba.com.br. ²Depto. de Entomologia (ESALQ/USP) C. Postal, 9, 13.418-900, Piracicaba, SP. E-mail: eberti@carpa.ciagri.usp.br.

Biological aspects of *Palmistichus elaeisis* Delvare & LaSalle, 1993 were studied in laboratory by using Lepidoptera host pupae of *Diatraea saccharalis* (Fabricius, 1794) (Crambidae), *Anticarsia gemunatalis* Hübner, 1818, *Heliothis virescens* (Fabricius, 1781), *Spodoptera frugiperda* (J.E. Smith, 1797) (Noctuidae) and *Thyrinteina arnobia* (Geometridae). The results were as follows: the life cycle of the parasitoid was 23.4 ± 0.24 days (n=120); the mean longevity was 31.5 and 5.2 days for the females and 20.0 and 3.5 days for the males with and without food respectively; the oviposition period was 11.4 days, with a mean of 1.1 days of preoviposition and 90.9 parasitoids per couple; the sex ratio was 0.95 and the virgin females produced only males. Key words: biological control, forest entomology, parasitoids.

[1493] APPARENT COMPETITION MEDIATED VIA INSECT PARASITOIDS IN HETEROGENEOUS ENVIRONMENTS

M.B. Bonsall¹ & M.P. Hassell¹, ¹Department of Biology and NERC Centre for Population Biology, Imperial College at Silwood Park, Ascot Berkshire, SL5 7PY, U.K.

Prey that exists exclusively on different resources can compete in an indirect manner if they share common natural enemics. This is colloquially known as apparent competition. The role of apparent competition in homogenous (uniform) environments is well known and often leads to the exclusion or dramatic reduction in abundance of one of the prey species. Here, we explore the effects of apparent competition in heterogeneous environments. We present novel experimental evidence of the impact of a shared parasitoid in a heterogeneous environment and demonstrate the effects of dynamic monophagy on the population dynamics of a host-parasitoid assemblage. By considering a styliked interaction between two hosts and a polyphagous parasitoid, we demonstrate, theoretically, how environmental heterogeneity can influence coexistence. In particular, we highlight (1) how the underlying spatial distribution of hosts is paramount in influencing coexistence, (2) the role of temporal switching effects on coexistence and (3) the effects of spatial aggregative behaviours. We emphasis the different sources of variation that are prevalent in promoting coexistence in host-parasitoid assemblages where indirect interactions occur.

Index terms: Venturia canescens; coexistence; modelling; multitrophic interactions.

[1495] CLIMATIC CONSTRAINTS ON BIOCONTROL AGENTS: TRICHILOGASTER ACAIAELONGIFOLIAE IN SOUTH AFRICA

M.J. Byrne and S. Langa, Univ. of the Witwatersrand, Animal, Plant and Environmental Sciences Dept., Ecophysiological Studies Research Programme, Johannesburg, Wits, 2050. South Africa. E-mail: marcus@gecko.biol.wits.ac.za.

Acacia longifolia was introduced from Australia, into the South African Cape Province in the early 19th century for dune binding and is still used as a shade species, and for charcoal. It is highly invasive, choking waterways and catchments and threatens the Cape Fynbos. The wasp, *Trichilogaster acaiaelongifoliae* was introduced in 1982 as a biocontrol agent that attacks only the reproductive structures of the tree, leaving other useful components intact. The wasps originated from three areas in Australia around Sydney, Melbourne and Hobart, where the climate is predominantly Meditteranean, winter rainfall and the mean maximum temperature is less than 22°C. 'This temperature was considered to be the upper thermal limit of the wasp and used to explain poor establishment outside of the Cape region. The lifecycle of the wasp was examined in a summer rainfall region where the mean maximum temperature to December, and development is virtually the same as that in a Meditteranean climate. Infested trees produce fewer flowers, loose more flowers and eventually produce significantly fewer seed-pods than uninfested trees. There is a direct relationship between the number of galls on a branch and the amount of the branch tip death. No parasitoids of the wasp were found from emergence or dissection of galls. The upper fethal temperature limit for the pupal and adult wasps was measured to be well above the mean maximum of $22^{\circ}C$. Tacacaelongifolia has been shown to survive and flourish in hot, summer rainfall areas outside of its predicted climatic range.

ingequiredly affected the dispersal and establishment of A, criticola, the presence of ratives as printerly affected the dispersal and establishment of A, criticola, the presence of ratives as printerly paraminal was higher than that presence as hyperparamines (he complete chails of A, criticola project was tool contact (usually one or two). Chemical control (averaged) and made cloud) in used in numerices and (or fresh market).

[1494] EFFECT OF ARTIFICIAL DEFOLIATION ON LANTANA GROWTH AND REPRODUCTION

<u>S. Broughton</u>, Entomology Division, Agriculture Western Australia, 3 Baron-Hay Crt, South Perth, Western Australia. E-mail smbroughton@agric.wa.gov.au.

Lantana camara L. (Verbenaceae), is a woody perennial weed that was introduced to Australia as an ornamental plant in the 1800's. Biological control of lantana commenced in 1914 and to date 26 insect species have been released for its control in Australia. Worldwide 38 species of insect have been released in 29 countries with varying levels of success. Only in parts of Hawaii, USA, is lantana considered to be under partial control. Since 71% of the released insect species mine, chew or suck the leaves resulting in defoliation, artificial defoliation techniques were used to examine the impact of frequency, timing and level of defoliation on lantana. Every three months (spring, summer, autumn), 0%, 50% or 100% of leaves were removed from plants. Changes in plant height, stem width and the number of stems were recorded one month after each episode of defoliation. At the end of the experiment all plants were harvested and the amount of biomass (dry weight) was calculated for the stens, roots, leaves and reproductive structures (buds, flowers and fruit). There were no significant decreases in vertical height or the number of stems produced, but plants defoliated in spring produced more stems than those defoliated in spring and autumn. Similarly, there were no differences in root, stem, leaf or reproductive structure biomass. However, differences in the proportion of biomass allocated to reproduction were recorded. Plants that had been defoliated three times allocated a higher proportion of their biomass to reproduction than those defoliated once or twice. Overall, these results suggest that lantana compensates for defoliation. Index terms: Lantana camara, artificial defoliation

[1496] PREDATION OF *PHYLLOPHAGA* (COLEOPTERA: SCARABAEIDAE) EGGS IN NO-TILL AND CONVENTIONAL-TILL MAIZE

C. K. Gerber¹, M. J. Stanyard¹, & T. J. Gibb¹, ¹Dept. of Entomology, Purdue Univ., West Lafayette, IN 47907-1158, USA.

Questions exist in Central and South America concerning the long term costs and benefits of no-tillage (NT) cultivation in maize fields compared with conventional-tillage (CT). White grubs of the genus *Phyllophaga* can cause significant economic danage in maize. To assess the costs and benefits of NT and CT, a survey of white grubs in both tillage practices was conducted. One aspect of the NT versus CT debate is the question of the relative impact of beneficial insects in the two systems. Anis are known to be a major predator on white grub eggs. Therefore, pitfall traps were used to assess ant activity in the soil profile. Correlations between tillage practices and ant populations were then used to explain any differences in grub densities. Results indicated that significantly more predation occurred in NT maize fields.

explain any differences in good state of boundaries of the second state of the second paramitzed eggs two species were collected: T anynevirilia and Tolenomus symmophylix. the latter found for the first time in equa of H, zero T, consequipting was previously described in Southern Parana parasitizing equal of Anti-arraig generately in suppressing the second Corn is usually grown in association with raybeins and T atoposizing has also been found in copiecase paramitring eggs of A. generatoria. The percibility of rearing T. approxidiat uning eggs of A. groundatic as hosts was investigated in laboratory. Its development, feenadity and Impevity were evaluated at 25°C and compared to T preutonan which is the mun egg paraciloid of A. gevenutalis. The developmental time of the immuture stages of $T_{\rm c}$ are prevention in equa of A. generalized id and differ from that of $T_{\rm c}$ pretrievant and lasted ca. 10 days at 25%. Females of T. anspovirilla hald on average of 104.5 eggs iloring their lifetime and survived for 11.4 days in the presence of host eggs. Their longevity was significantly reduced (6.7 dawi) in the absence of home, indicating that females feed on mariants extending from the eggs and thus increase their longevity when host eggs are available. The mean number of parasitoids emerged from each egg was 1.3. It is concluded that natural parasitians of R, yea ergs in low in Southern Parani, and T previously in the predominant purasitoid species. T. atopovirilia can also be reared in eggs of A. gemmatalis and its reproductive potential is similar to that of T. prediction.

Index terms: Biological control, corn carworm. Trichogramma, Televonus reamophylax.

[1497] CURRENT STATUS OF CITRUS LEAFMINER AND ITS PARASITOIDS IN CORRIENTES (ARGENTINA)

S. Cáceres, EEA INTA Bella Vista, Ctes. (Argentina) E-mail: intaexp@bvista.com.ar

Citrus leafminer (CLM), Phyllocnistis citrella, was detected in Corrientes in November 1996. Besides feeding injury, extensive lesions of citrus canker (a Northeast endemic disease) develop on leaves damaged by leafminer. Seasonal abundance and parasitism of the leafminer were investigated from 1997 through 1999 on lemon and orange groves with minimal insecticide spreads. The density of P. citrella was determined by randomly picking one flush per tree in 40 trees per grove, twice a month. Parasitoids were identified by J. LaSalle. Given the apparent low levels of control by native parasitoids, the importation and release of Ageniaspis citricola was considered; large number of pupae of *A. citricola* were brought to Corrientes from EEAOC (Tucumán, Argentina) where it had just established; 1052 adults emerged were released in five insecticide-free groves between April 30 and May 6, 1998. P. citrella population was higher (twice) in lemon flushes than in orange flushes. The number of larva + pupa per flush (orange and lemon) was high in 1997 fall and in 1998 summer-fall (more than 15 immature stages per flush in lemon). The presence of leafminer was considerably lower in 1999. Three species of native parasitoids attacked P. citrella immature stages: Cirrospilus sp. C, Cirrospilus sp. and Elasmus sp. Cirrospilus sp. C that parasites CLM larva 3, prepupa or pupa and Elasmus sp. that parasites only prepupa or pupa comprised 98% of the native parasitoids. Recoveries of A. citricola were made at the five released groves. A. citricola mass rearing was not successful and we found efficient to collect citrus leaves from insecticide-free groves and greenhouse pruned plants and rear out the parasitoid. 7233 A. citricola adults were released between March 15 (1999) and June 25 (1999) in 62 sites. In most releases (43%) 50-100 adults were used per site. A.. citricola has high reproductive rate (2.9 ± 0.4 pupae per CLM, Dec 98-Mar 99). Parasitism from A. citricola at monitored groves increased to almost 90% of total parasitism three moths after the release. Both natives Cirrospilus sp. C and Elasmus sp. were observed as primary parasitoids and as hyperparasitoids of A. citricola (facultative hyperparasitoids). Hyperparasitism has not negatively affected the dispersal and establishment of A. citricola; the presence of natives as primary parasitoid was higher than their presence as hyperparasites; the complete chain of A. citricola pupae was not consumed (usually one or two). Chemical control (avermectin and imidacloprid) is used in nurseries and for fresh market.

[1498] EGG PARASITOIDS OF *HELICOVERPA ZEA* IN SOUTHERN PARANÁ, BRAZIL AND REARING OF *TRICHOGRAMMA ATOPOVIRILIA* ON AN ALTERNATIVE HOST

C. L. Cañete¹, & L. A. Foerster¹, ¹ Dept. of Zoology, Univ. Federal do Paraná. P. O. Box 19.020 (81531-990) Curitiba, PR, Brazil. E-mail: caca@bio.ufpr.br

There are few studies related to natural parasitism in eggs of Helicoverpa zea in Brazil, despite the importance of this noctuid as a pest of corn ears. Previous surveys indicated the occurrence of Trichogramma pretiosum and T. atopovirilia parasitizing eggs of H. zea in Brazil. In order to evaluate the incidence of natural parasitism in eggs of H. zea, field surveys were carried out in corn during 1998 and 1999 in Southern Paraná State. The rate of parasitism in both years was estimated to assess the importance of egg parasitoids in the control of the corn earworm. Eggs were randomly collected in corn ears and transferred to the laboratory to determine the presence of parasitoids. In 1998, a total of 393 eggs of H. zea were collected and 4.9% were parasitized. In 1999, 734 eggs were sampled and 5.5% yielded parasitoids. Trichogramma pretiosum was the predominant species, accounting for 61.1% and 70.7% of the parasitoids emerged in laboratory. In the remaining of the parasitized eggs two species were collected: T. atopovirilia and Telenomus cyamophylax, the latter found for the first time in eggs of H. zea. T. cyamophylax was previously described in Southern Paraná parasitizing eggs of Anticarsia gemmatalis in soybeans. Corn is usually grown in association with soybeans and T. atopovirilia has also been found in soybeans parasitizing eggs of A. gemmatalis. The possibility of rearing T. atopovirilia using eggs of A. gemmatalis as hosts was investigated in laboratory. Its development, fecundity and longevity were evaluated at 25°C and compared to T. pretiosum which is the main egg parasitoid of A. gemmatalis. The developmental time of the immature stages of T. atopovirilia in eggs of A. gemmatalis did not differ from that of T. pretiosum and lasted ca. 10 days at 25°C. Females of T. atopovirilia laid an average of 104.5 eggs during their lifetime and survived for 11.4 days in the presence of host eggs. Their longevity was significantly reduced (6.7 days) in the absence of hosts, indicating that females feed on nutrients extruding from the eggs and thus increase their longevity when host eggs are available. The mean number of parasitoids emerged from each egg was 1.3. It is concluded that natural parasitism of H. zea eggs is low in Southern Paraná, and T. pretiosum is the predominant parasitoid species. T. atopovirilia can also be reared in eggs of A. gemmatalis and its reproductive potential is similar to that of T. pretiosum.

Index terms: Biological control, corn earworm, Trichogramma, Telenomus cyamophylax.

[1499] A FIRST APPROACH ON THE POTENTIAL ROLE OF *DICYPHUS CERASTII* WAGNER (HEMIPTERA: MIRIDAE), AS NATURAL CONTROL AGENT IN PORTUGUESE GREENHOUSES

"P. Carvalho¹", "F. Luz¹" & "<u>A.Mexia</u>², ¹ Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal, ppassos@isa.utl.pt ;² Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras ean@mail.telepac.pt

The most common mirid bug found in the Portuguese greenhouses of the Oeste region, the Dicyphinae *Dicyphus cerastii*, (Hemiptera: Miridae) was studied and the seasonal evolution of its population on protected tomato crops was elucidated as well as the role played by weeds. Its potential to predate the leafminer *Liriomyza huidobrensis* was shown in a laboratorial trial. In the laboratory it was also possible to demonstrate that necrophagy, occasionally observed in the field, is an adaptive advantage for this facultative phytophagous and predator insect, since feeding on entomological cadavers, increases the fertility.

Index terms: Miridae, biological control, greenhouse crops, Oeste region of Portugal.

[1500] THE ROLE OF CHRYSOPIDS AS NATURAL CONTROL AGENTS IN PORTUGUESE GREENHOUSES

P. Carvalho¹, C. Couto¹ & <u>A. Mexia²</u>, ¹ Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal ppassos@isa.utl.pt ;Instituto Nacional de Investigação Agrária, Estação Agronómica Nacional, Quinta do Marquês, 2780 Oeiras ean@mail.telepac.pt

Among the native polyphagous predators of the entomofauna in Portugal. 28 species of chrysopids have been observed. However there is a great lack of information related to their potential use as pest control agents. In Portugal, the most relevant data concerning chrysopids is mostly, if not all, based on *Chrysoperla carnea* ignoring the real significance of all other species, although some of them are very common (*Mallada* sp). Long term global climatic changes may be a reason for the current relative importance of *C. carnea* given that new adjustments of the different ecosystems might be taking place. In this work the most common species are listed and their relative importance is discussed; specifically with regard to protected crops in the Oeste region, using either ammonium dihydrogen phosphate + protein traps or yellow sticky traps. These traps were either used isolated in some experimental plots or combined, in other plots.

Index terms: Neuroptera: Chrysopidae, Chrysoperla camea, Mallada sp., natural control, greenhouse crops

[1501] HOST SPECIFICITY TESTING OF RODOLIA CARDINALIS, A CENTURY

C.E. Causton¹ & T. Poulsom¹, ¹Invertebrate Program, Charles Darwin Research Station, A.P. 17-01-3891, Quito, Ecuador, causton@fcdarwin.org.ec

Serious damage to indigenous plant species of the Galápagos Islands by the cottony cushion scale, *Icerya purchasi* Maskell, has led the Galápagos National Park Service and the Charles Darwin Research Station to consider the use of biological control in the archipelago for the first time. *Icerya purchasi* was discovered in the Galápagos in 1982 and has since spread to 12 islands. To date, 56 plant species are known to be affected by the scale insect. An advisory committee set up in 1996 approved the evaluation of *Rodolia cardinalis* to control this species. Concern that the feeding range of *R. cardinalis* has not been experimentally studied and that the agent might negatively impact endemic scale insects, most notably, an endemic margarodid, prompted studies on its host feeding range. Endemic and native representatives of Margarodidae, Orthezidae, Pseudococcidae, Eriococcidae, Diaspidae and Aphididae were tested on adults and larvae of *R. cardinalis* and the results of these studies are presented.

Index words: Vedalia beetle, Icerya purchasi, host range, Galápagos Islands.

[1502] AGENIASPIS CITRICOLA: INTRODUCTION, LABORATORY REARING AND ADAPTATION IN BRAZIL

M. C. M. Chagas¹, P. T. Yamamoto², P. Milano³, A. L. G. C. Parra³, A. M. Nascimento³ & J. R. P. Parra³, ¹Embrapa/Emparn, Caixa Postal 188, Natal-RN, Brazil, E-nail marcone@dmrh.emparn.br; ²Fundecitrus, Araraguara-SP, 14807-040; ³Dep. Entomol., Fitop. e Zool. Agrícola, ESALQ-USP, 13418-900, Piracicaba-SP, Brasil. Financial support: Fundecitrus.

A. citricola was introduced in Brazil in July, 1998, imported from Florida-U.S.A. In the quarantine facilities, emerged 450 wasps; after this period, in the laboratory of Insect Biology from the Department of Entomology, Plant Pathology and Agricultural Zoology, ESALQ/USP, a new system for the citrus leafminer rearing was developed, in order to improve the parasitoid production. The host is reared in Citrus limonia, cultivated in small black rigid plastic tubes, 20 cm height per 1.5 cm diameter containing vermiculite and vegetal compound (1:1) as substrate. In order to get flushing (leaves age preferred by citrus leaf miner oviposition), the plants are pruned approximately 1/3 below top, later properly fertilized and kept in metal grids (capacity for 40 small tubes). They are maintained in rearing rooms (temperature of 25 ± 1 °C; $60 \pm 10\%$ RH and 14 hour photophase) during 15-17 days until early flushings, that are exposed to P. citrella adults in the ratio of one newly-emerged insect to each three plants (1:3). The P. citrella eggs and/or first instar larvae are exposed for A. citricola parasitization during 3 to 5 days. The rearing system developed require little space, less time for hand labor. As a consequence it is possible to use incubators to maintain the plants and get the synchronization between host and parasitoid development by using thermal requirements for both. Thus, it is possible to keep an average of 400 plants/m² with a mean population potential of 6,300 parasitoids in an average period of 17 days under previously mentioned conditions. So, according to laboratory observations, one considered mean values of 4 leaves liable to egg lay/plant; 2 (two) eggs/leaf; production of 3.3 wasps/parasitized host, and 60% of parasitism viability. The first parasitoid releasing in Brazil, occurred in October, 1998, in Descalvado and Nova Granada counties, in the State of São Paulo. The goal of this program is the parasitoid inoculative releasing in this state, where the citrus grove area reaches 800.000 ha; and we are also releasing in other states of Brazil, as Paraná, Minas Gerais, Santa Catarina and Rio Grande do Sul, too. After a year of parasitoid rearing, we have released around 150,000 parasitoids in 53 localities and 57 citrus groves, corresponding to 15,000 ha. The parasitoid recovering was observed in different weather conditions.

Index terms: citrus leaf miner, biological control, rearing techniques, citrus pest.

Symposium and Poster Session

[1503] LABORATORY OBSERVATIONS ON THE LIFE HISTORY AND PREDATORY EFFICIENCY OF SEVEN SPECIES OF *PHILONTHUS* (COLEOPTERA: STAPHYLINIDAE) ON THE HOUSE FLY (DIPTERA: MUSCIDAE)

<u>M. R. Chani Posse</u>, Fundacion Miguel Lillo, Instituto Superior de Entomologia (INSUE), Miguel Lillo 205, (4000) Tucuman, Argentina. E-mail: march@impsat1.com.ar.

The Southamerican dung-beetle fauna includes many predatory and parasitic species belonging to the families Staphylinidae, Hydrophilidae and Histeridae (Fletchmann 1995; Cabrera Walsh et al. 1997; Guimaraes et al. 1998). Beetles from these three families have been shown to reduce populations of dung-breeding flies in both southern Africa (Fay 1980; Doube et al. 1987; Doube 1987) and North America (Roth 1982; Summunerlin et al. 1982; Fincher 1994; Hu et al. 1996; Hu et al. 1997). Staphylinids of the genus *Philonthus* have long been important predators of dung-breeding Diptera. However, the bionomics of local Philonthus species are virtually unknown. The present study constitutes a preliminary investigation about biological aspects of local Philonthus species and their ability to prey on dung-breeding flies under laboratory conditions. Seven species of Philonthus which are frequent inhabitants of cattle dung in Tucuman, Argentina, are considered for study. Potential predators were collected from naturally deposited dung by collecting the excrement in the field, returning the manure to the lab and removing the insects by flotation. Rearing techniques was developed by following the method of Hunter et al. (1986) for Philonthus. For observation, individual beetles from egg to adult were confined and house fly eggs and 1st instar larvae were provided for food. Data on egg hatch, larval molt, pupation and adult emergence, as well as counts of house fly eggs and larvae offered and consumed were recorded daily. Variables considered in data analysis were feeding rates of Philonthus larvae and adults as well as duration and size of each stage from egg to adult. Results derived from a cluster analysis showed that Philonthus rectangulus, P. bruchi and P. sp7 comprised a cluster associated primarily with the highest feeding rates and sizes. The other cluster comprised P. flavolimbatus, P.sp5 and P.sp6. These species were smaller and had lower feeding rates. P. pauxillus appeared as a separate taxa with the lowest feeding rates. Duration of life cycle from egg to adults are reported for all species. Based on these preliminary results, we conclude that Philonthus rectangulus, P. bruchi and P. sp7 appear to be prospective biological control agents of dung-breeding flies although additional field and laboratory investigations are required to accurately access their effectiveness.

Index terms: *Philonthus rectangulus*, *P. bruchi*, feeding rates, potential predators, house fly

[1504] THE EFFECT OF PREY DENSITY ON THE PREDATORY ABILITY OF THREE SPECIES OF *PHILONTHUS* (COLEOPTERA: STAPHYLINIDAE) ASSOCIATED WITH CATTLE DUNG

M. R. Chani Posse, Fundacion Miguel Lillo, Instituto Superior de Entomologia (INSUE), Miguel Lillo 205, (4000) Tucuman, Argentina. E-mail: march@impsat1.com.ar.

Insect predators inhabiting bovine dung pats may influence populations of dung breeding flies. Several species of predators have been reported attacking dung breeding Diptera in North America (Roth 1982; Summmerlin et al. 1982; Fincher 1994; Hu et al. 1996; Hu et al. 1997) and southern Africa (Fay 1980; Doube et al. 1987; Doube 1987) and they have long been viewed as potential biological control agents. The introduction of the horn fly Haematobia irritans irritans (Diptera: Muscidae), in southern Brazil, Paraguay, Uruguay and Argentina stimulated interest in research on the identification, biology, and utility of such species (Fletchmann 1995; Cabrera Walsh et al. 1997; Guimaraes et al. 1998; Lizarralde de Gosso et al. 1999). Predation by staphylinid beetles of the genus Philonthus has been implicated as a mortality factor of dung-breeding flies. Although the predation potential of Philonthus species appears well documented, there is only limited information published on the capacity of the southamerican fauna to prey upon the pre-adult stages of flies. Objectives of this study were to evaluate the functional responses of three *Philonthus* species frequently associated with cattle droppings in Tucuman, Argentina. Adult Philonthus spp. were collected from naturally deposited dung by collecting the excrement in the field, returning the manure to the lab and removing the insects by flotation. Rearing techniques was developed by following the method of Hunter et al. (1986) for Philonthus. For observation, individual beetles from egg to adult were confined under laboratory conditions and house fly (Diptera: Muscidae) eggs and 1st instar larvae were provided for food. The feeding rates of adults and larvae of Philonthus bruchi, P. flavolimbatus and P. pauxillus were compared at different densities of prey in the laboratory by measuring their patxinus were compared a unterent densities of prevail on habitatory of inclusion and the second sec (Neotropical species, collected in Tucuman) on the immature stages of house flies are reported. When confined with abundant prey, adults and larvae of P. bruchi had a higher predation rate than did those of P. flavolimbatus, which in turn had a higher rate than did those of P. pauxillus. The relationship derived from functional responses in both larvae and adults of these species was similar to the type II functional response.

Index terms: Philonthus bruchi, Philonthus flavolimbatus, Philonthus pauxillus, house fly, functional response

[1505] THE OCCURRENCE OF LEAFMINERS AND THEIR PARASITOIDS ON VEGETABLE CROPS AND WEEDS IN SOUTHEAST CHINA

X.X. Chen, Z.H. Xu, J.H. He, Y. Ma & R.Q. Rong, Department of Plant Protection, College of Agriculture and Biotechnology, Zhejiang University, No.286 Kaixuan Road, Huajiachi Campus, Hangzhou 310029 CHINA, E-mail xxchen@zju.edu.cn

A survey was carried out in Southeast China in 1998-1999 to determine the distribution of leafminers and their parasitoids on vegetable crops and weeds in the field. Leaves were collected weekly at random and taken to the laboratory and the number of galleries were counted and maintained in insectaries until the emergence of the parasitoids. The leafminer species found comprised Liriomyza bryoniae, L. chineneis, L. sativae, and Chromatomyia horticola, with Ch. horticola and L. sativae the most abundant in Spring and Autumn, respectively. In total 23 hymenopterous species of four families (16 eulophids, four pteromalids, one ceraphronid, and two braconids) were found. They are as follows: Hemiptarsenus dropion, Hemiptarsenus variconis, Diglyphus isaea, Diglyphus albiscapus, Closterocerus trifasciatus, Chrysocharis phryne, Chrysocharis peniheus, Pnigalio katonis, Neochrysocharis formosa, Neochrysocharis punctiventris, Pediobius mitsukurii, Teleopterus erxias, Diaulinopsis arenaria, Cirrospilus lyncus, Tetrastichus chara, Tetrastichus mandanis; Callitura sp., Sphegigaster humugurivora, Thinodytes cyzicus, Halticoptera circulus, Ceraphron sp., Opius pallipes, and Opius sp.. Among them 20 parasitoid species were reared from Ch. horticola, two species from L. chinensis, four species from L. bryoniae, and nine species from L. sativae. Six parasitoid species were reared from leafminers on four selected weeds: Diglyphus isaea, Diglyphus albiscapus, Pnigalio katonis, Neochrysocharis formosa, Halticoptera circulus, and Opius sp.. These parasitoids could possibly enhance the biological control of the leafminers on vegetable

crops. Index terms: leafminers, parasitoids, vegetable crops, weeds

A. I.Ciociola In¹, R.A. Zucchi¹ & R. Stouthamer², ¹Departmento de Entomologia, Fitopatologia e Zoologia Agrícola. Caixa Postal 9, CEP:13.418-900, ESALQ/USP, Piracicaba-SP, Brazil. E-mail: ciociola@carpa. ciagri.usp.br; ²Department of Plant Sciences, Laboratory of Entomology, Wageningen-UR Centre, P.O Box 8031, 6700EH Wageningen, The Netherlands.

Since the beginning of the 1970's, the *Trichogramma* identification is based on the morphological analysis of the male genitalia. Sometimes, identification of closely related species is difficult. A new technique is used in this paper to solve this problems. Using the ITS2 sequences of the ribosomal DNA together with some restriction enzymes, we are able to construct a simple and precise molecular key to some Brazilian species of *Trichogramma*. This key is easy to build and we can obtain quick results for the identification of this minute wasp (about 0.25 mm). Using this methodology we can also check for possible contaminations under laboratory rearings, and its easy to apply. To choose the best restriction enzyme to build the molecular key, we used a free program available in the internet, Webcutter 2.0 (http://www.ccsi.com/firstmarket/firsmarket/cutter/cut2.html). Enzymes that were able to distinguish between ITS2 products of similar size were tested to verify that they indeed cut the product at the predicted location. The key presented in this study is restricted to the collecting sites and the species analysed. It is important to know that for the success of this method, we must work together with a taxonomist.

[1508] CURRENT STATUS OF THE BIOLOGICAL CONTROL PROGRAM FOR THE MEALYBUG, ORACELLA ACUTA, IN THE PEOPLE'S REPUBLIC OF CHINA

S. R. Clarke¹, J. H. Sun², G. L. DeBarr³, H. B. Yu⁴ & M. R. Chen⁴, ¹Forest Health Protection. USDA Forest Service, 701 N 1st St., Lufkin, TX 75901, USA, E-mail sclarke/r8_tx@fc.fcd.us; ²Dept. of Forestry, Northeast Forestry University, Heilongjiang, Harbin 515004, China; ³Southern Research Station, USDA Forest Service, Athens, GA 30602, USA; ⁴Forest Disease and Pest Control Station, Guangdong Province, Guangzhou 510173, China.

A mealybug, Oracella acuta, was introduced into the Guangdong Province in the People's Republic of China in 1988. Insecticides and native natural enemies were unable to control the mealybug, and populations were spreading through slash pine plantations at a rate of up to 63 km/year. A cooperative project was initiated between the PRC and the United States to import natural enemies from the USA into the PRC to control the mealybug. Natural enemies keep mealybug populations at low levels in the southeastern USA, and appear to be the best method for control in the PRC. Efforts began in 1994 to both create Oracella populations in the USA and locate infested seed orchards to provide rearing material for parasitoids. Thirty-two shipments of three species of parasitoids, Alloitropa sp., Zarhopalus debarri, and Acerophagus coccois, have been sent to Guangdong since 1995. Though a mass-rearing program of these species in China has not yet proved successful, the parasitoids have been reared through at least one generation in a lab. Field releases, usually within cages around branches or whole trees, were made at several sites. A systematic monitoring program around the release sites was established in 1997, but no establishment of the released parasitoids has been recorded to date. The parasitoids do not appear to have significantly impacted the mealybug populations at this time. Continued parasitoid shipments and releases are planned for 2000. Another parasitoid, Anagyrus daciylopii, was discovered parasiting Oracella at some of the release sites. This parasitoid sin to host-specific, and competition trials between this species and the introduced parasitoids are scheduled. In 1999, the mealybug infestation spread into Guangxi Province, and is now very close to plantations of lobioly pine, its main host in the United States. Results from the current year's sampling will be reported. Index terms: Allotropa sp., Zarhopalus debarri, Anagyrus dactylopii, parasitoids

have released around 150,000 gamminude to \$3 locatilies and 57 cutum growns, corresponding to 15,000 ha. The paramoid recovering was observed in different weather conditions.

[1509] INFLUENCE OF PREY SIZE ON PREDATION SUCCESS BY ZELUS LONGIPES (HETEROPTERA: REDUVIDAE)

<u>R. Cogni</u>¹, A. V. L. Freitas¹ & B. F. Amaral Filho², ¹Museu de História Natural, Inst. de Biologia, Univ. Estadual de Campinas, CP 6109, 13083-970, Campinas-SP, Brazil, E-mail cogni@unicamp.br; ²Dept. de Zoologia, Inst. de Biologia, Univ. Estadual de Campinas, CP 6109, 13083-970, Campinas-SP, Brazil, Financial support: SAE-Univ. Estadual de Campinas.

We investigated the influence of prey size on attack rate, predator success, and feeding time, relating this to the behavior of a predator and the consequences to the predatory responses in an arthropod with extra-oral digestion. We made tests in laboratory using adults of the reduviid Zelus longipes as predator and the larva of the notuid moth Spadoptera frugiperda as prey. In tests with one caterpillar, we offered larvae of three different weight classes individually to the predator. The prey weight was positively correlated with relative weight gain by the predator (Spearman r, = 0.694), mean feeding time (r, = 0.0706) and discarded biomass (r, = 0.915), but not with the relative extraction rate (defined as the relative weight gain by the predator per feeding time) (r, = 0.097). The different sizes of caterpillars were attacked with the same frequency ($\chi^2 = 1.75$; d.f. = 2; p > 0.20), but the successful attacks were more frequent in small larvae ($\chi^2 = 32.2$; d.f. = 2; p < 0.001). The median mass of successfully attacked larvae (84.2 mg; n = 20) was also smaller than that of unsuccessfully attacked (279.0 mg; n = 30) (Mann-Whitney U = 26.0; p < 0.001). In tests with three caterpillars, we offered larvae of three weight classes at the same time; small caterpillars were more attacked and killed than the medium and large ones ($\chi^2 = 8.48$; d.f. = 2; p < 0.05). The results showed that even if larger prey resulted in more energy intake, when the choice is possible, smaller caterpillars were more attacked than medium and large. This is probably related with the fact that successful attacks were more frequent mediates attacks avere more energy intake, probably related with the fact that successful attacks were more frequent on small larvae (see the mediate mate in the same time; Spodoptera frugiperda. Noctuidae, feeding time, attack rate, extra-oral digestion.

[1510] USING BIOCHEMICAL APPROACHES FOR QUALITY CONTROL OF INSECTS REARED ON ARTIFICIAL DIETS

A. C. Cohen, BCMRRU P.O. Box 5367 Mississippi State University, MS 39762-5367, USA, e-mail acohen@bcmrru.msstate.edu

Polyclonal antibodies were used in ELISAs, dot blots, and Western blots to assess the vitellin quantity in *Lygus hesperus* and *Chrysoperla rufilabris* to detormine the correlation between biochemical characteristics and biological fitness as indicated by body weight, ovarian development, egg production, and survival time. The correlation between vitellin content and biological fitness was significant, and it was demonstrated that vitellin content, and possibly other biochemical characteristics, can be used as a measure of fitness and an early warning sign of colony deterioration or other problems in the quality of mass produced insects. Further analyses of yolk proteins in neonates also indicated that there is a high likelihood that biochemical characteristics can predict fitness and quality of early development stages of mass reared insects. Index terms: vitellin, predators, chrysopids.

[1511] USING KNOWLEDGE OF FEEDING BIOLOGY AND BIOCHEMISTRY TO DEVELOP ARTIFICIAL DIETS FOR PREDACEOUS AND PHYTOPHAGOUS INSECTS

A. C. Cohen, BCMRRU P.O. Box 5367 Mississippi State University, MS 39762-5367, USA, e-mail acohen@bcmrru.msstate.edu

Several artificial diets have been developed using a combination of methods that includes detailed studies of the biochemistry of the micro feeding behavior, digestive enzymes, and fanalysis of the composition of the natural foods of targeted arthropods. Success in development of diets for predators (such as *Chrysoperla rufflabris*, *Geocoris punctipes*, and *Orius insidiosus*) and for zoophytophages (such as *Lygus hesperus* and *L. lineolaris*) has been greatly enhanced by the recognition that these insects use extra-oral digestion to process nutritious portions of their prey or plant hosts: Such understanding, along with knowledge of specialized digestive enzymes, provides a clear profile of what macromolecular structures these insects are prepared to encounter. Furthermore, an exact: knowledge of food profiles (amounts of protein, lipids; carbohydrates, for example) gives greater resolution of ideal diet profiles to be targeted. A matrix that models the interplay between behavioral choices, enzyme types, and food profiles is presented as a means of optimizing diets for *L. hesperus* and *L. lineolaris*.

was anyore [2.8 to 3.0) in the 'untreased' experiment. The yields were literary and investely correlated to the increase in full armyworm erg must infentation and the yield reduction was 42.4% to the highers infention.

[1512] HOST SELECTION BEHAVIOR OF IN VIVO- AND IN VITRO-REARED ; TRICHOGRAMMA GALLOI AND T. PRETIOSUM (HYMENOPTERA: TRICHOGRAMMATIDAE)

F.L. Cônsoli¹ & J.R.P. Parra², ¹Department of Entomology, Texas A&M University, College Station, TX 77843-2475, USA; ²Departameneto de Entomologia, Fitopatologia e Zoologia Agrícola, Escola Superior de Agricultura "Luiz de Queirco"/USP, Caixa Postal 9, Piracicaba, SP 13418-900, Brasil, E-mail: f-consoli@tamu.edu.

Trichogramma is the only parasitoid that has been successfully mass-produced on artificial eggs and used in mass releasing programs to control agricultural pests. Chinese researchers are the only ones capable to use this technology in large scale, although researchers in Australia, Brazil, France and USA have improved their *in vitro* rearing techniques. Despite the possibility of mass producing these parasitoids on artificial diets, few have been the reports comparing the quality of the *in vitro*-reared wasps to those *in vivo*-reared. Most of *Trichogramma* species reared on artificial diets had their parasitization capacity and survivorship reduced if compared to those insects developing on their natural or factitious hosts. Although some biological traits were used to assess the quality of parasitoids produced on artificial diets, very little is known about their host selection behavior. We have reared *Trichogramma galloi* and *T. pretiosum* in artificial eggs by using different artificial diets, and we have compared the host selection behavior of *in vitro*-reared wasps was similar to those reared *in vivo*. However, females eclosed from low-quality dist showed reduced agressiveness, increased searching time and time for host exploitation (host evaluation, drilling and oviposition). The use of behavioral studies for the evaluation of the quality of *in vitro*-reared *Trichogramma* is also discussed, and the use of *in vitro*-rearing techniques as a tool for studying the host selection behavior of parasitoids is going to be addressed as well. Symposium and Poster Session

[1513] EFFECT OF A NUCLEAR POLYHEDROSIS VIRUS ON SPODOPTERA FRUGIPERDA LARVAE, ITS DAMAGE AND YIELD OF MAIZE CROP AT DIFFERENT EGG MASS INFESTATION LEVELS

Ivan Cruz¹, M. L. C. Figueiredo¹, A. C. Oliveira¹ & P. A. Viana¹, Embrapa Milho e Sorgo, Caixa Postal 151, 35700-970 Sete Lagoas, MG, Brasil. E-mail: ivancruz@cnpms.embrapa.br.

The efficiency of Baculovirus in a wettable powder formulation to control the fall armyworm Spodoptera frugiperda (Smith) was evaluated. The treatments were arranged in a randomized complete block with six replications. Plants at the 8-10-leaf growth stage were artificially infested with different densities of fall armyworm egg masses (0, 20, 40, 60, 80 and 100% of infested plants). The virus was applied using a dose of 50 grams per hectare (2.5 x 10¹¹ polyhedron inclusion bodies - PIB/ha) applied once as an aqueous suspension (300 l/ha) 72 days hours after egg hatching using a back-pack-manual sprayer at 40 PSI (2.8 kg/cm²) and a regular flat fan nozzle. Evaluation was based on larva mortality, leaf damage and yield. A comparison, a similar experiment was conducted without virus application ("untreated"). Larva mortality rate obtained on plots protected by the virus varied from 82.6% (100% infestation) to 93.2 (20% infestation level). The leaf damage (1 to 5 scale) was 3.5 and 2.3. The yield obtained from plots with infestation levels of up to 60% was similar to the yield obtained from non-infested plots. Leaf damage was severe (2.8 to 5.0) in the "untreated" experiment. The yields were linearly and inversely correlated to the increase in fall armyworm egg mass infestation and the yield reduction was 42.3% in the highest infestation.

Index terms: Insecta, fall armyworm, artificial infestation, biological control, Baculovirus, Zea maiz)

[1515] REMARKS ON THE SEXUAL RATIO OF THE CAMPOLETIS FLAVICINCTA IN LABORATORIAL REARING

S. T. Dequech¹, <u>R. F. da Silva²</u> & L. M. Fiuza³, ¹ Fitosanity Defense Dept. CCR – Univ. Fed. of Santa Maria. 97119-900 Santa Maria, RS, Br, E-mail soniabd@zaz.com.br; ^{1, 2} Health Plant Department, School of Agr., Univ. Fed. of Rio Grande do Sul, P. O. Box 776, 90001-970, Porto Alegre, RS, Br, E-mail rogeriop@vortex.ufrgs.br; ³ Microbiology Department / UNISINOS, Av. Unisinos, 950, 93022, São Leopoldo, RS, Br, E-mail fiuza@cirrus.unisinos.br.

Amongst the more important natural enemies of Spodoptera frugiperda is Campoletis flavicincta (Hym., Ichneumonidae). The rearing of this parasitoid in laboratory many times faces relative problems concerning the sexual ratio which is obtained, with much bigger predominance of males. The objective of the present work was to evaluate some factors which can possibly modify the ratio mentioned, such as: (1) formation of pairs at the moment of receiving hosts or before, (2) age of host organisms and (3) age of females when parasitism occurs. Pairs of C. flavicincta, with known age, were individualizated, fed with honey solution at 10% and kept in a B.O.D incubator regulated for 25°C, humidity of 65% and photoperiod of 12 h. In order to test objective 1, the sexual ratio of pairs formed before being exposed to the larvae was compared with the sexual ratio of the pairs formed at the moment of the larvae exposition. For objective 2, the sexual ratios of the parasitoids which emerged from larvae that, at the moment of the exposition, were on the 2nd or on the 3rd instar were compared. And for objective 3, different ages of females at the moment of exposition to the 2nd instar larvae were analysed. The values obtained for 374 parasitoids stemming from pairs formed prior to larvae exposition, compared with 530 ones which did not undergo such previous exposition, have resulted in the ratios of 1 female : 5.4 males and 1: 4.0, respectively, which was not statistically significant at the qui-square test (p=0.05). Considering the age of the exposed larvae, when at the 2^{nd} instar, the ratio was of 1: 4.3 for 680 analysed insects, and of 1: 4.2 for 149 parasitoids when the exposed harvae were at the 3rd instar, which also showed no significant difference. The results concerning the different ages of females are: 0-2 day-old females, ratio of 1 : 4.5; 3-6 day-old females, 1: 3.6; 7-10 day-old females, 1: 4.0; females older than 10 days, 1: 6.5. These results did not show a significant difference through the qui-square test (p=0.05). In contrast to results in papers found in the literature, the data obtained indicate that, in the conditions of this experiment, it was not possible to observe influence of the factors studied regarding the sexual ratio of the parasitoid.

Index terms: Spodoptera frugiperda, biological control, parasitoid.

[1514] BIOLOGY OF THE IMMATURE STAGES OF NORTH AMERICAN PLANT MINING GRACILLARIDAE (LEPIDOPTERA)

D. R. Davis¹ & D. L. Wagner², Dept. of Entomology, Smithsonian Institution, Washington, D.C., USA, 20560-0127; ² Dept. of Ecology & Evolutionary Biology, Univ. of Connecticut, Storrs, CT, USA. 06269-3043.

The complex hypermetamorphic development of gracillariid plant mining larvae involves numerous morphological and behavioral adaptations that reflect evolutionary history within the family. Gracillariid larvae begin as specialized sapfeders possessing a prognathous, flattened, apodal body form adapted for tunneling through restricted space immediately beneath the epidermis of the plant host. Their diet (and frass) is mostly liquid, with the larva filtering fluids from damaged subepidermal cells. Later instars typically assume a more generalized, hypognathous, caterpillar form that normally ingests solid food, feeds deeper into the parenchyma, and excretes granular frass. Numerous modifications of this basic developmental scenario have appeared throughout the family, which, when considered with corresponding morphological adaptations, help to resolve phylogenetic relationships at the generic level and above. The life stages of over 120 species of North American Gracillariidae, representing all 26 previously described and 6 new Nearctic genera, have been studied in detail. All instars were tabulated and their general biology noted. Morphological details of each major larval phase and pupa were documented with more than 3000 SEM photographs and drawings. An overview of the phylogeny of the North American genera and subfamilies based principally on the biology and morphology of their immature stages will be presented.

Index terms: Hypermetamorphism, larval adaptation, life history, phylogeny

[1516] DIET OF GENERALIST PREDATOR AFFECTS AVOIDANCE BEHAVIOUR OF PREY

Marcel Dicke & Paul Grostal, Lab. of Entomology, Wageningen Univ., P.O. Box 8031, NL-6700 EH Wageningen, The Netherlands. E-mail: marcel.dicke@users.ento.wag-ur.nl.

Accurate perception of the environment is crucial for animal survival. Thus, most behavioral decisions made by animals are shaped by the information about abiotic conditions, food, mates, competitors and natural enemies. Recognition of natural enemies is one of the most important forms of information gathering by animals, as mistakes are often fatal. We used predator-naive spider mites (Tetranychus urticae, Tetranychidae) to: 1) compare the responses of prey to chemical cues from enemy and non-enemy species, and 2) investigate the source of these cues. We observed the distribution of T. urticae in response to cues from nine mite species, including: a) predators of spider mites, b) predators / parasites of other animals, and c) fungivores / pollen-feeders. When given a choice over 24 h, spider mites foraged and oviposited in fewer numbers on leaf discs that were previously exposed to predatory or parasitic mites (including species incapable of attacking spider mites), than on clean leaf discs (unexposed to mites). Interestingly, previous exposure of leaf arenas to fungivores and pollen feeders had no significant effect provide the provided of the theory of the provided the provided of T unlike the theory of the provided the theory of T unlike the theory of the provided the theory of the theory o Tetranychus urticae showed stronger avoidance of leaf discs that were previously exposed to spider-mite-fed predators, than of discs exposed to pollen-fed predators.

Index terms: Tetranychus urticae, Phytoseiulus, Amblyseius, chemical ecology, behavioural ecology

[1517] PRELIMINARY EVALUATION OF AGENIASPIS CITRICOLA (HYM: ENCYRTIDAE) ATTACKING PHYLLOCNISTIS CITRELLA (CITRUS LEAFMINER) IN ARGENTINA

P. A. Diez¹, E. A. Frias², N. E. Ovruski³ & <u>A. A. P. Fidalgo²</u>, ¹Fac de Agronomía y Zootécnia, UNT, Av. Roca N° 1900, 4000, Tucumán, Argentina; ²Fund. Miguel Lillo, Miguel Lillo N° 251, 4000, Tucumán, Argentina; ³Fac. de Ciencias Naturales, UNT, Miguel Lillo N° 251, 4000, Tucumán, Argentina.

Between 1995 and 1996 Phyllocnistis citrella (Citrus leafminer, CLM), was registered in Northwestern Argentina. Very rapidly it was widespread in all the citrus areas of the country. In 1998 Ageniaspis citricola Logvinovskaya, a specific parasitoid of CLM, was introduced and released in Argentina. Probably due to a fortuitous introduccion, it had been recorded the previous year. A. citricola disperses slowly than the pest; therefore it has not been found in several areas yet. The aim of the present paper is to know the presence of A. citricola and the level of total parasitism. Samples in citrus orchards north to 32° parallel were taken periodically. In each of the areas affected by the pest, 300 to 1,500 leaf were taken and observed at the laboratory afterwards. When A. citricola was lacking, the percentages of the indigenous parasitoids varied beetween 0% and 18%. When A. citricola was present, total parasitism varied between 31% and 66.2%. These results suggest that the total level of parasitsm increased with presence of A. citricola into the monitoired areas. The indigenous parasitoids were Cirrospilus sp., Elasmus sp. and Galeopsomyia fausta, their individual numbers changing in diferent sampling region. These results have been explained by the diversity of abiotic and biotic factors, characteristc of each area. Index terms: Ageniaspis citricola, Phyllocnistis citrella, percentage of parasitism

[1519] COLD STORAGE OF IMMATURE STAGES OF TRISSOLCUS BASALIS AND TELENOMUS PODISI (HYMENOPTERA: SCELIONIDAE): EFFECT ON DEVELOPMENT, ADULT LONGEVITY AND REPRODUCTION

A K. Doetzer¹ & L. A Foerster¹, ¹Dept. of Zoology, Univ. Federal do Paraná, P.O. Box 19020 ZIP 81531-990, Curitiba - PR, Brazil. E-mail: doetzer@garoupa.bio.ufpr.br.

The development, survival and reproduction of the egg parasitoids Trissolcus basalis and Telenomus podisi stored in the stages of egg, larvae and pupae at 12° and 15°C were evaluated in laboratory, using respectively Nezara viridula and Euschistus heros eggs as hosts. To store eggs and larvae, three parasitized egg masses at 18°C were transferred to 12° and 15°C after 2 and 5 days of parasitism date and returned to 18°C after 20, 30 and 40 days, to emerge. Pupae were stored at low temperatures after rearing the parasitoids at 18°C for 15, 20, 25, 26, 28, 30 and 35 days. Adults were maintained in tubes and honey was provided as food. Reproductive capacity of stored females for a period of 3 and 5 months at 15°C was evaluated at 21°C, using emerged females obtained from the storage in the pupal stage after 30 days of parasitism date. After 10 days at 21°C, 10 E. heros eggs were daily supplied during 5 days. There was no emergence from storage of immatures at 12°C. Emergence of adults at 18°C after transference to 15°C in the egg and larval stages was low for both parasitoids, ranging from 0.0 to 35% and it was inversaly proporcional to storage time. The developmental time was similar for the parasitoids and increasead progressively with increasing storage time, ranging from 49 to 61 days. The maximum adult longevity deriving from the storage in the egg and larval stages at 15°C was 132 days, but the low percentage of emergence shows that the method is not suitable for the parasitoids production. Storage in the pupal stage at 15° C resulted in adult emergence in all treatments for *T. basalis*, ranging from 1.5 and 86.4%, when the egg masses were stored after 15 and 30 days of parasitism date, respectively. Emergence of T. podisi at 15°C ranged from 26.3 to 59.9%, at storage after 20 and 35 days of parasitism date, respectively. There was no emergence when the parasitoids were transferred to 15°C after 15 days at 18°C. Longevity of emerged females from the storage in the pupal stage at 15°C was 249,6 and 209,2 days for T. basalis and T. podisi respectively and decreased progressively with decreasing time at 18°C before the storage. Females of T. basalis stored for 3 and 5 months parasitized respectively 16.1 and 24.5 eggs during 5 days. Females of T. podisi stored for 3 months parasitized 3.0 eggs and failed to oviposit after storage for 5 months.

Index-terms: Nezara viridula, Euschistus heros, egg parasitoids, biological control

[1518] DEVELOPMENT, SURVIVAL AND REPRODUCTION OF TRISSOLCUS BASALIS AND TELENOMUS PODISI (HYMENOPTERA: SCELIONIDAE) REARED IN GREENHOUSE IN SOUTHERN PARANÁ STATE, BRAZIL

A.K. Doetzer¹ & L. A Foerster¹, ¹Dept. of Zoology, Univ. Federal do Paraná, P.O. Box 19020 ZIP 81531-990, Curitiba - PR, Brazil. E-mail: doetzer@garoupa.bio.ufpr.br.

Experiments were conducted in Curitiba, Paraná, Brazil to evaluate the development, survival and reproduction of the egg parasitoids Trissolcus basalis and Telenomus podisi reared in greenhouse, during autumn and winter, 1999. In laboratory, at 18°C, Nezara viridula and Euschistus heros egg masses were exposed respectively to T. basalis and T. podisi females for a period of 72 hours to allow oviposition. The parasitism occurred in autumn, using 10 egg masses in April, 10 in May and 10 in June, and after the eggs had been parasitized, the egg masses were transferred to the greenhouse. The duration of development and the number of emerged parasitoids were recorded. The emerged adults were maintained in tubes and honey was provided as food. After 2, 4 and 6 months in greenhouse, 30 females were transferred to the laboratory to evaluate their reproductive capacity at 21°C. After 2, 7 and 14 days at this temperature, 10 E. heros eggs were daily supplied for a period of 5 days. When the parasitism occurred in April, the developmental time was 29.1 days for *T. basalis* and 34.7 days for *T. podis*; the number of parasitoids that successfully emerged as adults was respectively 89.0 and 76.5%. Parasitized egg masses in May and June resulted in longer duration of development and lower emergence. Adults survival in winter was higher than 75% for both species, indicating that the parasitoids are capable of overwintering as adults. The mortality was higher in October and November; in December, 20% of the parasitoids were still alive. T, basalis and T, podisi females maintained in greenhouse for 2, 4 and 6 months parasitized E. heros eggs after their transference to 21° C. There was no significant difference between the three periods of pre-oviposition (2, 7 and 14 days) and the results were pooled. *T. basalis* females maintained in greenhouse for 2 and 4 months parasitized respectively 20.0 and 24.7 host eggs and the fecundity decreased after 6 months of maintenance in greenhouse (13.0 eggs/female). The fecundity of T. podisi was lower in relation to T. basalis and there was no significant difference between the treatments. After 2, 4 and 6 months in greenhouse, T. podisi females parasitized respectively 6.3, 8.8 and 5.2 host eggs for a period of 5 days.

Index-terms: Nezara viridula, Euschistus heros, egg parasitoids, overwintering, biological control

[1520] RESPONSE OF THE PREDACIOUS MITE, AMBLYSEIUS CYDNODACTYLON TO INCREASING PREY DENSITY OF THE TWO SPOTTED SPIDER MITE, TETRANYCHUS URTICAE IN ABSENCE OR PRESENCE OF NYMPHS OF TOBACCO WHITE FLY, BEMESIA TABACI (ACARI: PHYTOSEIIDAE)

E.M. El-Banhawy¹, S.M. Hafez² & S.A. Saber¹, ¹- National Research Centre, Dokki, Cairo, Egypt; ²- Faculty of Agriculture, Ain-Shams Univ., Cairo, Egypt.

The predacious mite, Amblyseius cydnodactylon Shehata&Zaher is a common natural enemy inhabiting low growing plants like cucumber. It has been recorded associated with infestations of the two-spotted spider mite, Tetranychus urticae Koch and the white fly, Bemesia tahaci (Genn.). Under laboratory conditions of 28-30°C and 70-80% R.H., the predator adult female consumed nymphs of T.urticae at the defferent experimented densities. However, the consumption rate increased by increasing prey densities up to 32 nymphs/female/day and decreased significantly at 64 and 128 nymphs/female/day. Addition of fixed number of the 1" instar nymph of B.tabaci (10 individuals) to every TSSM prey density significantly reduced consumption, although the predator female respond in similar fashion to increasing prey densities. Reproduction increased by increasing prey densities and reached a maximum at 32 nymphs/female/day. The addition of nymphs of B.tabaci substantially increased reproduction at every density. This increase in reproduction would have compensated the reduction in nymph prey consumption due to the presence of B.tabaci.

Index terms: Cucumber pests, consumption, reproduction

[1521] STUDIES ON WALNUT APHIDS AND THEIR NATURAL ENEMIES IN KARAJ

<u>P. A. Fard</u>³, Entomology Dept. College of Agriculture Univ. of Tehran, Karaj Iran 31584 E-mail:pafard@chamran.ut.ac.ir.

Two species of aphids, Green walnut aphid Chromaphis Juglandicola and Dusky-veined aphid Panaphis Juglandis are common in Karaj and vicinities. For studying factors affecting their population fluctuations, several unsprayed walnut trees in different parts of Karaj were kept under consideration. Aphids and their natural enemies were regularly collected and evaluated. Their investigations revealed that green walnut aphids are much smaller than dusky-veined aphids and are typically found scattered on the lower side of leaves while dusky-veined aphids feed in rows along the mid-vein on the upper surface. During the spring and summer, adult females commonly have wings. Dasky-veined aphids have wings with distinctive dusky marking along the veins. The nymphs of the dusky-veined aphid have dark-banded spots on the back, these spots are much less pronounced or absent on the nymphs of the walnut aphid. Both aphids are in the egg stage on the twigs during winter. Aphids are most damaging in spring and early summer. Temperatures of 38°C or more, maintained over several days in the orchard, suppress dusky-veined aphid populations, whereas the walnut is less susceptible to heat. Several parasites control their population density. Four species of ladybird beetles, three species of syrphid flies and lacewings are more common under Karaj conditions. Index terms: Veinedaphids-Parasites-Ladybird days, but the low percentage of consegure shows that the method is not soltable for the paraminide production. Storage in the pupil store at LPC resulted in adult emergence in all meanweath for T. Joanlie, ranging from 1.5 and 86.4%, when the east masses were moved after 15 and 20 days of parasitivity date, respectively, little rgence of T podist at 15°C ranged from 26.3 to 59.9%, at storage after 20 and 35 days of patasitions date. trapectively. There was no energence when the parametrize were transferred to 15° C after (5)Isys at ISC. Longevity of entargod females from the monge in the popul stage at 15% was 249.0 and 270.2 days for T branch and T product maps to be an observed pairs document progressively with decreasing time at 18°C before the diverge. Females of T branchis more or 3 and 5 months paramozed respectively 16.1 and 26.5 eggs dowing 5 days. [1523] ECOLOGICAL ASPECTS AND DAMAGE EVALUATION OF FUIT FLIES IN CAGAITA IN THE SAVANNAS OF GOIAS STATE, BRAZIL

G.A. Ferreira¹, V.R.S. Veloso¹, J.H.S. Lima¹, J.R. Braga Filho¹ & K.C.C. Rabelo¹, ¹Escola de Agronomia/Universidade Federal de Goiás. Campus II, Rod. Goiânia/Nova Veneza, km 0, Caixa Postal 131, CEP. 74001-970 Goiânia, Goiás E-mail: yveloso@agro.ufg.br.

The savanna ecosystem has greets environmental gradients. This fact conferring urge floral biodiversity and audible fruits in addition. Local people like fruitful, medicinal, and ornamental specie know the cagaita (Eugenia dysenterica D.C.) tree. The cagaita put is hosting of fruit flies attacks the pulp of fruits in oviposition phase. Oviposition points aid fitopatogenic agent's infection becoming impracticable the twit's utilization. This study was carried out in 19 counties of Goiás State from September to November 1998. It was studied occurrence of fruit flies and natural economics species and damaging level. Fruit samples were collected, counted, weight and disposed in plastic boxes containing sterilized and wet sand, and cowered with "voil" stuff. Afterwards, pupary were collected and transferred to appropriated adults emergence containers. Fruit flies were counted and fixed with 70% alcohol to posterior identification. The determination of number of species per fruit was carried out in nine couties with 50 fruits per plant disposed in plastic glasses. To damaging evaluation fruits were sliced reporting presence or absence of larvae. Identified species were Anastrepha fraterculus, A. abliqua and Ceratitis capitata. Other occurrence insects were Neosilba spp. (Lonchaeidae), Atherigona orientalis (Muscidae) and specimens of Family Oititidae, Natural enemies identified were Doryctobracon areolatus (Braconidae), Lopheucoila anastrephae, Aganaspis pelleranoi, A. nordlanderi (Eucoilidae), Spalangia endius, Pachycrepoideus vindemiae (Pteromalidae) and non-identified Pteromalidae specie. All identified species occurred concomitantly in fruits with pulp destruction by larvae and fruit depreciation by galleries and excrements. The damaging level got 44 at 100 per cent. Then cagaita plant way is considered natural source of fruit flics in Goiás State. This is the first reporting of parasitoids L. anastrephae, A. nordlanderi (Eucoilidae), P. vindemiae (Pteromalidae) of Tephritoidea in cagaita fruits. Index terms: Fruit fly, Savannas, Eugenia dysenterica, damaging evaluation, Parasitoids

[1524] ACARICIDES SELETIVITY EVALUATION ON CHRYSOPERLA EXTERNA (NEUROPTERA: CHRYSOPIDAE)

R. J. Ferreira¹, K. C. A. Senő², N. M. M. S. Albergarin², H. O. S. Dória² & S. de Freitas², ¹Depto, de Biologia, Univ. de São Paulo, CEP 14040-901, Ribeirão Preto, SP, Brasil, E-mail, raimundo@usp.br (Fapesp Fellowship); ²Depto, de Fitossanidade, Univ. Estadual Paulista, CEP 14870-000, Jaboticabal, SP, Brasil,

This work was carried out to evaluated the effect of two acaricides, frequently used in citros orchards, on larvae of Chrysoperla externa. The trial was accomplished in the Chrysopids Biosystematic Lab located at the Univ. of São Paulo State, Jaboticabal, SP, BR. The experimental desing used was completely randomized with 3 treatments and 5 replications. Each replication was composed by tem 1" instar larvae, previously fed and fastened by dorsal side on a slide microscope plate, came from 3rd lab generation and with 24 hour age. The treatment use were: 1-) oxide[enbutatin (Torque) - 0,8ml/l; cyhexatin (Cyhexatin PM) - 0.5g/l; 3-) checking (destiled water). The effect of treatments was evaluated 24, 48 and 72 hours after the larvae immersion and the results showed: 1-) cyhexatin presented higher level of larvae mortality after 72 hours; oxifenbutatin and checking did not differ to each other in all evaluations and presented low larvae mortality index. was 29.1 days for T. Joundie and 34 Index terms: bioassay, chrysopid, generalist predator. masses to May and June resulted in trager mention of development and lower emergence Adults survival in winter was higher than 75% for both species, industing that the paramonits are capable of overwisiering as adults. The mortality was higher in October and November, in December, 20% of the parasitolith were still slive, T feasible and T

perfect females maintained in prevaluance for 2, 4 and 6 months providered 4. here eggs after their transference to 21%. There was no againficial difference between the these periods of me-responsion (2, 2 and 14 days) and the results were peopled. T. bandli females maintained in prevaluance for 2 and 4 months paramitized respectively 20,0 and 24.7 here eggs and the ferendity decrement after 6 months of maintenance in greenhouse (13.0 eggs/female). The ferendity decrement after 6 months of maintenance in greenhouse (13.0 eggs/female). The ferendity of *T*, polarit was lower in relation to *T*, fearfit and there was no significant difference between the transmust. After 2, 4 and 6 months in greenhouse. To possible females paramitized respectively 6.3, 8.8 and 3.2 heat oggs for a period of 5 days.

[1522] TUTA ABSOLUTA PARASITISM BY TRICHOGRAMMA PRETIOSUM WITH NOTES ON HOST SITE C.A. Faria¹, J.B. Torres², A.M.I. Farias³ & A.M.V. Fernandes³, ¹DBA/Entomologia, UFV, Viçosa, MG, 36570-000, Brazil, E-mail: cristina@insecta.ufv.br; ²DEPA-Fitossanidade, UFRPE, Ave. Dom Manoel de Medeiros s/n, Dois Irmãos, Recife, PE, 52171-900, Brazil; ³CCB-Zoologia, UFPE, Ave. Prof. Moraes Rego s/n, Recife, PE, 51123-900, Brazil.

This study aimed to evaluate the response of *Trichogramma pretiosum* females to *Tuta absoluta* oviposition site on tomato (var. IPA - 5) plant capoy. The tests were conducted in individually caged plants. In each cage 5-15 *T. absoluta* moths were released, followed by the release of 15 *T. pretiosum* females 12 h later. After 24 h, the oviposition was quantified and its site determined, and the total levels of parasitism were assessed after 4 days. The parasitism tanged from 1,5 to 28%. Both *T. absoluta* oviposition and its parasitism by *T. pretiosum* were higher in the plant apex, decreasing along canopy. The results show that *T. pretiosum* can locate and parasite *T. absoluta* eggs at different densities. Moreover, the parasitism was related to the host spatial distribution on the host plant. The data obtained in this study suggest that the response of *T. pretiosum* to *T. absoluta* eggs is spatially density-dependent.

Index terms: Chemister petts, committen reproduction.

[1525] DISPERSAL OF THE FILTH FLY PARASITOID MUSCIDIFURAX RAPTORELLUS (HYMENOPTERA: PTEROMALIDAE) FOLLOWING MASS-RELEASES IN CATTLE CONFINEMENTS

K. D. Floate¹, P. Coghlin¹ & G. A. P. Gibson², ¹Agriculture and Agri-Food Canada, Lethbridge Research Centre, P.O. Box 3000, Lethbridge, AB, Canada, T1J 4B1, E-mail: floatek@em.agr.ca; ²AAFC, Eastern Cereal and Oilseed Research Centre,K. W. Neatby, Bldg., 960 Carling Avenue, Ottawa, ON, Canada, K1A 0C6.

Pupae of house fly, Musca domestica L. (Diptera: Muscidae), reared in the laboratory were used to assess the movement of *Muscidifurax raptorellus* Kogan & Legner (Hymenoptera: Pteromalidae) following mass-releases of this filth fly parasitoid in cattle confinements. Parasitism of sentinel pupae was 34%, averaged for three mass-releases (ca. 220,000 individuals/release) at each of two sites. Parasitism declined only slightly with the distance (1 to 100 m) of pupe from the point of parasitoid release (for data combined from all releases, P < 0.001, $r^2 = 0.032$). Wind direction had no consistent effect on parasitism for six releases (P > 0.05). Twenty-nine specimens of *M. raptorellus* were recovered in 1998, following release of more than 1.3 million individuals in previous years. Because the winter of 1997-98 was unusually warm, further studies are required to determine whether the parasitoid can survive winters more typical of southern Alberta. These results suggest that: 1) mass-releases of M. raptorellus can be used to help manage populations of stable fly and house fly in cattle confinements, 2) mass-releases at intervals of 200 m should achieve fairly uniform coverage of the confinement facility with parasitoids, and 3) mass-releases will be required each year. Eight additional species of parasitoids (Hymenoptera) were recovered from pupae during the study. Each of these species previously has been reported from southern Alberta, with the exception of Eupelmus (Macroneura) vesicularis (Retzius) (Eupelmidae).

Index terms: Musca domestica; Stomoxys calcitrans; biological control

[1527] EGG PARASITOIDS OF ANTICARSIA GEMMATALIS (LEPIDOPTERA: NOCTUIDAE) ON SOYBEANS IN BRAZIL

L. A. Foerster¹ <u>M.R. F. Avanci</u>¹, J.M.R. Martins¹ & C.L. Cañete¹, ¹Depto. de Zoologia, Univ. Federal do Paraná, P.O. Box 19.020 (81531-990) Curitiba, PR, Brazil. e-mail: foerster@bio.ufpr.br

Until 1995 only Trichogramma pretiosum was described parasitizing eggs of the velvetbean caterpillar Anticarsia gemmatalis in Brazil. Since then, the Laboratory of Integrated Insect Control of Universidade Federal do Paraná has set up field surveys on soybean fields in Southern Paraná State to investigate the incidence of parasitism in eggs of A. gemmatalis. Eggs laid on soybean leaves were collected and transferred to the laboratory to check for the presence of parasitoids. Colonies of the collected species were maintained in laboratory for bio-ecological studies. Between 1995 and 1998 five species of parasitoids belonging to three families were reared from eggs of A. gemmatalis: Trichogramma pretiosum, T. rojasi and T. atopovirilia (Trichogrammatidae), Telenomus cyamophylax (Scelionidae) and Encarsia porteri (Aphelinidae). In 1999, another two species of Trichogramma were found, namely T. acacioi and T. lassalei. This is the first record of both species in eggs of A. gemmatalis. In 1998, weekly samplings were taken during the vegetative and reproductive stages of the crop. Parasitized eggs were collected still during the vegetative stage of soybeans, however the highest levels of incidence occurred during the pod-filling stage of the crop. Overall percentage of parasitized eggs reached 23.3% in 1998. T. pretiosum was the predominant species, representing 94% of the parasitoids sampled in the field. Eggs of the noctuids Pseudaletia sequax, Spodoptera eridania and Pseudoplusia includens were tested in laboratory as alternative hosts for T. cyamophylax and some of the Trichogramma species reared in laboratory. T. cyamophylax, T. pretiosum and T. rojasi developed successfully in eggs of P. sequat. However, neither T. pretiosum, nor T. cyamophylax developed satisfactorily in eggs of S. eridania. Eggs of P. includens were suitable for rearing T. pretiosum, T. atopovirilia and T. acacioi. Only males of E. porteri have been obtained from eggs of A. gemmatalis, and this is probably an heterotrophic parasitoid, like other species of *Encarsia*, in which the female progeny develops on whiteflies and the male progeny is produced on eggs of lepidopterous hosts. The diversity of parasitoid species found on eggs of A. gemmatalis shows the potential of this egg parasitoids for the control of the velvetbean caterpillar. Index terms: Biological control, velvetbean caterpillar, Trichogramma, Telenomus, Encarsia.

[1526] SUBLETHAL EFFECTS OF BACILLUS THURINGIENSIS VAR. ISRAELENSIS (VECTOBAC G & AS) ON LIFE PARAMETERS OF AEDES AEGYPTI

A.E. Flores, G. Ponce, M.H. Badii & M.L. Rodríguez, ¹Autonomus University of Nuevo Leon, AP. 391. San Nicolas de los Garza, Nuevo Leon, 66450, México, e- mail adflores@ccr.dsi.uanl.mx

Beginning in the 1960's, Abate (temephos) has been used in control of mosquito larvae in Mexico and has generated several ecological as well as environmental problems. This has created a need for environmentally sound alternatives such as the utilization in US, Central and South America of highly toxic and specific *Bacillus thuringiensis* var. *israelensis* against *Aedes aegypti*. Some studies indicate there is an alteration of the life cycle as well as the reproductive parameters in 1⁴⁴ generation (FI) progeny of this vector. The purpose of this investigation is to determine the toxicity of *B.t.i* (Vectobac G and AS) on the 2nd and 3nd larval instars of *Aedes aegypti* under laboratory conditions as well as the sublethal effects (LC30, LC50 and LC70) of the same microbial agent on survival, fecundity and life cycle of *Aedes aegypti*. Based on bioassays, LC30, LC50 and LC70 of the commercial product Vectobac G and AS at 24h exposure on 2nd and 3nd larval instars of *Ae. aegypti* 26,000 and 2,6098 ppm).

[1528] PHENOLOGICAL PATTERNS FOR PARASITOIDS SPECIALIZED IN ATTACKING SOLENOPSIS FIRE ANTS, AT THE RESERVA ECOLÓGICA COSTANERA SUR, ARGENTINA

P. J. Folgarait¹, O. A. Bruzzone¹, & L. E. Gilbert², ⁴Centro de Estudios e Investigaciones, Universidad Nacional de Quilmes, Roque Saenz Peña 180, 1876 Bernal, Bs As, Argentina, E-mail pfolgarait@unq.edu.ar; ²Department of Zoology, University of Texas, Austin, TX 78712, USA.

We have been sampling every month phorid populations attacking Solenopsis richteri ants at the Reserva Ecológica Costanera Sur, Argentina, for the past four years. We estimated the abundance of phorids as the number of phorids collected per hour of sampling effort; data presented here show phorid abundance per month joining data for all the years. Phenological data showed strong seasonal patterns related to temperature and precipitation, and allowed the discrimination between season and trail/mound generalist versus specialist species and abundant versus rare species. The most abundant and constant species was the mound-specialist P. borgmeieri, being the single species present during the winter; its abundance was negatively correlated with temperatures and precipitation and was classified as a winter specialist. P. obtusus was a trail specialist and the most rare one, found only during the fall and spring; its abundance was positively correlated with temperature and precipitation. The other 4 species were present in 8 of the 12 months. The most abundant P. curvatus showed its peak during the summer when temperatures were greatest and precipitation intermediate, and was considered a hot specialist. The second most abundant was the fall specialist *P. nudicornis* which attained greatest abundance during the fall, and less during spring, when temperatures were intermediate but precipitation highest; we classified it as a fall specialist. P. comatus, the other mound-specialist, had intermediate to low but constant abundances that were correlated positively with temperature and precipitation. P. tricuspis with the least abundance seemed to be a summer species which activity was positively correlated to temperature but not to precipitation. Phorid abundance showed a negative relationship with wind speed at ground level. Phorids seemed to track ant activity throughout the year with a peak of activity for both groups during the summer. The abundance of moundphorids resembled the total abundance of phorids, with a peak in March mainly due to the generalists P. curvatus and P. nudicornis. The abundance of trail-phorids peaked in January. From a biological control perspective, it will be profitable to consider for introduction more than one species, selecting those with greater abundance and complementary phenology and searching behavior. Selected species should have complementary phenology and searching behavior. similarities in climatic conditions between sites of origin and of introduction of these phorid species.

Index terms: Argentina, biological control, climate, fire ants, phorids

Symposium and Poster Session

[1529] FUNCTIONAL RESPONSE OF CHRYSOPERLA EXTERNA FED ON SCHIZAPHIS GRAMINUM

<u>A.R. Fonseca¹</u>, C.F. Carvallo¹, B. Souza¹ & C.C. Ecole¹, ¹Dept. of Entomology, Federal Univ. of Lavras, Caixa Postal 37, CEP. 37200-000, MG, Brazil, E-mail rsjorge@ufla.br

The functional response of Chrysoperla externa fed on Schizaphis graminum under five densities of prey was studied. The experimental design was completely randomized with five treatments and ten replications. The tests were conducted in growth chambers at 25 ± 1 °C, RH of 70 ± 10 % and photophase of 12 hours. An increase in consumption, in function of increased prey density offered, was observed for three instars. There was, however, a consumption stabilization tendency starting from a pre established average density of prey, except for the first instar, which showed a constant increase in aphid consumption. The duration of the first and third instars and of the larval phase, as a whole, increased in function of the increased prey availability. The duration of the second instar, however, decreased in function of increased prey availability. The results for the 1st, 2nd and 3rd instars and the larval phase as a whole showed a Type II functional response. Handling and searching time was verified for second instar larvae while the first instar showed the highest searching and handling time. Handling time diminished progressively with larvae development, the third instar having the lowest handling time.

Index terms: green lacewing, predation, consumption, searching time, handling time.

[1531] PARASITISM OF EGGS OF APPLE LEAF ROLLER BONAGOTA CRANAODES (LEPIDOPTERA: TORTRICIDAE) BY TRICHOGRAMMA SP. IN FIELD CONDITIONS

M. S. Garcia¹, <u>A. Kovaleski²</u>, A. D. Grützmacher¹, A. E. Loeck¹, J. Foresti¹, F. L. Fonseca¹, ¹Dept. de Fitossanidade, FAEM/UFPel, P. O. Box 354, 96.010-900, Pelotas, RS, Brazil, E-mail: msgarcia@ufpel.tche.br; ²Embrapa – Centro Nacional de Pesquisa de Uva e Vinho, P. O. Box 30, 95.700-000, Bento Gonçalves, RS, Brazil.

The apple leaf roller Bonagota cranaodes has been characterized in the last years as one of the main pest of the Brazilian apple production. Now the control is done with insecticides of wide action spectrum, presenting a variable efficiency from 40 to 80%. New control alternatives are being studied, mainly biological control, through parasitoids of eggs of the genus Trichogramma. With the objective of to identify species with control potential for the pest surveys in localities of Pelotas, Bento Gonçalves and Vacaria in the State of Rio Grande do Sul (Brazil). Egg depositions of B. cranaodes, are liberated in soy, corn, tomato, peach and apple. The eggs of the apple leaf roller are obtained in the laboratory in ribbons of transparent plastic. The plastic contend the postures it is cut and stapled in rectangles of celestial blue cardboard of $6,0 \times 2,0$ cm. The eggs are placed in the medium part of the plants during 48 hours, and then brought to the laboratory. In each cardboard it is stapled one egg deposition. In Vacaria important area of apple production, parasitism of eggs was not yet verified in commercial orchards. In this locality the parasitism was registered in eggs of B. cranaodes liberated in tomato plants. Observations made in 120 egg depositions, distributed randomly in tomato plants, in Bento Gonçalves, showed an index of natural parasitism for *Trichogramma* sp. of 51% of the egg depositions and 13% of parasitism for the total of distributed eggs. These results demonstrated that there is a potential for use of species of the genus *Trichogramma* in massive liberations for biological control of *B. cranaodes* in apple orchards, being an important component (or the system of integrated production of apple.

Index terms: Benagota cranaodes, Trichogramma, biological control.

[1530] BIOLOGICAL CONTROL OF FLORIDA RED SCALE IN TEXAS CITRUS

J. V. French¹, J. C. Legaspi², J. Anciso³ & D. Flores⁴, ¹Texas A&M-Kingsville Citrus Center, P.O. Box 1150, Weslaco, TX 78599, USA; ²Texas Ag. Expt. Sta., 2415 E. Hwy 83, Weslaco, TX 78596, USA; ³Texas Ag. Ext. Service, P. O. Box 6700, Edinburg, TX 78540, USA; ⁴USDA-APHIS-PPQ Mission Plant Protection Center, Mission, TX 78573, USA.

Infestations of Florida red scale (FRS), Chrysomphalus aonidum, have increased significantly in the Lower Rio Grande Valley (LRGV) citrus orchards during the 1998 scason. Beginning in December 1998, we surveyed the population densities of FRS (and other armored scale species) in LRGV commercial citrus orchards. FRS infested fruit and foliage were collected and processed in the laboratory for parasite emergence, identification and collection. Citrus and non-citrus plant hosts were evaluated for culturing of FRS to mass rear Aphytis holoxanthus parasites. Release and redistribution of newly emerged A. holoxanthus into FRS-infested orchards, and monitoring of parasitism levels is currently underway. The twice-stabbed ladybeetle predator, *Chilocorus stigma*, was evaluated in laboratory feeding studies for its efficacy as a biological control agent of FRS. In surveys of over 50 LRGV orchard sites during 1998-99, the identified armored scale species in order of decreasing abundance were: California red scale, Florida red scale and chaff scale. California red scale infestations were prevalent in orchards throughout the 3 county (Hidalgo, Cameron and Willacy) LRGV citrus growing area, while FRS was more localized in orchards in Western Hidalgo County. In December 1998, FRS orchard infestations were high, but declined rapidly in January 1999, with populations remaining low throughout the spring and early summer. FRS infestations then increased dramatically during late summer and fall (Aug.-Nov.) of 1999. Surveys confirmed that the dominant parasite of FRS in LRGV orchards was *Aphytis holoxanthus*. Parasite numbers were very low, except in a few survey orchards and these sites were then more intensively monitored. Sustained peak parasite populations occurred during September--November 1999, and were generally much higher on FRS infested fruit versus leaves. Preliminary laboratory feeding studies showed that individual adult C. stigma can consume up to 50 FRS crawlers (1" stage larvae) per day. Based on these predation studies several hundred adult ladybeetles were collected from citrus trees at the Texas Agricultural Experiment Station in Weslaco, Texas and released in two nearby FRS infested commercial orchards. Early observations indicated predator establishment and feeding, with the two orchard sites still being monitored to better evaluate efficacy of C. stigma as a biological control agent of FRS under field conditions

[1532] EFFECTS OF WASP DENSITY ON THE BIOLOGY OF TRICHOGRAMMA CORDUBENSIS

P. V. Garcia¹, L. M. Oliveira¹ & J. C. Tavares¹, ¹Univ. dos Açores, Dept⁰. de Biologia, Rua da Mãe de Deus 58, P-9500 Ponta Delgada, Açores, Portugal. e-mail: patriciag@notes.uac.pt.

In mass rearing and inundative releases, which involve a large number of parasitoids, the relations between wasps are very important with consequences on the species biology. The effects of such relations depend on the number of suitable hosts available for oviposition, influencing the fecundity, longevity, sex ratio of the parasitoids populations (Waage, 1986). The effect of the density of *Trichogramma cordubensis* (Hymenoptera: Trichogrammatidae) on female fecundity, superparasitism and offspring emergence rates were analysed in this work. Groups with 1, 2, 3, 4, 8, 16 and 32 females with less than 24h old were isolated in glass tubes (7x1 cm) containing and a drop of honey and a card with 200 Ephestia kuehniella (Lepidoptera: Pyralidae) eggs aged less than 24 h and ultra-violet irradiated for 20 minutes. The wasps were left to parasitize the hosts for 24h and then removed. The experiments were run in an environmental chamber at 20 ± 0.5 °C, 75 ± 5 % r.h. and L16:D8. Cards with parasitized eggs were maintained under the same conditions for offspring development. The fecundity was determined by counting the host eggs that turned black. Analyses of variance (ANOVA) were conducted on all data. Where statistical differences existed between data sets (P<0.05), Fisher's Protected Least Significant Difference tests (PLSD) were used to separate differing means (Zar, 1996). As the number of wasps increased, the mean fecundity per female decreased. However, this decrease was only found to be significant (p<0.05, PLSD Tests) for the groups with more than 8 females per egg card. Up to 8 females per egg card the superparasitism was very low. Offspring emergence rates decreased with the increasing female density. According to Smith (1996) ratios of females to small host eggs of 1:10 are often used to maintain parasitism of 70-80% in rearing facilities. Our results show that for T. cordubensis this ratio should be lower (1:50) in order to simultaneously keep superparasitism low and maximise the wasp fecundity. Smith, S. M. 1996. Biological control with Trichogramma: Advances, successes and potential of their use. Annual Review of Entomology, 41: 375-406. Waage, J. K. 1986. Family planning in parasitoids: adaptive patterns of progeny and sex allocation. In: Waage J. & D. Grathead (eds.), Insect Parasitoids. Academic Press, UK, pp. 63-95. Zar, J. H., 1996. [1533] SURVEY OF PARASITOIDS OF THE FALL ARMYWORM, SPODOPTERA FRUGIPERDA (LEPIDOPTERA: NOCTUIDAE), IN FERNANDÓPOLIS REGION, SÃO PAULO STATE, BRAZIL

F. S. Gielfi¹, A. G. Koga¹, J. L. B. Andrade¹ & L. E. B. Silveira¹, ¹Faculdade de Ciências Agrarias, Univ. Camilo Castelo Branco, Estrada Projetada F-1, Fazenda Santa Rita. ZIP: 15600-000, Fernandópolis, São Paulo State, Brazil. E-mail gielfi@fcav.unesp.br.

The fall armyworm is the major corn pest in Fernandópolis region. The control of this insect have been mainly with chemical insecticides, in detriment of the biological control, a of the main tatics of the IPM programs. The objective of this work was evaluate the parasitoids species in the population regulation these insect and the parasitism percentage. Larvae of age differents were collect at three counties of the Fernandópolis region (Mira Estrela, Dolcinópolis and Turmalina), whole seven distinct farms, during the 1998/99 growing season. The larvae were individualize at glasses box (Gerbox model), with moistened paper, fed with natural diet (corn leaf) and maintened in a environmental chamber at 27°C±0,5°C and photophase of 12 h. Daily evaluations were realized to determine the larvae and pupae parasitism and the parasitism percentage. Of the total of the collected larvae (509), ascertained the parasitism in 24.0% (124), but only 43.5% (54) could be identified. The parasitoids recorded were Chelonus insularis (Hymenoptera: Braconidae), wich reached 37.3% of parasitism; Archytas marmoratus (Diptera: Tachinidae), which reached 37.3%; and Campoletis sp. (Hymenoptera: Ichneumonidae), which reached 25.4%. The parasitoid A. marmoratus emerges only of pupae. The results indicate that the larvae parasitism is elevate and thus, the farmers might utize the selective insecticides to conserve the population parasitoids in the corn agroecossystem. Index terms: Chelonus insularis, Campoletis sp., Archytas marmoratus, biological control.

[1535] EFFECTS OF MOLASSES GRASS (*MELINIS MINUTIFLORA*) VOLATILES ON THE FORAGING BEHAVIOUR OF THE STEMBORER PARASITOID COTESIA SESAMIAE

I. S. Gohole^{1,2}, L. E. M. Vet¹, W. A. Overholt² & Z.R. Khan², ¹ Department of Entomology, Wageningen Agricultural University, P.O. Box 8031, 6700 EH Wageningen, The Netherlands. ² The International Centre for Insect Physiology and Ecology, P.O. Box 30772, Nairobi, Kenya. E-mail: Igohole@icipe.org

Information about multitrophic-level interactions may provide an essential foundation for designing effective biological control. The role of a non-host plant, molasses grass (Melinis minutiflora), in enhancing attraction of the cereal stemborer parasitoid, Cotesia sesamiae, to its hosts was investigated. Previous work had shown that this grass was highly attractive to C. sesamiae, and suggested that it could be used to attract stemborer natural enemies to a maize-molasses grass intercrop. However, no studies have examined the relative attractiveness of molasses grass and sorghum. Thus, observations were made on the response of the parasitoid to volatile cues from molasses grass, uninfested sorghum and infested sorghum, in a Y- tube olfactometer. In comparison to a control of a pot of soil, C. sesamiae was more attracted to odours from the molasses grass, uninfested sorghum and infested sorghum. When exposed to two odour sources, C. sesamiae was more attracted to volatiles from infested sorghum than those from molasses grass, or uninfested sorghum. No preference was exhibited between volatiles from molasses grass and uninfested sorghum. When offered a combination of odour sources, infested sorghum alone proved to be more attractive than the molasses grass combined with infested sorghun. A molasses grass + infested sorghum combination was significantly more attractive than molasses grass alone. The wasps did not discriminate between a combination of molasses grass + uninfested sorghum over either uninfested sorghum alone or molasses grass alone. The investigations also revealed a difference in response to molasses grass populations collected from two different locations, Thika and Mbita. The Thika population was significantly attractive than the population from Mbita. Key words: Multitrophic interactions, sorghum, Melinis minutiflora, Cotesia sesamiae, Y-

Key words: Multitrophic interactions, sorghum, Melinis minutiflora, Cotesia sesamiae, Ytube olfactometer.

[1534] THE BIOLOGICAL CONTROL OF HOUSEFLIES ASSOCIATED WITH POULTRY PRODUCTION

J. II. Giliomee & J. P. T. Kapongo, Dept. of Entomology & Nematology, Univ. of Stellenbosch, Private Bag X1, Matieland 7602, South Africa, E-mail jhg@maties.sun.ac.za.

Several species of flies breed in the manure which accumulates when poultry are kept in units for egg or meat production. The most common species are *Musca domestica* and *Fannia* spp. The flies are not only a nuisance in surrounding households, but can also act as vectors of serious diseases. They are difficult to control chemically, although the IGR cyromazine, added to poultry food, is effective albeit expensive. In an attempt to find alternative control measures we have searched for natural enemies and found several species of parasitoids (Hymenoptera: Pteromalidae) which attack the mature larva or young pupa. The natural levels of parasitism appear to be too low for effective control, although correct manure management and additives with which we are experimenting can increase these. One of the parasitoid species *Muscidifurax raptor* could easily be reared in large numbers, lives long (20 days), parasitizes both *Musca* and *Fannia* and can affect more than 90% of exposed pupae. Field trials were carried out to evaluate the effectivences of these experiments indicate that the parasitoids are as effective as cyromazine.

Index terms: Muscidifurax raptor, Musca domestica, Fannia sp

[1536] DEVELOPMENT OF TRICHOGRAMMA PRETIOSUM (HYMENOPTERA: TRICHOGRAMMATIDAE) IN ARTIFICIAL DIET, FOCUSING ON PROTEIN UTILIZATION

<u>S. Gomes^{1, 2}</u>, S. Grenier¹, G. Febvay¹, J. Guillaud¹ & J.R.P. Parra², ¹Laboratoire de Biologie Appliquée, INRA-INSA, Bât. 406, 20 av. Einstein, 69621 Villeurbanne France, E-mail gomes@jouy.inra.fr; ²Laboratory of Insect Biology, ESALQ / USP, Piracicaba, Brazil.

The oophagous Trichogramma can be produced on Ephestia kuchniella eggs as substitution host, Development is also possible in artificial conditions with diets mainly composed of insect-originated elements (hemolymph, body or egg juices). To try to define new artificial diets, and improve the performances of the existing diets, we studied some nutritional and metabolism traits of Trichogramma pretiosum. The artificial dict tested contains hemolymph of Mamestra brassicae, chicken egg yolk, semi-skimmed cow milk, Neisenheimer salt solution and distilled water as basic components. Proteins are key components for the nutrition of parasitoid insects. Biochemical analyses were conducted on total and free amino acid contents of T, pretiosum pupae reared in diets with or without addition of casein. The addition of casein (1.6 %) allows an increase of the protein content of pupae from 7.2 to 7.9 %. To better understand the nutritional value of proteins, a new method was developed for studying the assimilation of these nutrients by pre-imaginal stages of Trichogramma. The method consists in addition of a mixture of free 14C-labeled amino acids to the diet, containing more or less protein. The comparison of the specific activity of total aminoacids in pupae with the specific activity of free and protein aminoacids in diet allow to determine the degree and the way of the utilization of the protein. This work was supported by a CAPES/COFECUB project (261/98). Index terms: Trichogramma, entomophagous insect, nutrition, in vitro rearing

Symposium and Poster Session

[1537] EFFECT OF THE AGE OF APHIDIUS COLEMANI FEMALES (HYMENOPTERA: APHIDIDAE) ON THE GREEN APHID SCHIZAPHIS GRAMINUM (HOMOPTERA: APHIDIDAE) PARASITISM

R.C.R. Gonçalves-Gervásio¹, <u>LaV.C. Santa-Cecília¹</u>, V.L. de Carvalho¹, L.V. Foureaux², C.M. Kato² & M.G. Campelo², ¹EPAMIG-CTSM P.O.Box 176, 37200-000 Lavras, MG, Brazil. e-mail: scecilia@ufla.br; ²IMA, Br 040, Km 527, 32.145-900, Contagem, MG, Brazil. e-mail: foureaux@acesso.com.br

The effects of the age of Aphidius colemani Viereck females on the parasitism of the green aphid Schizaphis graminum (Rond.) were studied. After mating, an A. colemani female was placed into a cage containing 50 nymphs of 3^{cd} and 4^{th} instars of the green aphid. Daily, this female was transferred into a new cage until the eight-day period completed. By taking into account a daily population of 50 nymphs of S. graminum, it was found that an A. colemani female parasited, on average, 90 aphids for the eight days of lifetime, with the greatest concentration of the parasitism in the former, decreasing linearly up to the eight day. A percentage of emergence of the adults of the order of 75,5% and a period of mummy formation until the emergence of 0,51 was noticed which went through influence of the age of females of A. colemani.

Index terms: Insecta, parasitoid, biological control, green aphid, sorghum.

[1539] AN EXOTIC APHID SPECIES IS FAVOURED BY ADJACENT TROPHIC LEVELS: HOST PLANT AND NATURAL ENEMY IMPACT ON CEREAL APHID COMPETITION

W. L. Gonzáles¹, E. Fuentes-Contreras² & Hermann M. Niemeyer¹, ¹Departamento de Ciencias Ecológicas, Facultad de Ciencias, Univ. de Chile, Casilla 653, Santiago, Chile, willy@abulafia.ciencias.uchile.cl. ²Departamento de Producción Agrícola, Facultad de Ciencias Agrarias, Univ de Talca, Casilla 747, Talca, Chile

Successful establishment of an introduced species depend of its biological traits and interactions with other species in the new environment. Phloem sucking, colonial or aggregative, exotic, phytophagous insects frequently establish competitive interactions which are mediated by the natural enemies or host plant quality. Sipha flava, a newlyintroduced aphid in Chile, shows some biological traits that could enhance its competitive abilities: 1) low level of parasitism by braconids (an important group of aphid natural enemies), and 2) it produces change on the host plant quality. The relationship between S. flava and Rhopalosiphum maidis on a common host plant, Sorghum halepense was evaluated during two seasons, fall and spring, in environments with and without natural enemics (garden experiment). Additionally, the effects of Lysiphlebus testaceipes (the major natural enemy associated to this system), and the changes on S. halepense by aphid attack, on the aphid - aphid relationship, were evaluated under laboratory conditions. Finally, the effects of temperature and photoperiod on time to first reproduction, number of nymphs and longevity of aphids were studied. Both aphids were negatively affected by interspecific competition during fall (with or without natural enemies), when S. flava was practically excluded by R. maidis. During spring, without natural enemies, R. maidis was negatively affected by S. flava, but this aphid was not affected by R. maidis; with natural enemies, R. maidis diluted the negative impact of natural enemies on S. flava. Both changes in host plant quality induced by S. flava attack, and presence of L. testaceipes negatively affected *R. maidis*. Finally, changes in temperature and photoperiod strongly affected *S. flava* and showed its susceptibility to these abiotic changes typical of each season; however, *R. maidis* was much less strongly affected. The consequences of the adjacent trophic levels on the S. flava - R. maidis interactions are discussed. Index terms: Sipha flava, aphid competition, host plant quality, natural enemies

[1538] FOOD CONSUMPTION OF CHRYSOPERLA EXTERNA (NEUROPTERA: CHRYSOPIDAE) IN THE DIFFERENT DEVELOPMENTAL PHASES OF DYSMICOCCUS BREVIPES (HEMIPTERA: PSEUDOCOCCIDAE), UNDER LABORATORY CONDITIONS

R. de C.R. Gonçalves-Gervásio¹, <u>L.V.C. Santa-Cecília¹</u> & M.V. Sousa¹, ¹EPAMIG-CTSM P.O.Box 176, 37200-000 Lavras, MG, Brazil. e-mail: scecilia@ufla.br

The damages provoked by the mealybug Dysmicoccus brevipes (Hemiptera: Pseudococcidae) have been one of the chief causes of the unsuccess of pineapple culture in the main producing regions being able to cause looses in the yield of the order of 70 %. That mealybug undergoes the action of predators which can contribute to the redution of the pest's population. With a view to evaluating both the consumption and feeding preference of larvae of *Crysoperla externa*, by utilizing as a prey the pineapple mealybug at its different developmental phases, an experiment with randomized block design in split plot sheme with five replicates at temperature of 25 ± 2 °C and relative humidity of 70 ± 10 % was set up at the Biological Control Laboratory of EPAMIG/CTSM. The results showed that during the predator's larval phase were consumed on average, 70, 50 and 15,8 mealybugs of the 1st, 2nd and 3nd instar, respectively and 10 adult females amounting to 145,8 individuals. It was noticed that 51,0% of the total number of mealybugs consumed shows that *C. externa* presents a potential to be utilized in biological control of the mealybug *D. brevipes*.

Index terms: Biological Control, pineapple, green lacewing, mealybug.

[1540] STABILITY OF THE WOLBACHIA TRANSFER FROM TRICHOGRAMMA PRETIOSUM TO T. DENDROLIMI

S. Grenier¹, B. Pintureau¹, A. Heddi¹ & F. Lassablière^{1,2}, ¹INSA, UA INRA 203, Lab. Biologie appliquée, Bât. 406, 20 Ave. A. Einstein, 69621-Villeurbanne-cedex, France, Enail: pinture@jouy.inra.fr; ³Present address: Univ. J. Monnet, Fac. Médecine, Lab. Biochimie, 42023-Saint Etienne-cedex 2, France

Wolbachia symbionts (Bacteria: Rickettsiaceae) induce the thelytokous reproduction in several egg parasitoid species of the Trichogramma genus (Hym.: Trichogrammatidae). Purified Wolbachia from an infected species, T. preliosum, were transferred by microinjection into in vitro developed pupae of a naturally uninfected species, T. dendrolimi. The presence or absence of Wolbachia was checked using DAPI staining, PCR (ftsZ primers), Fluorescence In Situ Hybridization (F.I.S.H.) using the 16S ribosomal DNA probes, and ftsZ gene sequencing. An ftsZ gene fragment from microinjected T. dendrolimi was shown to be identical to that of T. pretiosum, confirming that transfer was successful. Wolbachia were still present 48 and 60 generations after the transfer in two recipient strains of T. dendrolimi, although no obvious induction of thelytoky was observed. F.I.S.H. allows a semi-quantitative estimation of symbiont abundance and a control of their dynamics in the course of generations. It was showed that Wolbachia have a low metabolic activity and abundance in microinjected lines and that eggs of these lines are polymorphic for the infection. Comparison of the intraline and interline variances of the symbiont abundance did not allow to suspect a genetic variability for this character. Moreover, unlike naturally infected lines, *Wolbachia* are not concentrated at the posterior pole of eggs in microinjected lines. The lack of induction of thelytoky in microinjected lines of *Trichogramma* revealed the existence of interactions between hosts and symbionts, and probably a relative specificity of Wolbachia for their hosts. The lower metabolic activity and abundance of Wolbachia in microinjected lines could indicate the progressive elimination of a symbiont possibly insufficiently adapted to its host. Index terms: Bacteria, co-adaptation, egg parasitoid, interaction, symbiosis.

[1541] REARING IN ARTIFICIAL CONDITIONS AS A TOOL FOR PHYSIOLOGICAL OR BEHAVIOURAL STUDIES OF EGG PARASITOID INSECTS

S. Grenier, Labo. Biologie Appliquée, UA INRA 203, INSA Bât. 406, 20 av. A. Einstein, 69621 Villeurbanne Cedex France, E-mail: sgrenier@jouy.inra.fr

The production of parasitoids for their use in biological control programs is the first and more evident aim for the investigations on the development in artificial diets of these entomophagous insects. There is a second aim also very important, especially with endoparasitoids: the utilization of this technique of rearing as a powerful tool for different kinds of physiological and behavioral studies. Trichogramma sp., an egg parasitoid worldwide used as biological control agent against many lepidopterous pest insects, can develop on artificial diet proposed as artificial host eggs. i) Different factors, such as the components present on the surface of the eggshell, the eggshell itself, and the components of the egg content, govern the stimulation of the egg laying by Trichogramma females. To show the role of these factors, we tested artificial host eggs made of different kinds of membrane (polyethylene, polypropylene of various thickness), smeared with different chemicals (hydrocarbons, scale insect extracts), containing artificial media, more or less rich in free amino-acids, ii) The nutritional needs could be evaluated thanks to the development of Trichogramma in artificial host eggs using various diets. iii) The sensibility to bacterial and antifungal agents was tested by adding increasing percentages of different preservative agents inside the media and checking efficiency against contaminants and induced mortality in pre-imaginal stages of Trichogramma. iv) Trichogramma nymphs developed in artificial conditions were used as recipient species for studying the artificial transfer of Wolbachia, a Rickettsial symbiont that induces thelytokous parthenogenesis in some Trichogramma species. A special technique was developed to inject some nanolitres of a solution containing the symbionts extracted from donor species naturally harboring the symbiont into recipient species devoid of this symbiont. The artificial culture allows to choose the most favorable time for the injection. Successful transfer of Wolbachia was performed from T. pretiosum to T. dendrolimi. Index terms: Trichogramma, Wolbachia, symbiont, egg laying, nutrition

[1542] CONSEQUENCES OF INBREEDING AND HYBRIDIZATION IN THE GREGARIOUS PARASITOID COTESIA GLOMERATA

H. Gu & S. Dorn, Institute of Plant Sciences/Applied Entomology, Swiss Federal Institute of Technology, Zurich, CH-8092, Switzerland, E-mail hainan.gu@ipw.agrl.ethz.ch.

Inbreeding and outbreeding in parasitoids are important issues of relevance to all aspects of biological control. A consequence of inbreeding is the increase of homozygotes; as a result, the expression of recessive deleterious alleles increases in inbred populations, which can lead to the loss of fitness, i.e. inbreeding depression. The gregarious parasitoid Hymenoptera are thought to inbreed chronically due to sib-mating, and one would predict that such parasitoid species suffer very little from inbreeding. However, experiment evidence does not always support this prediction. In Cotesia glomerata (L.), a well-known gregarious parasitoid, mating between brothers and sisters not only causes a male-biased sex ratio but also leads to significant inbreeding depression in some fitness traits, including larval development and adult body size. The opposite of inbreeding depression is heterosis. Heterosis is referred to as the performance of F1 hybrids that exceeds the average parental performance, due to over-dominance of genes in heterozygous individuals. The haplodiploidy of parasitoid Hymenoptera is presumed to facilitate population divergence. Hybridisation between the genetically differentiated populations of such species may cause outbreeding depression due to incompatibility rather than heterosis. Our experiments with Cotesia glomerata, on the other hand, demonstrate significant heterosis in a number of female-related traits, such as sex ratio, larval developmental rate and adult body size. The F1 hybrids of crosses between a Swiss strain and a Holland strain produce a lower ratio of males to females, faster larval development and larger female wasps. The implication of these findings to breeding and mass production of parasitoids will be discussed.

Index terms: Cotesia glomerata, inbreeding depression, heterosis

[1543] UPDATING THE KNOWLEDGE OF INDIAN PHYTOSEIID MITES (ACARI) AND HIGHLIGHTING THE POTENTIALLY IMPORTANT INDIGENOUS PREDATORY SPECIES FOR BIOCONTROL PROGRAMME

S.K.Gupta, 1C/10 Anandam Housing Complex, 7 K.B Sarani, Calcutta- 700080, India.

Phytoseiid mites received importance in India from the middle of the last century and due to its growing importance as efficient biocontrol agents, reasonably good work has been done in this country not only towards explorations of fauna but also to generate data on bio-ecological aspects, food preference, predator-prey interaction, mass culture, etc. The available results indicate that uptil now 173 species under 11 generand 3 subfamilies are high degree of endemism. Six species have been identified as most efficient predators while another six are there which are of occasional importance and for many of those species studies have been conducted on biology seasonal occurrence, food preference, feeding potentiality, predator- prey interaction, effect of pesticides on predatory phytoseiids, mass culture, etc. This paper reviews all the available informations on Indian Phytoseiidae, discusses the future lines of work and concludes that there is a good scope in commercial exploitation, mass multiplication and release of promising predatory phytoseiids which will keep the pest mite population under check and lessen our heavy dependence on pesticides to fulfill the two main objectives of the modern pest management concept.

Index terms: Indian Phytoseiidae, biocontrol, indigenous predators.

[1544] SURVEY FOR NATIVE TRICHOGRAMMATID SPECIES IN KENYA

A. T. Haile¹, <u>S. Sithanantham¹</u>, C.K.P.O. Ogol², J.C. Monje³ & C.P.W. Zebitz³. ¹International Centre of Insect Physiology & Ecology, P.O. Box 30772, Nairobi, Kenya sithanantam@icipe.org; ²Kenyatta University, P.O. Box 43844, Nairobi, Kenya; ³University of Hohenheim, D-70593 Stuttgart, Germany.

In Kenya, past records of trichogrammatid egg parasitoid species have been limited to two species of Trichogramma and four species of Trichogrammatoidea. These included Trichogramma sp. nr. exiguum and Trichogramma sp. nr. mwanzai on Chilo spp., and Trichogrammatoidea armigera, Trichogrammatoidea eldanae, Trichogrammatoidea lutea and Trichogrammatoidea simmondsi on Helicoverpa armigera. As part of an initiative to promote utilization of native egg parasitoids in augmentative biocontrol of Helicoverpa armigera and Plutella xylostella, surveys were undertaken in 1998-99 in different parts of the country. Naturally occurring egg parasitoid collections were made from Plutella xylostella (48), Helicoverpa armigera (5) and Chilo spp.(43) and are being maintained as live cultures. Interestingly, eggs of Chilo laid on maize and occasionally also on kale (Brassica oleracea variety Collards) both harbored trichogrammatid parasitoids. The collections include Trichogramma bournieri, recovered from Chilo partellus on maize at Mbita (near Lake Victoria), which is a new record for Kenya. This species has been so far reported only from Comoros Islands off Eastern Africa. The natural occurrence of trichogrammati species on Plutella xylostella is a new record for Kenya, and also for Eastern Africa. Further studies on the species status of the collections are in progress. Index terms: Trichogramma, native species, survey, Kenya

Symposium and Poster Session

[1545] AN EDIBLE ALGINATE FORMULATION OF STEINERNEMA CARPOCAPSAE – ITS INSECTICIDAL EFFECT AND MOISTURE-HOLDING PROPERTIES

S. Han, S. Lee & Y. Kim, School of Bioresource Sciences, College of Natural Sciences, Andong National University, Andong, Korea 760-749

Field application of the entomopathogenic nematode, Steinernema carpocapsae Weiser, is limited by its susceptibility to UV irradiation and desiccation especially in leaf spray This study was conducted to develop the control technique using alginate control. biocapsulation of the nematodes against the beet armyworm, Spodoptera exigua (Hübner) and the tobacco cutworm, Sp. litura. The alginate capsules including the infective juveniles resulted in the oral toxicities to the larvae of two lepidopteran species. The mortality increased with the nematode densities embedded in the capsules and showed the typical sigmoid responses. Water content in the capsule was critical to the survival of the infective juvenile nematodes. More than 80% nematodes could survive above 10% moisture content remained in the capsules. The degree of moisture loss within the capsules was not affected by the citric acid reaction time during capsulation, but by the capsule size, ambient temperature, and relative humidity. More than 80% of infective juveniles in the alginate capsules could survive in distilled water at 15°C for 60 days. These results indicate that the alginate capsulation can be used to be an edible nematode carrier to control the larvae of two lepidopteran species, and that its moisture content was critical to the survival of the nematodes.

Index words - Steinernema carpocapsae, alginate, biocapsulation

[1547] POSSIBILITIES FOR THE USE OF ENCARSIA HISPIDA DE SANTIS (HYMENOPTERA: APHELINIDAE) IN THE BIOLOGICAL CONTROL OF THE SPIRALLING WHITEFLIES ALEURODICUS DISPERSUS RUSSELL AND LECANOIDEUS FLOCCISSIMUS MARTIN ET AL. (HEMIPTERA: ALEYRODIDAE)

E. Hernández-Suárez, <u>A. Carnero</u>, P. Brito, J.C. Febles & M. Hernández-García, Inst. Canario de Investigaciones Agrarias, P.B. 60 - E38200 La Laguna, Tenerife, Canary Islands, Spain

The spiralling whiteflies Aleurodicus dispersus and Lecanoideus floccissimus, a relative new arrival, are important pests of economic crops in the Canary Islands. A study conducted over the last two years recorded them on more than 40 plant species. Heavy populations were found on economic crops such as banana (Musa acuminata), papaya (Carica papaya), guava (Psidium guajava), and mango (Mangifera indica). As chemical control of spiralling whiteflies has not proved successful, a project has been initiated to develop control strategies, largely based on biological control. A survey was conducted to determine natural enemies' species, primarily parasitoids, present in our islands to be evaluated for potential as biological control agents. Thus, whitefly-infested leaves were collected from the field and the whiteflies reared through in the laboratory. Parasitized A. dispersus individuals were found developing in more than 15 host plants in six of the seven Canary Islands. Identification of emerged parasitoids indicated that 100% of the parasitism was due to Encarsia hispida. On the other hand, none parasitism has been found on L. floccissimus. E. hispida is in the process of being evaluated as candidate for improvement of natural control of A. dispersus and as biological control agent of L. floccissimus. Studies included biological attributes, interspecific interactions, host species, and stage preferences. In this poster authors present the first results of these studies. Data on distribution, hosts, host plants and interaction with other whitefly parasitoid species in the Canaries are provided. In particular, data are reported here on adult longevity, fertility and preimaginal developmental time of E. hispida on A. dispersus at different temperatures. Initial results of laboratory trials on the parasitism of L. floccissimus by E. hispida are also provided. Possibilities for the use of this parasitoid as biological control agent of the spiralling whiteflies in the archipelago are discussed.

Index terms: Encarsia hispida, Aleurodicus dispersus, Lecanoideus floccissimus, biological control

[1546] IMPLEMENTING AN ECOLOGICAL PERSPECTIVE OF HOST-NATURAL ENEMY INTERACTIONS TO AUGMENTATION BIOLOGICAL CONTROL

K. M. Heinz, Department of Entomology; Texas A&M University; College Station, Texas; 77843-2475; U.S.A.

It has frequently been proclaimed that ecology has contributed less to pest management than pest management has contributed to ecology. If this proclamation is true, it may be a result of ecological entomologists focusing on questions that address "how" systems operate rather than "why" they operate the way they do. This pattern is easily explained by the positive correlation between pest status and research effort. However, the proximate "how" approach provides little predictive power relative to the ultimate "why" approach as to how systems will respond to environmental perturbations. To achieve this predictive power in the case of augmentation biological control, research entomologists must construct and evaluate a body of theory that is implementable by biological control practitioners. In the first part of my presentation I will give a brief overview of the utility of ecological theory to pest management research. While most cringe at the thought of theory, it provides binomial, testable hypotheses that may be most easily studied experimentally in agricultural systems. In the second part of my presentation, I will develop the theory and tests of parasitoid sex allocation, parasitoid dispersal biology, and predator prey switching behavior as examples whereby ecological thought has contributed to predictable pest management strategies applicable to biological control within greenhouses. I will conclude by constructing a framework whereby ecological thought may be applied to pest management research. This framework will address the roles of fundamental and applied research in developing robust solutions to augmentation biological control problems.

[1548] DEVELOPMENTAL BIOLOGY OF *GYMNOSOMA ROTUNDATA* (DIPTERA: TACHINIDAE) PARASITIZING BROWN-WINGED GREEN BUG (HETEROPTERA: PENTATOMIDAE) AND ITS EFFECTS ON REPRODUCTION OF THE HOST

M. Higaki, Laboratory of Entomology, Department of Plant Protection, National Institute of Fruit Tree Science, Tsukuba 305-8605, Japan, E-mail scarabee@fruit.offrc.go.jp

Three species of stink bugs, Plautia crossota stali, Glaucias subpunctatus and Halyomorpha halys are well-known as serious fruit pests in Japan. Among them, P. c. stali is the most dreadful. Because P. c. stali reproduces mainly in the coniferous forests and occasionally migrates into fruit orchards, this pest is difficult to be controlled by appropriate spraying of insecticides. Therefore, the control of P. c. stali by natural enemies is desired. The tachinid fly, Gymnosoma rotundata is a parasitoid of P. c. stali. I studied the developmental biology of G. rotundata on P. c. stali and the reproductive ability of parasitized hosts in the laboratory (LD 16:8 h at 21-22°C). G. rotundata females laid 100 eggs on the average during their oviposition period of about two weeks on the abdominal tergum of P. c. stali adults. The newly-hatched maggot bored into the host body and a mature maggot emerged from the host to purate. Even if the fly deposited more than one egg onto a single host, only one maggot could survive to maturity. Parasitized hosts had shorter longevity than unparasitized ones, and without exception, died within a day after the maggot emerged. The mean periods of the larval and pupal stage of G. rotundata were 18 and 15 days, respectively. The mean adults body size of G. rotundata was 2.8 mm in head width. There were no significant differences in such the developmental periods and the body size between the two sexes of the fly. However, there was a tendency that larger G. rotundata adults emerged from larger hosts. Parasitized P. c. stali could retain the reproductive abilities for a while, but lost them as tachinid maggots matured. In females, both the number of laid eggs and the percentage of viable eggs decreased rapidly after the 8th day of parasitization. In males, the number of individuals that could fertilize eggs and/or copulate with female decreased rapidly after the 7th day of parasitization.

Îndex terms: Tachinidae, Gymnosoma rotundata, parasitoid, parasitic effects, Plautia crossota stali

[1549] HOST-PARASITE RELATIONSHIP BETWEEN THE MIGRANT BUTTERFLY, PARANTICA SITA (LEPIDOPTERA: DANAIDAE), AND ITS TACHINID PARASITOID, STURMIA BELLA (DIPTERA: TACHINIDAE), AT THREE HABITATS IN THE KII PENINSULA, CENTRAL JAPAN

N. Hirai & M. Ishii, Entomological Laboratory, Graduate School of Agriculture and Biological Sciences, Osaka Prefecture University, Sakai, Osaka 599-8531, Japan, E-mail n_hirai@plant.osakafu-u.ac.jp

It has become known that the migrant butterfly, Parantica sita, migrates sometimes over 1,000 km toward northeast or highland in spring, and vice versa in autumn in Japan. We made field researches in 3 habitats of *P. sita*, Sites A. B and C, in the Kii Peninsula from February 1998 to February 2000. The results revealed that Site A (alt.: about 20 m), located on the south coast facing the Pacific Ocean, was used mainly by the larvae of overwintering generation and few individuals were seen between spring and autumn. At Site B (alt.: about 360 m), located at the southern foot of the Izumi Range, individuals of immature stages were seen almost through the year, although the density was low. Most of the individuals were found on the evergreen milkvine, Marsdenia tomentosa (Asclepiadaceae), in both Sites A and B. At Site C (att.: 1,100 m), located on the eastern slope of the mountain, lots of adults were seen from July to August, and eggs and larvae were also seen on the deciduous milkvine, Cynanchum caudatum (Asclepiadaceae). The tachinid fly, Sturmia bella, is the most major parasitoid of larval P. sita in Japan. Female adults of this tachinid deposit nucrotype eggs on foliage of nost's food plants and the prasitization starts by ingestion of eggs with leaf tissue. We found eggs of this tachinid on the food plant of P. sita, and more than 80 % of individuals were parasitized by this tachinid in both Sites A and B, while we had not found both tachinid eggs and prasitized P. sita at Site C. We discuss the relationship between host's migration and parasitization of S. bella from the field observations.

Index terms: Parantica sita, Sturmia bella, host-parasite relationship, migration, Japan

[1551] *HYDROTAEA AENESCENS*, A LARVAL PREDATOR OF THE HOUSE FLY: A SUMMARY OF RECENT RESERCH

J. A. Hogsette¹, R. Farkas², R. Ripa³ & C. Arancibia³, ¹USDA-ARS, P.O. Box 14565, Gainesville, FL 32604, USA, E-mail: jbogsette@gainesville.usda.ufl.edu; ²Szent István University, Faculty of Veterinary Science, Pf. 2., H-1400 Budapest, Hungary; ³Instituto de Investigaciones Agropecuarias, Subestacion Experimental La Cruz, Chorrillos 86 - Casilla 3, La Cruz, Chile.

Hydrotaea aenescens, the black dump fly, is native to the Western Hemisphere except for parts of western Canada. It was transported by commerce to Europe, with the exception of the U.K., and has moved across Europe into western parts of the former Soviet Union and south into the Levant. Naturally occurring dominant populations of H. aenescens have been observed in open-sided caged layer poultry houses in the U.S. and Chile. In these situations house flies all but disappear because of predation by Hydrotaea. In Florida, H. aenescens larvae and pupae were released in very wet pullet houses in an attempt to establish black dump fly populations. H. aenescens did not become established, but instead dispersed 0.3 km to adjacent layer houses where they not only became established in large numbers, but controlled house flies for more than 1 year. During this period, Hydrotaea adults did not become a nuisance on the layer farm or at nearby houses or at a nearby dairy farm. Release and establishment of colonized Hydrotaea on farms is still not easy because manure habitats may differ greatly from artificial laboratory diets in which colonized Hydrotaea populations have been reared, particularly in moisture content. Thus the laboratory populations have become acclimated to a narrow moisture range while field populations become adapted to a much wider moisture range. Hydrotaea can compete well with house flies in swine and poultry manure. Although Hydrotaea has not been associated with manures from ruminant animals, this fly can develop successfully in the manure of unweaned calves. Hydrotaea has been established on dairies by releasing larvae in calf-rearing areas. Field populations of H. aenescens are subjected to attack by many natural enemies of the house fly, like coleopteran predators and hymenopteran parasitoids. So after H. aenescens destroys the house fly populations, it in turn becomes the prey. In most of its range, *H. aenescens* is viewed as a beneficial biological control organism. However in many parts of South America, *H. aenescens* is viewed as a potential vector of disease and carrier of the eggs of Dematobia hominis. Tests are underway to better define the role of H. aenescens in these activities and possibly to change the image of H. aenescens from bad to good.

Index terms: black dump fly, biological control, poultry, swine, dairy

[1550] INOCULATIVE RELEASES OF TRICHOGRAMMA OSTRINIAE FOR EUROPEAN CORN BORER CONTROL

M.P. Hoffmann, M. G. Wright, S. Chenus, J. Gardner, Dept. of Entomology, Cornell University, Ithaca, NY 14853, USA, E-Mail mph3@cornell.edu.

European corn borer (Ostrinia nubilalis) is an important pest of sweet corn in the USA. Chemical control is the principal means of control of this pest, but because of regulatory changes, insecticides currently available for its control are likely to be withdrawn. Alternative management techniques for O. nubilalis are therefore clearly needed. Inundative biological control has not been effective for O. nubilalis in the USA, as the egg parasitoids evaluated were unable to parasitize adequate proportions of eggs and adequately reduce damage. We report on inoculative release of Trichogramma ostriniae, made early in the season at low densities (75 000 females ha⁻¹) in New York, USA. Results of research conducted over three years have been very promising. High proportions of egg masses were parasitized throughout the growing season, even where initial O. nubilalis activity was low. The wasps showed no density dependant functional response to egg or egg mass density under field conditions. They also showed a propensity for rapid dispersal, yet demonstrated considerable fidelity for their release field, with parasitism continuing to occur far and near from release points, throughout the season. A method for accounting for mortality to T. ostriniae and inclusion in threshold and scouting protocols is presented. It is suggested that T. ostriniae has potential to become an important biological control agent of O. nubilalis in the USA.

Index terms: Inoculative release, Ostrinia nubilalis, sweet corn, Trichogramma ostriniae.

[1552] EFFECT OF TEMPORARY HOST DEPRIVATION ON THE REPRODUCTION AND SURVIVAL OF WOLBACHIA-INFECTED AND UNINFECTED TRICHOGRAMMA KAYKAI PINTO AND STOUTHAMER (HYMENOPTERA: TRICHOGRAMMATIDAE)

C. L. Hohmann¹ & R. F. Luck², ¹Inst. Agronômico do Paraná/IAPAR, C. Postal, 481, 86001-970 Londrina, PR, Brazil, E-mail celuiz@pr.gov.br; ²Dept. of Entomology, Univ. of California. Riverside, CA 92521, USA.

The effect of temporary host deprivation on the reproduction and survival of Trichogramma kaykai Pinto and Stouthamer (Hymenoptera: Trichogrammatidae) was determined by comparing a Wolbachia-infected (= thelytokous) and a field-collected arrhenotokous line of T. kaykai when reared on Trichoplusia ni Hübner (Lepidoptera: Noctuidae) eggs. The progeny of both arrhenotokous and thelytokous females decreased with increasing periods of host deprivation but, arrhenotokous females produced significantly more progeny than thelytokous females regardless of the period of host deprivation (0 to 10 days). They also produced more daughters. Host deprivation did not affect brood size within arrhenotokous or thelytokous lines. However, fewer wasps emerged from hosts parasitized by Welbachia-infected than those parasitized by uninfected T. kaykai. A direct relationship existed between longevity and the length of time an arthenotokous or a thelytokous wasp was deprived of hosts. The longer the deprivation period, the longer they lived. However, arrhenotokous females lived longer than their thelytokous counterparts. The results suggest that a cost exists in infected wasps when they are compared with uniafected wasps and that this cost has potential consequences on the dynamics of these two co-existing, conspecific populations. Index terms: arthenotokous, parthenogenesis, reproductive success, thelytokous, Wolbachia.

[1553] SUPERPARASITISM IN ARRHENOTOKOUS AND THELYTOKOUS TRICHOGRAMMA KAYKAI PINTO AND STOUTHAMER (HYMENOPTERA: TRICHOGRAMMATIDAE)

C. L Hohmann¹ & R. F. Luck², ¹Inst. Agronômico do Paraná/IAPAR, C. Postal 481, 86001-970 Londrina, PR, Brazil, E-mail celso@pr.gov.br; ²Dept. of Entomology, Univ. of California. Riverside, CA 92521, USA.

The ovipositional behavior of field-collected arrhenotokous and Wolbachia-infected (thelytokous) female Trichogramma kaykai Pinto and Stouthamer (Hymenoptera: Trichogrammatidae) was evaluated, using Trichoplusia ni Hübner (Lepidoptera: Noctuidae) eggs as hosts. Both arrhenotokous and thelytokous females rejected significantly more parasitized than unparasitized hosts, but arrhenotokous females rejected fewer such hosts. The rejection rate for both reproductive forms increased as the elapsed time increased between the initial oviposition and subsequent host encounter. When an arrhenotokous female oviposited in a host that had been parasitized by a thelytokous female 2 h earlier, she usually laid a single female egg. She usually laid a male egg when she superparasitized a host 5 h after its initial parasitization. A thelytokous female usually laid a clutch of a single female egg when she was exposed to a host previously parasitized by her arrhenotokous counterpart. Ten to eighteen percent of the eggs laid by arrhenotokous females and 66 to 78% of those laid by a thelytokous female in previously parasitized hosts died during development. In contrast, only 2 % of the eggs laid by an arrhenotokous female and 28% of the eggs laid by a thelytokous female in previously unparasitized hosts died during development. The degree of mortality suffered by the eggs of a thelytokous female in a superparasitized host depended on the clutch size laid by the arrhenotokous female. When the arrhenotokous female added a single egg in a previously parasitized host, 54% of the thelytokous eggs died during development. When she added two eggs to the host, 90% of the thelytokous eggs died during development. Thus, the offspring of Wolbachia-infected females suffered higher mortality than arrhenotokous females when they were the sole offspring in a host. They suffered disproportionately greater mortality when they competed with arrhenotokous offspring in a host. The greater mortality of eggs laid by the thelytokous wasp likely explains the smaller broods that emerged from the hosts they parasitized when compared with those parasitized by arrhenotokous wasps.

Index terms: egg parasitoid, conspecific superparasitism, Wolhachia infection.

[1554] DEVELOPMENT OF AN ARTIFICIAL DIET FOR REARING EDOVUM PUTTLERI, AN EGG PARASITOID OF THE COLORADO POTATO BEETLE, LEPTINOTARSA DECEMLINEATA

J. S. Hu, <u>D. B. Gelman</u>, M. G. Rojas¹, M. J. Loeb, D. E. Lynn and R. A. Bell, Insect Biocontrol Lab, U.S. Dept. of Agric., Bldg. 306, Rm. 322, BARC East, Beltsville, MD 20705 USA and ¹USDA, ARS, Southern Region Research Center, New Orleans LA 70179 USA.

Edovum puttleri has been shown to effectively control Colorado potato beetle (CPB) populations on eggplant crops so that plant damage is kept below economic threshold Since E. puttleri is unable to overwinter in temperate climates, yearly augmentative releases are necessary to prevent CPB damage. However, the current method for rearing E. puttleri using eggs produced by CPB reared on potato plants is not cost effective. A variety of semi-defined artificial diets have been developed and tested for their ability to support the in vitro development of E. puttleri. A diet containing high levels of hen egg yolk and egg homogenate and/or hemolymph prepared from Manduca sexta was able to support parasitoid development to the pupal stage. An extract of M. sexta pupal fat body tissue was able to replace the hemolymph component of the diet as was conditioned medium prepared from cell lines of CPB embryos. The effects of 13 amino acids and 20 carbohydrates (in the absence of all insect components) on the growth and development of the parasitoid were also tested. Glutamine in combination with lactose or sorbitol, and threonine in combination with fructose, gentiobiose, glucose, lactose, sorbitol or trehalose (lactose or sorbitol were most effective) promoted pupation. Both glutamine and threonine were present in relatively high concentrations in 0-48-h-old (preferred time for parasitization) CPB eggs, with glutamine being present at 2-6 times higher levels than threonine. Proline, asparagine, serine, glutamic acid, lysine and tyrosine were also present in significant quantities, but were not effective in promoting pupation. In 0-48-h-old CPB eggs, physiologically active ecdysteroid (20-hydroxyecdysone and perhaps, ecdysone) was present at concentrations of between 50 and 200 pg/egg. Index terms: cell line-conditioned medium, fat body factor, amino acids, sugars,

Index terms: cell line-conditioned medium, lat body lactor, amino actus, sugars, ecdysteroids

[1555] A DISCUSSION ON THE PRELIMINARY OBSERVATIONS OF THE RELATIONSHIP BETWEEN XENOS VESPARUM ROSSI AND IT'S HOST POLISTES DOMINULUS CHRIST (HYMENOPTERA)

David Hughes1, Jeyaraney Kathirithamby1 & Stefano Turillazzi2, 1 Department of Zoology, South Parks Rd., Oxford OX1 3PS, UK; 2 Dipartimento di Biologia Animale e Genetica, Universita di Firenza, Via Romana 17, 50125, Firenze, Italy.

Strepsiptera are unusual and interesting in terms of life history and morphological adaptations. Previous work has focused mainly on the morphology and phylogenetic position of the order. Here we present our initial findings into the relationship between the parasite and the host. In particular, alteration and possible manipulation of host behaviour due to the presence of the parasite, behaviour of the parasite (during copulation and host infestation) and the change in behaviour of colony members towards parasitized (stylopised) individuals. The future direction of this study will also be discussed. Key words: host-parasite, behaviour, host manipulation

[1556] THE EFFECT OF ALTERNATIVE FOOD ON ORIUS LAEVIGATUS, ITS PREY FRANKLINIELLA OCCIDENTALIS AND THEIR INTERACTION

J. Hulshof & I. Vänninen, Agricultural Research Centre, Plant Production Research, Plant Protection, FIN-31600 Jokioinen, Finland, E-mail: jan.hulshof@mtt.fi.

In the absence of prey, alternative food sources (e.g. pollen or nectar), appear to play a role in the establishment and persistence of oligophagous predators. Such predators remain in pollenbearing crops in the absence of prey, whereas their numbers decline in crops lacking pollen. We studied the potential of introducing the predatory bug Orius laevigatus on non-pollenbearing cucumber with the help of alternative food sources. First, the suitability of different food sources for both O. laevigatus and its prey Frankliniella occidentalis was studied. The aim was to select food sources that would facilitate the development and reproduction of the bugs, but that the thrips could utilize to a lesser extent. The bugs were unable to develop into adults on 6 studied food sources: pollen of Salix spp., the common cattail, broad bean and firewced (bee and hand collected), or a mix of milk powder and yeast. Feeding the bugs with six other food sources: Ephestia kuehnielln eggs, an entomophage diet and the pollen of pine, hazel, birch and sweet pepper supported the development of nymphs into adults. Except hazel pollen, five of these food sources resulted in a positive intrinsic rate of increase (rm), with a maximum of 0.092 for bugs fed with Ephestia eggs, followed by 0.084 and 0.049, resp., for those fed with pine and sweet pepper pollen. All food sources, except the mix of milk powder and yeast, enhanced the population development of the thrips, mainly their fecundity. The thrips benefited most from pine pollen: the r_m of thrips fed with encumber leaf was 0.175 and it rose to 0.256 when pine pollen were added to the leaf. We conclude that for the tested types of food, O. laevigatus has a smaller food range than the thrips. Next, the effect of the presence of an alternative food source on the predator-prey interaction, and specifically the searching behavior of the bugs, was studied in two-choice situations. Sweet pepper pollen (the pollen species that was found most quickly by the bugs in preceding experiments) placed on one half of a cucumber leaf was offered simultaneously with either thrips larvae and their damage, or mere thrips damage on the other half of the leaf. The bugs searched longer on the leaf half showing thrips damage, both in presence or absence of thrips larvae, than on the half containing sweet pepper pollen. Further experiments will concentrate on the predation behavior of the bugs in the presence of alternative food. The importance of alternative food for the bugs in times of prey scarceness, and the potential of the use of alternative food for O. laevigatus on non-pollen bearing crops will be discussed. Index terms: pollen, thrips biocontrol, cucumber, intrinsic rate of increase

[1557] SUBLETHAL EFFECTS OF INSECTICIDES ON THE BEHAVIOUR OF TWO PARASITOIDS : INFLUENCE OF INDIVIDUAL EXPERIENCE AND GENETIC VARIABILITY

L. Kaiser¹, N. Desneux¹, H. Rafalimanana², J.M. Delpuech³ & M.II. Pham-Delègue¹, ¹INRA, BP23, 91440 Bures-sur-Yvette, France, E-mail kaiser@jouy.inra.fr; ²ESSA, BP 175, Antananarivo, Madagascar; ³Lab. Biométrie, Génétique & Biologie des Populations, Univ. Lyon1, 69622 Villeurbanne Cedex, France.

Most insecticides are neurotoxic. Non target Arthropods are exposed to residues so their behaviour can be impaired. Among them, parasitoids represent an important group by limiting pest insect populations and for their abundance and diversity. Reproduction success lies on finding suitable hosts. Few studies examined how insecticide exposure could affect this skill. In addition, responses involved in host location can vary depending on individual experience, and genetic variability was also reported. We examined the influence of geographical populations and individual oviposition experience on the susceptibility of orientation and probing responses to odors. We report the results from two studies, one on a parasitoid of Drosophila larvae, Leptopilina heterotoma, exposed to an organophosphorus insecticide ; the second on an aphid parasitoid, Aphidius ervi, exposed to a pyrethroid. Laboratory experiments were conducted. Wasps were exposed for 24h to dry residues of the active ingredients, chlorpyrifos-ethyl and lambda-cyhalothrine respectively. In L. heterotoma, females probe fruits with their ovipositor to find larvae. This can be triggered by fruit odors. We compared two strains with high and low probing activity. High activity is viewed as a response to competition. These contrasted levels caracterize naive females, i.e. searching for their first host ; activities are equalized once the fruit odour has been learned when perceived during oviposition. Females were exposed to a LD 20. Probing responses of the less active strain were more numerous after this exposure, and further more after learning. These effects were not visible in the more active strain, of which responses were too high to be significantly augmented. The situation was very different with A. ervi exposed to the pyrethroid. In this species, females are attracted by the odour from host-infested plant (here, Myzus persicae on oilseed rape). This attraction is prolonged by previous oviposition on a host-infested leaf. Only one strain was studied. Exposure to LD 0.1 but not to LD 20 weakened responses of naive females, whereas experienced responses were robust to the insecticide exposure. In both studied systems, the insecticide effects disappeared within 24h following the end of exposure. Then this work shows that in addition to insecticide nature and doses, biotic factors like individual experience and genetic variability should be considered to understand consequences of exposure on parasitoids behaviours.

Index terms: Leptopilina heterotoma, Aphidius ervi, olfaction, ecotoxicity

[1558] THE INFLUENCE OF CITRUS SPECIES ON THE PARASITIZATION OF APHIS GOSSYPHI BY VARIOUS PARASITOIDS

N. G. Kavallieratos & D. P. Lykouressis, Lab. of Agr. Zoology and Entomology, Agricultural University of Athens, 75 Iera Odos, 118 55, Athens, GREECE, E-mail esimou@auadec.aua.gr

Aphids are very important pests of citrus in several citrus growing areas of the world. Amongst them Aphis gossypii is one of the most abundant species on citrus trees in Greece. The aim of this work was to investigate the possible role of three citrus species on the parasitization of A. gossypii by various aphidiids. For that purpose, leaf samples, bearing mummified aphids, were taken from Citrus aurantium, Citrus deliciosa and Citrus sinensis from different areas of the country in 1996 and 1997. The species of aphidiids which were found to have a significantly different preference on A. gossypii were Aphidius colemani, Aphidius matricariae, Lysiphlebus testaceipes and Trioxys (Binodoxys) angelicae. Parasitization rates by various parasitoids of A. gossypii were affected by citrus species in a different way amongst the investigated regions. A special case was the area of Southern - Western Greece, a unique region amongst the others, in which L. testaceipes is very well established dominating other aphidiids. In the remainder of the regions this parasitoid was recorded in low levels from A. gossypii. However, parasitization rate by A. matricariae on C. deliciosa was significantly different to that on C. aurantium in Northern Western Greece and Southern - Eastern Greece. Similarly, in Southern - Western and Eastern Greece parasitization rate by A. colemani on C. deliciosa was Southern significantly different than that on C. sinensis. Irrespective of study area, A. colemani on C. aurantium did not express a considerable variation. On the contrary, T. (B.) angelicae, on the same citrus species and study areas as before, appeared to be area depended. Index terms: Aphis gossypii, parasitoids, citrus species

[1559] BIOLOGICAL CONTROL OF VECTOR INSECTS IN CITRUS: A CASE STUDY IN TURKEY

U. Kersting, Faculty of Agricultural Sciences & Technologies, European University of Lefke, Gemikonagi, Mersin 10, Turkey, E-mail kersting@vuni.lefke.edu.tr

Many virus and virus-like diseases seriously damage citrus plants all over the world. The causal agents of some of the most devastating diseases, such as citrus tristeza virus, African greening and huanglungbin, witches' broom disease of lime, and citrus variegated chlorosis are transmitted by insects, making the control of these diseases even more difficult. Successful reports on biological control of insect vectors in citrus are limited. A major reason is that the primary objective of biological control is reducing insect populations to economically insignificant low levels, rather than eradication. This approach may fail for insect vectors, as even a single individual is capable of virus transmission, and thus the disease may continue to spread even at low population densities. The aleyrodid Parabemisia myricae (Kuwana) was first noticed in the citrusgrowing areas of the east Mediterranean region of Turkey in 1982 and later spread to many other countries in the Mediterranean basin. It soon became the major citrus pest and as chemical control was unsuccessful, a biological control program was launched in 1987. After mass releases of the specific aphelinid Eretmocerus debachi Rose & Rosen, the whitefly populations on citrus dropped sharply from more than 60 to far less than 0.1 individuals per leaf within five years. By the end of the 1980's a new citrus disease of possible viral etiology (citrus chlorotic dwarf, CCD) was observed in the Mersin district, which quickly spread throughout the western parts of the east Mediterranean region. About 50% of all citrus trees were affected with more severe symptoms on lemon and grapefruit than on orange. Laboratory experiments revealed that the causal agent of CCD is highly transmissible by P. myricae, but not by other citrus whiteflies or by pruning. The spread of the disease slowed down considerably from 1992 onwards and never reached the eastern parts of the citrus-growing area. Moreover, several thousand virus-tested trees planted in the most affected areas after 1990 have not been found infected with CCD when surveyed in 1994/95. The use of E. debachi to control P. myricae is one of the very few examples of a highly successful biological control program for insect vectors worldwide. The high success of this program was apparently due to several factors: i.) early launch of a successful parasitoid release program, ii) high efficiency and high searching activity of E. debachi even at very low host population densities, iii) the lack of hyperparasitoids, and iv) the high number of alternative host plants of P. myricae serving as important refuges for the vector and the parasitoid.

Index terms: Parabemisia myrica, Eretmocerus debachi, citrus chlorotic dwarf

[1560] DEVELOPMENT AND REPRODUCTION OF PREDATORY INSECTS STETHORUS JAPONICUS (COLEOPTERA: COCCINELLIDAE), OLIGOTA KASHMIRICA BENEFICA (COLEOPTERA: STAPHYLINIDAE) AND SCOLOTHRIPS TAKHASHII (THYSANOPTERA: THRIPIDAE) REARED ON DIFFERENT SPECIES OF SPIDER MITES (ACARI: TETRANYCHIDAE)

II. Kishimoto, Lab. of Entomology, Dep. of plant protection, National Institute of Fruit Tree Science, Fujimoto 2-1, Tsukuba, Ibaraki 305-8605, Japan, E-mail kisimoto@fruit.affrc.go.jp.

The development and reproduction of three predatory insects Stethorus japonicus H. Kamiya, Oligota kashmirica benefica Naomi, and Scolothrips takahashii Priesner were studied when they were reared on different species of spider mites at 27°C;16L8D. Eggs and deutonymphs of three species of spider mites, Panonychus mori Yokoyama, Tetranychus urticae Koch and Amphitetranychus viennensis (Zacher), which are serious pests on pear, were provided as the prey. DEVELOPMENT: Most of S. japonicus larvae died during the first instar and only about 10% of larvae developed to pupae when they were reared on eggs of P. mori. The shells of P. mori eggs were too hard for the first instar of S. japonicus to feed on. More than 80% of larvae, however, developed to pupae, when they were reared on P. mori deutonymphs, and the eggs and deutonymphs of both T. urticae and A. viennensis. Most of O. kashmirica benefica larvae reared on P. mori eggs also died during the first instar for the same reason as S. japonicus larvae. On the other hand, S. takahashii larvae could successfully develop to pupae regardless of the prey species and stages. REPRODUCTION: The oviposition rates of S. japonicus differed significantly among the prey species: females reared on A. viennensis laid more eggs than those reared on P. mori, and females reared on T. urticae showed an intermediate number of eggs. On the other hand, the oviposition rates of O. kashmirica benefica were not significantly different among all the prey species or stages provided. The oviposition rates of S. takahashii will be examined in the future. These differences in the suitability of prey species for each predatory species enabled to illustrate the different patterns of species composition between spider mites and their predators in Japanese pear orchards.

Index terms: Stethorus japonicus, Oligota kashmirica henefica, Scolothrips takahashii, development and reproduction, prey species

[1561] EFFECTS OF SOME PLANTS ON PARASITIZATION OF EURYGASTER INTEGRICEPS EGGS BY TRISSOLCUS SEMISTRIATUS

M. Kivan¹ & N. Kilie¹, ¹Dept. of Plant Protection, Agric. Faculty, Univ. of Trakya, 59030, Tekirdag, TURKEY, E-mail tzfbitkikoruma@superonline.com.

The egg parasitoid Trissolcus semistriatus (Hymenoptera, Scelionidae) is the natural nemy of sunn pest, Eurygaster integriceps (Heteroptera, Scutelleridae), which is one of sost destructive pests of wheat. An examination was conducted to determinate whether ome plant species have an effect on the parasitism of T.semistriatus at 26±2 °C, 60±10 % slative humidity and 16:8 hr photoperiod. The parasitism rate of T. semistriatus on E. ntegriceps eggs was investigated in the absence and presence of plants. The plants used vere wheat (Triticum vulgare), cow cockle (Vaccaria pyramidata var. grandiflora), bifora Bifora radians), common vetch (Vicia sativa) and turnipweed (Rapistrum rugosum). hese plants were chosen because they were common in or near the cereal fields in lekirdag and also hosts of pentatomids which are secondary host of egg parasitoids. The plants significantly affected the parasitism rate, adult emergence and sexual ratio (p<0.05) of T.semistriatus. The presence of turnipweed and cow cockle leaves resulted in lower parasitism ratio than the others or alone eggs. However, developmental period of male and emale were not influenced by plants. It was concluded that some plants or absence of plant did not change the parasitism, while some plants, as cow cockle and turnipweed, reduced the parasitism. As a result, it could be suggested that the responses of egg parasitoid to plant semiochemicals involved probably in host recognition should be determined.

Index terms: Trissolcus semistriatus, Eurygaster integriceps, plants, parasitism

[1563] LARVAE OF CHRYSOPID AND FALL WEBWORM HAVE PREFERENCE FOR PARTIALLY DRIED FOOD TO FRESH ONE

T. Kubota¹, ¹Kitakarasuyama 6-31-2, Setagaya, Tokyo 157-0061, Japan, E-mail: tkubota@mtd.biglobe.ne.jp

It is commonly believed that insects whose known food is living animal/plant have preference for fresh food to desiccated one. Although explicit verification for this has not been given, it is quite difficult to demonstrate food preference in a reliable and quantitative manner, especially when partially dried food is compared to its fresh counterpart. In this study, the author developed a method, based upon two-choice test, in which larvae are individually given desiccated food with controlled degree of dryness and fresh food to choose between them so that the food preference can be measured accurately for each individual animal. The author used larvae of Chrysoperla carnea, Pseudomallada alcestes (Neuroptera, Chrysopidae; food, eggs of Tribolium castaneum) and Hyphantria cunea (Lepidoptera, Arctiidae; food, leaves of mulberry, Morus alba). Four drying methods were employed to prepare food with various extent of dryness as measured by reduction of total food weight from untreated one: first, cutting leaf, which resulted in weight reduction by 5 %. Second, brief desiccation in drying-oven at 35 °C temperature for 35 min for Morus leaves and 38 °C for 60 min for Tribolium eggs, with weight reduction by 14% and by 8%, respectively. And third, 7-h desiccation of leaves at room temperature with 30 % reduction in weight and forth is 6-weeks of refrigeration (at 5 °C temperature) of Tribolium eggs with weight reduction by 8 %. The author observed statistically significant (5% level) preference for partially dried food prepared by the first two methods described above in both animal species. More specifically, a prominent shift of food preference toward partially dried one was observed in the following 3 cases: 4th instar *II. cunea* larvae preferred the cut edge of Morus leaf to the intact edge and did oven-dried Morus leaf to the intact leaf and 1st instar larvae of Pm. alcestes did for oven-dried Tribolium eggs to fresh ones. Furthermore, the frequency of larvae which preferred partially dried food declined linearly with larval development in Pseudomallada alcestes (significant at 5% analyzed by logistic regression model) and the same frequency in Hyphantria cunea showed also a decline during 4th to 5th larval instar (significant at 5% by logistic regression model). In conclusion, the author developed a statistical behavioral analysis, which confirmed significant food preference for partially dried in animals previously believed to favor fresh food to dried one.

Index terms: food preference, partial desiccation, Hyphantria cunea, Pseudomallada alcestes, Chrysoperla carnea.

[1562] SAMPLING PREDATORY INSECTS AND SPIDERS IN COTTON

A. E. Knutson¹, L. T. Wilson², S. E. Naranjo³ & M. A. Muegge⁴, ¹Texas A&M Research and Extension Center, 17360 Coit Road, Dallas, TX 75252-6599, USA, E-mail a-knutson@tamu.edu; ²Texas A&M Research & Extension Center, Rt 7, Box 999, Beaumont, TX 77713 USA; ³ USDA-ARS 4135 E. Broadway Rd, Phoenix AZ 85040, ⁴Texas A&M Research and Extension Center, Box 1298, Ft. Stockton, TX, 79735-1298, USA.

Predatory insects and spiders have been demonstrated to suppress populations of cotton pests including Helicoverpa zea, H. armigera, Heliothis virescens, Spodoptera exigua, and Aphis gossypii. However, there are few guidelines on how to use field information on predatory arthropods to aid pest management decisions in cotton IPM programs. A major constraint to the development and adoption of these guidelines has been the lack of a reliable and efficient sampling method for estimating predator densities in commercial monitoring programs. Adult and immature Orius spp. and Geocoris puncitpes, adult Hippodiamia convergens and Pseudatomoscelis seriatus, immature Chrysoperla spp. and spiders, primarily Misumenops spp. and Oxyopes salticus, were sampled in cotton with a sweep net, drop cloth, beat bucket, shake bucket and by visual search of the plant. The density-dependent sample size (n) was estimated for each predator species/group using the relationship $n = ax^{(b-2)}/D^2$ where a and b = Taylor's coefficients, and D = desired level of precision. The cost (product of sampling time and sample size) was calculated for each method and predator. The relative cost-efficiency was estimated as the ratio of the products of the estimated sample size (n) and the cost (c) per sample unit $(n_x c_y/n_y c_y)$ for each method (x) relative to the visual search method (v). The beat bucket method was one of the most cost efficient methods for sampling Orius adults and nymphs, Chrysoperla larvae and spiders which together accounted for 82% of the total predators recovered in an "absolute" sampling method. The beat bucket was constructed from a common 18 liter, white plastic pail (37 cm X 27 cm). The bottom was removed and fitted with a large plastic funnel to direct predators into a plastic jar. The bucket was held at a 45° angle to the ground and the top 20-24 cm of a single cotton plant was quickly grasped by the lower stem and bent into the bucket. The plant was beaten against the sides of the bucket for 3-4 seconds to dislodge predators. The plant was removed, the bucket was held upright and the sides sharply taped with the hand until all arthropods had fallen through the funnel. Sample units of 1, 3, 5 and 10 plants per beat bucket sample were collected in Texas and Arizona. Three or 5 plants/beat bucket sample provided the most cost-efficient estimate for most predator groups. Sample size for a mean density of 0.5/plant ranged from as few 8 for H. convergens to 48 for immature Orius spp.

Index Terms: Orius, Geocoris, Hippodiamia, Chrysoperla, Misumenops,

[1564] JALISCO FLY (DIPTERA: TACHINIDAE) AS A BIOLOGICAL CONTROL AGAINST MEXICAN RICE BORER (LEPIDOPTERA: PYRALIDAE) IN TEXAS SUGARCANE

J. C. Legaspi¹, B. C. Legaspi, Jr.¹, I. Lauzière¹, J. W. Smith, Jr.², L. A. Rodríguezdel-Bosque², & W. A. Jones⁴, ¹Texas Ag. Expt. Sta., 2415 East Hwy 83, Weslaco, TX 78596, USA; ²Dept. Entomol., Texas A&M Univ., College Station TX 77843, USA; ³INIFAP, PO Box 79, Progress TX 78579, USA; ⁴USDA ARS 2413 East Hwy 83, Weslaco, TX 78596, USA.

The Mexican rice borer, Eoreuma loftini (Dyar) (Lepidoptera: Pyralidae), injures -20% of sugarcane (Saccharum spp.) internodes in Texas, causing estimated annual losses of \$10 to 20 million. Interest has focused on the Jalisco fly, Lydella jalisco Woodley (Diptera: Tachinidae), which causes field parasitism levels of about 33% in its native Mexico. In 1998, a collaborative research effort was made to import and evaluate L. jalisco as a biological control agent. Borer larvae were collected in Mexico from August 1998 to March 1999 to measure parasitism and to initiate a parasite colony. Sugarcane injury from E. loftini was relatively low, ranging from 3-4.4% bored internodes. Injury caused by Diatraea considerata Heinrich (Pyralidae) ranged from 1.3-6.3% bored internodes. The extant stalkborer population was almost equally divided between the 2 species. A total of 3,040 E. loftini larvae were collected of which 209 were parasitized (6.9%). Lydella jalisco was collected most consistently from the Los Lirios, Ejido Caimanero locality, which yielded 16.1% parasitism (193 fly larvae / 1197 borer larvae). Parasitism by L. jalisco was highest from mid-August (1998) to mid-October at ~30%. After mid-October, L. jalisco declined and parasitism was predominantly due to the egg-larval parasite Chelonus sonorensis Cameron (Hymenoptera: Braconidae). Surveys and field collections were performed in the subsequent sugarcane season, and data are currently being analyzed. We are also interested in assessing the efficacy of L jalisco on different graminaceous host plants should E. loftini become a significant pest of those crops. In a greenhouse experiment, L. jalisco was evaluated on: a) sugarcane; b) corn, Zea mays; c) sorghum, Sorghum bicolor, d) rice, Oryza sativa; and, e) johnsongrass, Sorghum halepense (weed alternative host). Parasitism was significantly different among the host plants, being highest on sugarcane (81.4%), lowest on johnsongrass (10.0%), and intermediate in the other plants (corn = 54.6%, sorghum = 22.0%, rice = 14.9%). Therefore, the Jalisco fly can successfully parasitize Mexican rice borer larvae on alternative graminaceous host plants such as corn, sorghum or rice despite its documented geographical and biological specificity. Currently, studies are underway to assess efficacy in the field. Index terms: Eoreuma loftini, Lydella jalisco, damage, parasitism, preference

Session 08 - ENTOMOPHAGOUS INSECTS AND BIOLOGICAL CONTROL

[1565] OBSERVATIONS ON CULTURING *DIADEGMA INSULARE*, AN IMPORTANT PARASITOID OF THE DIAMONDBACK MOTH

G. L. Leibee & K. E. Savage, Mid-FL Res. & Ed. Ctr, IFAS, Univ. of FL 2725 Binion Rd, Apopka, FL 32703-8504, USA, E-mail glle@gnv.ifas.ufl.edu.

One of the most important parasitoids of the diamondback moth, *Plutella xylostella*, is *Diadegma insulare*. Augmentative releases of this species could be an important component of a management program for the diamondback moth. However, unlike several other species of diamondback moth parasitoids, *D. insulare* is not readily available from commercial insectaries. One apparent reason for this is that *D. insulare* is difficult to keep in continuous culture. One obvious and characteristic "symptom" often associated with a problem culture is a gradual increase in the number of males relative to number of females, often referred to as "going to male." We have cultured *D. insulare* for months at a time without experiencing difficulties, and have produced numbers in the thousands for experimentation and release. We describe our method of culturing the diamondback moth and *D. insulare* to contribute knowledge that might facilitate the use of this parasitoid in the management of the diamondback moth.

Index terms: Diadegma insulare, Plutella xylostella, diamondback moth, culturing

[1567] PREDATOR-PREY INTERACTIONS AT VARIOUS SPATIAL SCALES: BIOLOGICAL CONTROL OF THE BULB MITE, *RHIZOGLYPHUS ROBINI*, BY THE PREDATORY MITE, *HYPOASPIS ACULEIFER*, ON LILIES

I. Lesun¹, M. W. Sabelis¹ & C.G.M. Conijn², ¹ Section Population Biology, University of Amsterdam, Kruislaan 320, 1098 SM Amsterdam, The Netherlands, E-mail: lesna@bio.uva.nl; ² Bulb Research Centre, Vennestraat 22, Lisse, The Netherlands.

(1) Experiments in closed jars with lily bulbs showed that the predator, Hypoaspis aculeifer, can suppress populations of its prey, the bulb mite Rhizoglyphus robini, to very low levels. When the bulbs were decomposed into scales, the prey was suppressed earlier, supposedly because of increased accessibility to the sites where bulb mites reside. (2) Repeating the experiment in open jars also led to strong suppression of the prey population: the predators did not leave the jars until almost all prey was eaten. (3) To assess possibilities for biocontrol of bulb mites in lilies at a larger spatial scale, experiments were carried out in closed plastic bags filled with lily bulb scales and vermiculite, as is common practice in lily bulb propagation. The results showed that H. aculeifer was able to suppress its prey to very low densities, but probably due to a more complex spatial structure (i.e. vermiculite), prey suppression took longer. (4) Experiments in the greenhouse and in the field showed that in absence of predatory mites populations of the bulb mite, Rhizoglyphus robini, on lily bulbs increased, whereas the release of predatory mites either slowed down the increase – as observed in the field – or caused the bulb mite populations to decrease - as observed in the greenhouse. In all cases the population of predatory mites increased as long as bulb mite densities were not too low. (5) The initial predator-to-prey ratios required to achieve suppression (c. 1 : 2) or elimination (3:1) in the soil environment are much higher than those required for bulb mite elimination when lily bulb scales were embedded in a medium of vermiculite (c. 1 : 20). Possible causes will be discussed. (6) Since 1996 the predatory mite Hypoaspis aculeifer is commercially available under the trade name ENTOMITE.

Index terms: biological control, predator-prey interactions, spatial complexity, bulb mites, predatory mites, lily bulbs, soil

[1566] PARASITOIDS OF THE CITRUS LEAFMINER *PHYLLOCNISTIS CITRELLA* (LEP: GRACILLARIDAE) IN THE PIEDMONT OF THE DEPARTMENT OF META

G. A. León M. & J. C. Campos P., Centro de Investigación La Lebertad, CORPOICA, A.A. 3129 Villavicencio, Colombia. E-mail: gleon@corpoica.org.co

Studies about presence and abundance of native parasitoids of citrus leafminer *Phyllocnistis* citrella, was done during March 1997 to August 1998 in Acacias, Restrepo, Lejanias and Villavicencio, four citrus productive zones of eastern plains piedmont, located in the Department of Meta, Colombia. It was determinate the presence of nine different species parasitoids of larvae and pupae of citrus leafminer. Results show that most frequent parasitoids are *Cirrospilus* spp., *Closterocerus* sp. and *Galeopsomyia fausta*. (Hymenoptera: Pteromalidae), Each of them were found in all citrus areas in the Meta Department, specially in the localities of Acacías, Restrepo and Lejanias. There are tree new country records among the reported species: *Closterocerus* sp., *Horismenus* sp., and *Cirrospilus* spp. In addition to this fact, *Galeopsomyia fausta* is a pupae parasitoid and *Closterocerus* sp. a larval superparasitoid. The presence of this beneficial insects represent a high possibility of natural pest regulation and a great biological control potential to citrus leafminer in the region. Parasitoids were identified by Dr. Jhon LaSalle from International Institute of Entomology IIE Key words: Populational dynamics; citrus pest; pest-natural Institute – USA.

Key words: Phyllocnistis citrella. Natural control. Cítrus.

[1568] STRUCTURE OF A TROPICAL LEAFMINER-PARASITOID COMMUNITY

O.T. Lewis, Department of Entomology, The Natural History Museum, UK & NERC Centre for Population Biology, Imperial College at Silwood Park, Ascot, Berkshire SL5 7PY, UK. Email: o.lewis@ic.ac.uk.

Understanding the enormous diversity of tropical insects is one of the major challenges facing ecologists today. Quantitative food webs may provide insights into some of the dynamic processes underlying tropical diversity. In a quantitative host-parasitoid food web the abundance of hosts and parasitoids, and the magnitude of the trophic interactions among them, are all quantified in the same units. I describe a quantitative food web for generated by sampling systematically in a 0.85 ha plot over a 1-year period, and rearing over 5000 hosts and parasitoid for subsequent identification. The web contains 93 host species and 71 parasitoid species. Overall, 50% of leafminers were killed by parasitoids. There is little tendency for one or a few hosts or parasitoids to dominate the web, and most of the parasitoid species are generalists. Seasonal food webs indicate considerable variation in the composition of the community during the year, particularly among the hosts. Some of the factors influencing the parasitism fractions and parasitoid species load experienced by different host species about community interactions is highlighted.

Index terms: rainforest, food webs, biodiversity

Session 08 - ENTOMOPHAGOUS INSECTS AND BIOLOGICAL CONTROL

[1569] EFFECT OF THE FILARIAL PARASITE WUCHERERIA BANCROFTI (NEMATODA: FILARIDAE) ON THE REPRODUCTION OF CULEX QUINQUEFASCIATUS (DIPTERA:CULICIDAE)

C. A. Lima¹, <u>C. M. R. Alburguerque¹</u> & H. Hurd², ¹Mest.em Biologia Animal, Dept. de Zoologia, Univ. Federal de Pernambuco-Av. Moraes Rego s/n, Recife PE, CEP-50670 420, Brazil, E-mail cleide@npd.ufpe.br. ²Centre for Applied Entomology and Parasitology, School of Life Sciences, Huxley Building, Keele Univ., Staffordshire, STS 5BG, UK. Financial support:FACEPE, CNPq

Lymphatic filariasis is one of the most important human diseases transmitted by mosquitoes. Understanding of vector/parasite interactions is essential for rational development of filariasis control. A recent survey in Recife, a Brazilian coastal city has shown a prevalence rates of Wuchereria bancrofti ranging from 0.64 to 14.95% in several areas. This study was undertaken in order to determine whether the filarial parasite would interfere with the reproductive fitness of the mosquito Culex quinquefasciatus, vector of W. bancrofti in Recife. Mosquito, emerged from pupa collected in the field, were infected via a membrane feeding procedure, using blood from donors who participated in a survey carried out by Centro de Pesquisas Aggeu Magalhães, after written informed consent. Number of parasites in the blood ranged between 600-2900 mf/ml¹. Approximately 83% of engorged females (n=64) assessed after an infective blood meal were infected. A reduction of 32.4% in the number of positive insects was observed four days later. In three experiments, infected mosquitoes produced significantly fewer eggs (81.9 ± 21.5, n=127) than uninfected mosquitoes (96.11 ± 23.9, n=165) (Student's t test P<0.05). However, in 2 others experiments infected females produced significantly more eggs (96.8 ± 21.8, n= 52) than uninfected ones (84.1 ± 22.4) (Student's t test P<0.05). The mean size of females (measure by wing length) showed significant difference amongst different experiments ANOVA (F=29.3 P<0.05) but not when infected and uninfected females were compared via pairwise comparisons using Student t test. There was no significant difference (ANOVA) in the amount of haematin excreted by uninfected (14.9 \pm 1.9 mg, n=285) and infected mosquitoes (15.2 \pm 1.9, n=199). These results suggest that the effect of W. bancrofti infection on C. quinquefasciatus reproduction is variable.

Index terms: Culex quinquefasciatus, Wuchereria bancrofti, reproduction.

[1571] THE TYPES OF ENCYRTIDAE (HYMENOPTERA, CHALCIDOIDEA) HOUSED IN THE MUSEO DE LA PLATA

M. S. Loiácono¹, N. B. Dias¹, F. E. Gallardo¹ and C. B. Margaría¹, ¹Dept. Cient. de Entomologia, Univ. Nac. de La Plata, Passeo del Bosque s/n, 1900, La Plata, Argentina, Email: loiacono@museo.fcnym.unlp.edu.ar

According to De Santis (1998) the knowledge of this family has a singular importance for the number of species that it includes and because many of them have been used in the biological or integrated control against other insects and acari of economic or sanitary importance. The data of Grissell and Schauff (1990) indicate 3277 known species, 390 species of these are neartics and 236 neotropicals, distributed in 135 and 153 genera, respectively. For the Argentina there are 157 species, about 100 are studied in the revision of De Santis (1964) which would represent 4,7% of the known species. The study of types is fundamental to subsequent revisions and reliable identifications, mostly in this group of "Parasitica" in which so often new species of economic importance are described. This contribution gives information on the types of species described by De Santis principally, besides other authors. The 371 types (63 holotypes, 27 sintypes, 18 allotypes, 262 paratypes and one paralectotype) of Encyrtidae housed in Museo de La Plata (Departamento Científico de Entomologia) were examined and listed. These types belonging to 101 species and 2 subspecies of Encyrtinae. They were contributed by the following authors: De Santis (70), Erdoes (8), Annecke (6), Annecke & Mynhardt (5), Blanchard (3), Noyes (3), Brèthes (2), Bennet (1), Compere (1), Fidalgo (1), Gahan (1), Ghesquiere (1), Hoffer (1) Kerrich (1), Mercet (1). The genera and the species are in alphabetical order. For each taxon complete information about original and valid names, publication, subsequens combination, collection data and condition are given. Index terms: catalogue, entomological types, encyrtines, Museo de La Plata collection

[1570] NEOTROPICAL MYRMECOPHILIC DIAPRIID WASPS ASSOCIATED WITH MYRMICINAE AND FORMICINAE ANTS (HYMENOPTERA, PROCTOTRUPOIDEA, DIAPRIIDAE)

<u>M.S. Loiácono¹</u>, C.B. Margaría¹, E. Quirán² & B. Corró Molas², ¹Dept. Cient. de Entomología, Univ. Nac. de La Plata, Paseo del Bosque s/n, 1900, La Plata, Argentina, Email loiacono@museo.fcnym.unlp.edu.ar; ² Univ. Nac. de La Pampa, Uruguay 151, 6300, Santa Rosa, Argentina.

Representatives of three subfamilies of ants (Myrmicinae, Formicinae and Dorylinae) are the main hosts of myrmecophilic diapriine wasps (Diapriidae: Diapriinae). Within Myrmecinae, the genera known to be associated with diapriines are Solenopsis, Tetramorium, Acromyrmex and possibily Myrmica. Formicinae hosts include the genera Formica, Camponotus, Lasius and Plagiolepis. The main objectives of the present contribution are to study some diapriids associated with ants of the genera Acromyrmex. Solenopsis (Myrmicinae) and Camponotus (Formicinae) from Argentina, Brazil and Uruguay. The material studied belongs to the Canadian National Collection, Ottawa, Canada; Museo de La Plata, Buenos Aires, Argentina, and Fundación e Instituto Miguel Lillo de San Miguel de Tucumán, Argentina. The samples come from ant mounds of A. lobicornis and A. ambiguus. They are composed for more than 300 formicid mature larvae parasited by the diapriids. The larvae and pupae of the microhimenoptera were extracted and clarified for microscopic preparations; the adults of diapriids were studied following the usual techniques. Sixteen species of diapriids associated with the ants mentioned herein are treated. Two new species of Gymnopria and Trichopria are shown to be parasitoids of larvae of the ant Acromyrmex lobicornis in Argentina. Seven new species of Gymnopria from Brazil are described and illustrated; a redescription of the genus considering the new taxa is presented, and cladistic analyisis of the nine known species of Gymnopria are included. The diapriids of the genus Bruchopria associated with ants of the genus Solenopsis in Argentina and Brazil are also considered; an extended redescription of Bruchopria and its species are given; B. hexatoma distribution is amplified. Species of Bruchopria show a number a features correlated with myrmecophilous habits in diapriids, such as reduced eye size, integument similar to ants', and dealation. So, we consider that these species might behave as true mirmecophilous. The presence of tegula with normal development and wing stump demonstrate that the apterism has a secondary origin, caused by autotomy or by the host ants. Diapriids associated with the ant Camponotus rufipes are considered: Coecopria plaumanni, C. pygmaea, Doliopria flavipes and Paramesius sp. The two last species are mentioned for the first time associated with this ant. Ant's data and available host records are included.

Index terms: diapriids, myrmechophilous, Myrmicinae, Formicinae, ants

[1572] HOW THE EFFICIENCY OF A PREDATOR VARIES WITH RICE VARIETY: FORAGING BEHAVIOR, POPULATION INCREASE AND FUNCTIONAL RESPONSE + B201

Y. Lou, J. Cheng, M. Du & II. Guo, Dept. of Plant Protection, Zhejiang Univ., Hangzhou 310029, P. R. China

Many studies have revealed large differences among rice varieties in suitability for population increase of the brown planthopper (BPH), Nilaparvata lugens (Stal), one of main insect pests on rice. This paper addresses the question whether rice varieties that differ in suitability for BPH are equally suitable for *Cyrtorhimus lividipennis* Reuter, a main predator of BPH. We chose five varieties with different level resistance to BPH and investigated: 1) whether rice volatiles emitted from various varieties differ in attractiveness to the predator, 2) whether the population increase rate of the predator is affected by rice varieties, and 3) whether predators feeding BPH on different varieties differ in functional responses to BPH. The results showed that rice varieties could influence not only the searching behavior and population growth rate of the predator, but also functional responses of the predator to BPH. And in general, the stronger the attractiveness of volatiles emitted from one variety to the predator, the higher or stronger the population increase rate and functional response of the predator on this variety. However, these were not corresponding to the resistance of rice varieties to BPH. In conclusion, Our data demonstrate that the number and quality of the predator could be influenced by rice varieties. Applying rice varieties with characteristics enhancing the effectiveness of natural enemies may improve the control of insect pests.

Key words: rice varieties, Cyrtorhinus lividipennis, Nilaparvata lugens, tritrophic interactions

[1573] INTERACTIONS BETWEEN THE APHID PARASITOID PRAON VOLUCRE AND THE PREDATOR COCCINELLA SEPTEMPUCTATA

G. L. Lövei, D. Lola-Luz, Danish Institute of Agricultural Sciences, Department of Crop Protection, Research Centre Flakkebjerg, DK-4200 Slagelse, Denmark.

We studied the interactions between the aphid parasitoid, *Praon volucre* and the predator, *Coccinella septempuctata* in laboratory cages, enclosing wheat plants infested with the aphid *Sitobion avenae*. Behavioural observations showed that the two natural enemies did not interfere with each other: coccinellids consumed similar number of aphids in the presence or absence of parasitoids while parasitoids parasitised more aphids when a coccinellid larva was present. The effect natural enemies on aphid density was compared in three treatments: predators (coccinellid larvae) only, aphid parasitoids only and both natural enemies present. Aphid population growth was-11.3 % in the presence of *Praon volucre* and -0.3% with *Coccinella septempuctata*. In the combination treatment the growth rate of the aphids was -45.0%. These results suggested that coccinellid larvae did not impair the oviposition behaviour of the parasitoid. With 2 parasitoids, while ladybird larvae caused a decrease (-51.4%). The former was still significantly below the growth rate of the aphids wintout natural enemies (control). The data suggested that there was no intra-guild predation effect, direct or indirect, in this experimental system but a synergistic interaction seemed to operate.

Keywords: Biological control, intra-guild predation, parasitoids, predators, aphids

[1575] COMPARISON AND DEVELOPMENT OF ARTIFICIAL DIETS FOR BRACON HEBETOR (HYMENOPTERA: BRACONIDAE) REARING

<u>S.R. Magro</u>¹ & J.R.P. Parra¹, ¹Dep. Entomologia, Fitopatologia e Zoologia Agrícola, ESALQ-USP, 13418-900, Piracicaba-SP, Brasil, E-mail srmagro@carpa.ciagri.usp.br

Bracon hebetor Say is a larval ectoparasitoid of several lepidopteran pests attacking stored grains and is considered an efficient biological control agent. The biological aspects of *B. hebetor* were evaluated in the natural host rearing, *Anagasta kuehniella* (Zeller) (selected as the most suitable for the species among six other lepidopterans) and compared to those found in seven artificial media prepared for *Trichogramma* spp. One of the artificial diets (60% pupal holotissues of *Diatraea saccharalis* (Fabricius); 12% fetal bovine serum, 12% lactalbumin hydrolysate, 16% egg yolk) was considerably similar to the natural host, for the lenght of the cycle (egg-adult) was the same and the adults promptly paralyzed and parasitized the larvae, although at a lower rate than that presented by for those reared on *A. kuehniella*. The longevity of females reared *in vitro* was statistically similar to that found when reared was on *A. kuehniella*; however, approximately 60% of the larvae developed on the diets failed to spin the protective cocoons during the pupal stage. No morphological differences was verified in the salivary glands of the insects producing or not silk, and this deficiency is probably due to the chemical differences of the glands.

Index terms: Biological control, in vitro rearing, ectoparasitoid, cocoon spinning,

[1574] STUDIES ON THE KAIROMONE INFLUENCING PARASITE OF TRICHOGRAMMA OSTRINIAE ON ARTIFICIAL EGGS

C. Luo & Zhili Zhang, Inst. of Plant and Environmental Protection Beijing Acad. of Agric. and Forestry Sciences Beijing 100089, China

The materials located in the anal tuft of the female moth Ostrinia furnacalis can be nhexane extracted. The extracts greatly influenced the host-searching and oviposition behavior of *Trichogramma ostriniae*. If they were applied to artificial eggs, the time of the detaining will be lengthened, and the parasite efficiency will be improved. Index words: Ostrinia furnacalis, Extracts, Host-searching, Oviposition [1576] INFLUENCE OF TEMPERATURE ON THE WEIGHT OF LARVAE AND ADULTS OF CIIRYSOPERLA EXTERNA (NEUROPTERA: CHRYSOPIDAE) FED ON SCHIZAPHIS GRAMINUM (HEMIPTERA: APHIDIDAE)

W. J. M. S. Maia¹, C. F. Carvalho¹, B. Souza¹, L. P. M. Macedo¹, M. M. Goussain Jr¹, ¹Dept⁰ de Entomologia, Univ. Federal de Lavras, Caixa Postal 37, Lavras-MG, 37.200-000, Brasil, E-mail: wjmsmaia@ufla

Chrysopids are insects naturally occurring in several agroecosystems contributing for the biological control of pest insects. Nevertheless, the knowledge of the biology of those insects and their interactions with the abiotic factors to reach success in the mass production arming to support applied biological control programs, has become necessary. Among those factors, temperature which influences both directly affecting its development and its comportment and indirectly affecting its feeding. This work was designed to study the indirect influence of temperature on the weight of *Chrysoperla externa* larvae and adults fed on aphid *Schizaphis graminum*. The works were developed in the Insect Biology Laboratory of the UFLA Entomology Department in climat chambers at 15, 21, 24, 27 and 30 °C, RH of 70 \pm 10 % and 12-hour photophase. Average weights in all larval instars, stages of prepupa and pupa 48 hours later and of adults freshly-emerged before the meconium release, were evaluated. Considering the existence of a direct relationship between temperature and insects' developmental velocity, the weight of 1st, 2^{md} and 3rd instars larvae of *C. externa* with the temperature of 21 to 30 °C, differed from the larvae's weight kept at 15 °C, but there were no differences among the weights when compared with the total larval stage and weight of freshly-emerged adults.

Index terms: green lacewing, predator, development, abiotic factors, aphid.

[1577] COMPOSITION AND EFFICIENCY OF A YEAST FREE LARVAL DIET FOR THE MEDITERRANEAN FRUIT FLY

A. G. Manoukas & E. N. Zografou, Institute of Biology, NCSR "Demokritoos", Aghia Pareaskevi 15310 Attiki, GREECE

The larval diets, used today, for research, production and release of the mediterranean fruit fly Ceratitis capitata Wied. contain yeast. Yeast is expensive, variable in composition, has a short shelf life and it is not produced in many countries. This presentation reports the nutritional composition and the biological efficiency of a practical yeast free larval diet (YF) for rearing the mediterranean fruit fly. The results were compared with those of a yeast containing diet, which is widely used for rearing this fly. The YF diet was made up of low cost ingredients supplemented with amino acids, salts and vitamins and the control of brewers yeast, sugar and wheat bran. The control and YF diet contained, based on proximate analysis 57.4 and 65.3 moisture, 8 and 6.7 protein, 0.8 and 0.9 lipids, 1.7 and 3.5 ash, 4.5 and 4.3 fiber and 27.5 and 23.7 nitrogen free extract (by difference from 100), respectively. The YF diet was tested with eggs obtained from flies of white pupa strain (IAEA, Austria) for three generations and from wild flies (Attiki, Greece) for seven generations. 25 eggs/g.diet were placed in all treatments. Records were kept on hatched eggs, number of pupae, pupal weight and adult emergence. YF diet gave 18, 16 and 17.1 pupae per gram diet compared to 10.3, 7.3 and 13.2 of the control for the first, second and third generation, respectively. All other biological parameters were satisfactory and did not differ significantly between the two diets. Similar were the results with eggs from wild flies. It was calculated that overall dietary efficiency of YF diet was at least 50% higher than the control. The results will be discussed with reference to nutritional ecology of this fly.

Index terms: Ceratitis capitata, insect nutrition, rearing.

[1579] PARASITISM AND PERSISTENCE IN THE FIELD OF ENTOMOPATIIOGENIC NEMATODES AND OTHER NATURAL ENEMIES OF THE LARVAE *DIAPREPES ABBREVIATUS* (COLEOPTERA: CURCULIONIDAE)

C. W. McCor¹, D. L. Shapiro² & L. W. Duncan¹, ¹ Dept. of Entomology, Univ. of Fla., Citrus Res. and Ed. Ctr., 700 Experiment Sta. Rd., Lk. Alfred, FL 33850, USA, E-mail cwmy@lal.ufl.edu; ²USDA-ARS SE Fruit and Tree Nut Res. Lab., Byron, GA 31008.

Parasitism and persistence of three species of entomopathogenic nematodes, Steinernema riobrave Cabanillas, Poinar and Raulston, Heterorhabditis bacteriophora Poinar, and Heterorhabditis indica Poinar, Karunakar and David were evaluated as biopesticides against larvae of Diaprepes abbreviatus L. in a mature citrus grove using different soil In three separate tests, commercial formulations of different sampling methods. nematodes were applied with herbicide delivery equipment at rates from 11 to 216 IJ's/cm2 to the soil beneath the tree. The prevalence of parasitism and/or predation by either commercially-applied nematodes or indigenous natural enemies associated with weevil larvae in the soil was also measured using larvae-baited screened cages placed in the soil before and after nematode application. Ant predation and nematode parasitism were the dominant mortality factors of caged, 6th instar D. abbreviatus during 7 days exposure to field soil. Entomopathogenic fungi and bacteria were incidental. Inoculative applications of different rates of entomopathogenic nematodes showed a positive quadratic relationship between number of nematodes applied per given area (log scale) and parasitism of caged larvae. Higher rates (>54 IJ's/cm²) were required to achieve levels of parasitism significantly greater than that in the controls. Nematode parasitism of D. abbreviatus larvae was similar in caged versus no cage comparisons conducted in the greenhouse. Nematode numbers in the soil declined over time, reaching pretreatment levels at 14 days post-treatment based on a modified Baermann sampling procedure. The use of larvae-baited soil cages as indicators of nematode efficacy in the field is discussed. The feasibility of inoculative applications of nematodes at a time when natural control by indigenous nematodes is high is also addressed.

Keywords: ant predation; biological control; Heterorhabditis; Steinernema

[1578] PERSPECTIVES IN THE BIOLOGICAL CONTROL OF *NEMATUS* OLIGOSPILUS FOERSTER (HYMENOPTERA; TENTHREDINIDAE) PEST OF WILLOWS IN ARGENTINA AND CHILE

Alderete Mariela & <u>Fidalzo Patricio</u>, INSUE, CONICET, prOIMI, Miguel Lillo N° 205. C.P. 4000. Tucumán. Argentina, e- mail: amariela@infovia.com.ar.

Nematus oligospilus Foerster (=N. desantisi Smith) is a sawfly of holartic origin where has wide distribution. It was accidentaly introduced in Argentina and Chile in the 80's, in South Africa in 1993 and more recently in New Zeland in 1997. The larva eats the leaves of Salix spp. In the holartic region the single known host of N. oligospilus is S. lasiolepis which distribution is limited to the west of North America and Mexico. In the introduced areas presents periodical outbreaks causing up to 100% of defolations in willows trees. At the Delta of Paraná in Argentina, where 50.000 has of willows are cultivated, this sawfly produces lost of 60% in wood commercial production. In Arizona, where its populations were observed during more than 10 years, it has been uncommon and never visibly damaged its host plant, suggesting that it maintains stable in low density populations. The character of nonoutbreaking species in its home range could be the result of control agents that regulate its populations. Little information is available about the natural enemies of N. oligospilus in holartic region: Ctenochira frigida (Ichneumonidae: Tryphoninae), larval parasitoid, and an unidentified parasitoid of eggs. Both are the single parasitoids registered in the litterature. In Argentina, Chile and South Africa several parasitoids were recorded attacking the sawfly but the level of parasitism ranged from 0,1 to 0.8 % during high and low density populations. The typical parasitoid complex of nematine is composed mainly by monophagous and oligophagous Ichneumonids of the subfamilies Tryphoninae, Ctenopelmatinae and Campopleginae. While in the introduced areas the parasitoid complex is composed of poliphagous chalcidoids. Because of the wide distribution of this sawfly in the northern hemisphere and there is no information about the place of origin of the introduced strain in this region, we recommend to look for parasitoids in the range of distribution of S. lasiolepis and to introduce species of the Tryphoninae subfamily that are oligophagous. These control agents will act in Argentina and Chile as "monophagous" because N. oligospilus is the single present nematine in these countries.

Index terms: Nematus oligospilus, oligophagous, Triphoninae, Salix lasiolepis.

[1580] CLASSICAL BIOLOGICAL CONTROL OF SOLANUM VIARUM (SOLANACEAE) IN THE USA

J.C. Medal¹, D.Gandolfo², R.A. Pitelli³, A. Santana³, D.Ohashi⁴, J.P. Cuda¹, ¹University of Florida-Department of Entomology & Nematology, Gainesville, FL.32605 USA;² USDA-South-American Biological Control laboratory, Hurlingham, Buenos Aires Province, Argentina; ³Universidade Estadual Paulista, Jaboticabal campus, Sao Paulo state, Brasil; ⁴Inta-Agricultural Experiment Station, Cerro Azul, Misiones, Argentina.

Solanum viarum (Solanaceae) is a perennial weed, native to southern Brazil, north-east Argentina, Paraguay and Uruguay that has been spreading in the United States at an alarming rate during the 1990s. *S. viarum* was first reported in the middle 1980s in Florida, and is currently present in Alabama, Georgia, Louisiana, Mississippi, North Carolina, Pennsylvania, South Carolina, Tennessee, and Puerto Rico. The rapid spread in the USA can be partially attributed to the great reproductive potential (40,000 to 50,000 seeds per plant), highly effective seed dispersal by cattle and wild life, such as deer, feral hogs, raccoons and birds that feed on the fruits. Control of S. viarum in pasture lands are based on herbicide applications and mechanical (mowing) practices. These control methods only provide a temporary weed suppression that in addition of being expensive, are not always practical in rough terrain or inaccessible areas. Initial explorations in Brazil and Paraguay searching for potential biocontrol agents were started in June 1994 by Medal (Univ. of Fl.) in collaboration with Pitelli and Santana (Universidade Estadual Brazil). Initial surveys revealed several potential candidates Pualista, Jaboticabal, including two chrysomelid beetles (Metriona elatior and Gratiana boliviana). Screening tests have been conducted since December 1996. Further plant surveys in South America in collaboration with Gandolfo (USDA-South-American Biocontrol Laboratory, Argentina) have revealed a weevil that feeds on S. viarum bud-flowers (Authononus terebrosus) whose screening tests will be initiated soon. Host-range specificity tests, field surveys in South-America (Argentina, Brazil, Paraguay, Uruguay), and the lack of unfavorable host records in the scientific literature provide strong evidence that M. elatior and G. boliviana are safe for biocontrol of S. viarum Approval of the petition to release M. elatior in Florida is pending, and the request to release G. boliviana will be submitted to the Technical Advisory Group for Biological Control of Weeds (TAG) in April 2000. Weed Biocontrol, Metriona elatior, Gratiana boliviana, Anthonomus Index terms: tenebrosus

[1581] CONTROL OF THE SOUTH AMERICAN TOMATO PINWORM IN GLASSHOUSE WITH T. PRETIOSUM: BIOLOGICAL AND ECONOMICAL EFFICIENCY

M. A. Medeiros, F. H. França & N. J. Vilela, Embrapa Hortaliças, Caixa Postal 218, 70.359-970. Brasília, D.F. Brazil, E-mail: malice@cnph.embrapa.br.

The economic and biological efficiency of controlling the South American Tomato Pinworm through inundative releases of *Trichogramma pretiosum* on tomato plants cultivated in glasshouse was evaluated at farm level. The experiment was conducted in Luziania County, Goiás, Brazil during the summer of 1999/2000 in two glasshouses, each submitted to the following pest control regimes: (1) commom farmer practice: pesticides sprayed weekly on a rotation basis (OP; PY; Bt; abamectin; imidacloprid) (2) inundative release of T. pretiosum associated with weekly sprays of Bacillus thuringiensis. Insecticide sprays and parasitoid mass release were initiated soon after the first catch of moths. Mass release consisted of 2 cards/week (20x30 cm) that were gradually increased until reaching 6 cards/week at the end of the harvest of tomato crop. Pest control efficiency was determined through the number of eggs, mines and larvae from 50 leaflets colected from 50 plants chosen at random. Collected eggs were stored in gelatin capsules and kept in BOD chambers at a 25 ± 2° C, 70% RH and 14 hours photophase until the emergence of either larvae or parasitoid. Tomato productivity and percent fruit damage was determined for both systems tested. The cost of production for both systems were the same except for the fact that in the biological control system was included the mass rearing production costs of T. pretiosum. The results show that pest control efficiency in both systems were similar. Egg parasitism level was as high as 33%. Tomato production in the glasshouse submitted to chemical control was lower than that in the biological control system. Tomato fruit damage averaged about 4% and 8%, respectively. The economic analysis revealed that tomato produced in the biological system provided a better income to the farmer.

Index terms: Trichogramma pretiosum, Tuta absoluta, biological control, economic analysis.

[1582] BIOLOGICAL ASPECTS OF *PODISUS NIGRISPINUS* (HETEROPTERA: PENTATOMIDAE) BEING AS PREY SPODOPTERA FRUGIPERDA (LEPIDOPTERA: NOCTUIDAE)

S.S.A. Medeiros¹, <u>M.G.A. Lima²</u> & J.A. Mezzomo¹, ¹Laboratory of Biological Control, Dept. of Pharmacy and Biology, Paraíba State Univ., Félix Araújo Square, 13B, 58101-450, Campina Grande, PB, Brazil, E-mail jamezzo@zaz.com.br; ²Dept. of Biology, Ceará State Univ., P.O. Box 1531, 60740-020, Fortaleza, CE, Brazil, E-mail goretti@uece.br

The fall armyworm, Spodoptera frugiperda, is the principal pest of corn culture in Brazil, causing great economic losses when not controled. For its control are used principally chemical products, which are hazardous to humans and the environment. So, alternative controls should be sought that don't offer risks to the environment, like the usage of predators. The objective of this research was to assess some biological aspects of the predator Podisus nigrispinus having as prey the fall armyworm. The study was done under a temperature of 25 ± 2° C, relative humidity of 60 ± 10% and photophase of 12 hours. Were used 30 nymphs of the 2nd instar, individualized in plastic cups, offering water and a larvae of the 2nd, 3rd, 4th and 5th instar every 24 hours, being these denominated, respectively, diets I, II, III and IV. The duration and viability of each instar were assessed, and in the adults the weight, sex ratio, number of eggs and layings. The results were submitted to analysis of variance and the averages compared to the test of Tukey at the level of 1% of probability. Only the duration of the 2nd instar didn't differ significantly with the increase in the size of the prey. The 3rd, 4th and 5th instars presented a significant increase in the duration, principally when they preyed on the 2nd instar. The duration of the nymph phase was inversely proportional to the size of the prey, while the survival of each instar was greater when larger prey were offered. The heaviest adults were those originated from nymphs fed on larger prey. In all the diets tested, except the diet I, a sex ratio near 0,50 was seen, or one female for each male. As to the reproductive characteristics, the females originated from nymphs fed on diet III presented the largest number of layings and largest number of eggs. It was concluded that the duration of the nymph phase, of each instar and the weight of the adult of P. nigrispinus depended on the size of the prey. The number of adults of the predator increased when the nymphs were fed with larger prey. Therefore, S. frugiperda showed itself to be an adequate prey for the development of P. nigrispinus.

Index terms: Insecta, predator, biology, fall armyworm.

Symposium and Poster Session

[1583] THE COCCINELLID BEETLE, OENOPIA CONGLOBATA, AN IMPORTANT PREDATOR OF THE COMMON PISTACHIO PSYLLA

M.R. Mehrneiad, Pistachio Research Institute, P. O. Box 77175.435, Rafsanjan, Iran.

The common pistachio psylla, Agonoscena pistaciae, is considered as the major pistachio pest in Iran. Several species of parasitoids and predators attack the common pistachio psylla in the pistachio growing areas of the country. The wide investigation are managed to organise an IPM programme to control of this pest. The predatory beetle, Oenopia conglobata is an important natural enemy of A. pistaciae, in the main pistachio plantation areas of the country (Kerman province). The adult beetles overwinter under the stem's bark of the hedge trees (e.g. Elaeagnus angustifolia) in the pistachio orchards. Although O. conglobata was known as the aphids predator, this beetle attacks A. pistaciae from early spring to late summer. The larvae and adults of this species feed upon psyllid eggs and nymphs as well as psyllid honeydew. Development and fecundity of O. conglobata was growing in the controlled condition $(27\pm0.5^{\circ}C, 55\pm5\%$ r.h. and 16L:8D) on fourth stage psyllids in the four larval instars, and the larval development completed in 9.44 days. Developmental period from egg to adult lasted 18.44 days and the male coccinellid emerged about one day early. The female ladybird laid 245 eggs during the first 15 days of her life span, moreover, she consumed 165 (on average) fourth stage psyllids per day.

[1584] A LABORATORY SELECTION EXPERIMENT: EVOLUTION OF DROSOPHILA MELANOGASTER UNDER THE ATTACK OF THE PUPAL PARASITOID PACHYCREPOIDEUS VINDEMIAE

M. de S. Mendonca Jr.¹, A. R. Kraaijeveld¹ & H.C.J. Godfray¹, ¹ Centre for Population Biology & Dept. of Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, UK. E-mail: m.mendoncajr@ic.ac.uk

Laboratory selection experiments using natural enemies can reveal aspects of ecological interactions from an evolutionary perspective, providing insights into the evolution of these interactions in the field. Replicate D. melanogaster populations were exposed to P. vindemiae attack for 12 generations. We expected parasitoid selection to result in resistance: shorter pupal development times or thicker puparium. Flies were cultured in standard medium, with 3rd instar larvae taken to banana slices. These were placed in cages, where parasitoids were released for selected lines, but not for controls. Surviving flies were used to breed the next generation. After the end of selection, flies were assayed in optimal conditions for life history traits comparing control and selected lines. Parasitism was highly variable, but averaged at 40% for all lines. Time to emergence of the flies during aelection showed that selected lines had significantly shorter development times than controls. This reflects a parasitisation pattern: as the faster developing flics emerge and escape parasitism, the smaller number of remaining pupae face attack by the same number of female parasitoids, increasing parasitism rate. Despite being variable, parasitism decreased significantly towards the end of the selection procedure, indicating a possible adaptation to parasitoid attack. The assays revealed that development time did not change genotypically. The proposed explanation is that the emergence pattern under a light-dark cycle (most flies emerge in the morning) interferes with the phenotypic expression of development time (selection for shorter development time in D. melanogaster is only successful under constant light conditions). A selection syndrome of evolving traits was detected: selected flies had faster feeding rates, attaining larger sizes as adults, and higher pupal viability; they had lower larval viability and a lower early fecundity for the females. No difference in puparium thickness was found, but it seems that selection involved this trait somehow since it is correlated with puparium size: lárger puparia are also thicker in absolute terms. Fecundity and body size are usually correlated in life history studies but not in this case, fecundity representing the cost to resistance. This work highlights the importance of a) correlations between life history traits in the evolution of defense against natural enemies and b) environmental conditions acting as constraints on the evolution of these traits.

Index terms: life history, body size, development time.

[1585] EFFECTS OF LARVAL DENSITY AND PREDATION BY TOXORHYNCHITES AMBOINENSIS (DIPTERA; CULICIDAE) UPON AEDES POLYNESIENSIS PRODUCTION

D. R. Mercer^{1,2}, G. R. Wettach³ & J. L. Smith³, ¹Inst. Territorial de Recherches Médicales Louis Malardé, B. P. 30, Papeete, Tahiti, French Polynesia, ²Dept. of Biology, Univ. Northern Iowa, Cedar Falls, IA 50614-0421 USA (current address), ³Gump Biological Research Station, Univ. California, Berkeley, B. P. 244, Temae, French Polynesia.

Biological control agents of disease vectors should reduce numbers of host-seeking adults without providing fitness benefits to survivors developing among fewer competitors with increased per capita resources. Survival in nature and vector efficiency of Aedes polynesiensis for human Bancroftian filariasis may be greater for larger female adults. Therefore, biological control agents that produce fewer but larger vectors may actually increase rates of disease transmission. We investigated the effects of predation by Toxorhynchites amboinensis upon the production of Ae. polynesiensis adults at three larval density of Ae. polynesiensis in rat-chewed coconuts, a prominent larval developmental site thoughout French Polynesia. The presence of predators significantly reduced the survival rates of Ae. polynesiensis and the numbers of both males and females produced from coconuts compared with cohorts of comparable initial densities reared in coconuts without predators. Adults from larval cohorts exposed to predators emerged at the same time and were equal in size to adults emerging from predator-free cohorts. No differences were detected in the numbers or sizes Ae. polynesiensis reaching adulthood among the larval densities tested. Therefore, at least for this common natural habitat, Tx. amboinensis provided a good level of biological control of the vector Ae. polynesiensis.

[1586] FIRST APPROACH ON THE POTENTIAL ROLE OF SEVERAL SPECIES (NEUROPTERA: CHHRYSOPIDAE), AS NATURAL CONTROL AGENT IN PORTUGUESE GREENHOUSES

A. Mexia; C. Couto; <u>P. Passos</u>, Secção Autónoma de Protecção Integrada, DPPF, Instituto Superior de Agronomia, Tapada da Ajuda, 1349-017, Lisboa - Portugal.

Several species are among the native polyphagous predators of the entomofauna in Portugal. Although 28 species have been observed in Portugal, here is a big lack of information related with their potential use as pest control agents. In Portugal, the more relevant data concerning Chrysopids are, most of them, if not all, based on *Chrysopida carnea* (Stephens) ignoring the real significance of all other species, some of them very common. In this work the most common species are listed and its relative importance is discussed, specifically in protected crops in the Oeste region, based either in Ammonium dihydrogen phosphate and protein traps, or on yellow sticky traps, used isolated in some experimental plots or combined, in other plots.

Key words: (Neuroptera: Chrysopidae), Chrysoperla carnea, natural limitation, greenhouse crops

[1587] BIOLOGICAL CONTROL OF THE PINK HIBISCUS MEALYBUG, MACONELLICOCCUS HIRSUTUS (GREEN), IN THE CARIBBEAN

D. E. Meverdirk, US Department of Agriculture, Animal and Plant Health Inspection Service, Plant Protection and Quarantine, National Biological Control Institute, 4700 River Rd. Unit 135, Riverdale, MD 20737, USA.

The pink hibiscus mealybug (PHM), Maconellicoccus hirsutus (Green), was first found in the Western Hemisphere in Grenada in 1994, and has now expanded its geographical distribution to over 25 Caribbean Islands, Guyana in South America and most recently to Southern California in August and in Belize, Central America in September of 1999. It was first found in St. Kitts and Trinidad and Tobago in 1996, US Virgin Islands by May of 1997, in Vieques and Culebra by June and December of 1997 respectively, and on the mainland of Puerto Rico by April of 1998. PHM attacks over 200 host plant species in more then 74 plant families, but most common on hibiscus and sour sop (Annona muricata) in the Caribbean. It has been observed to commonly kill hibiscus plants and closely related species and even some forest trees (Samanea saman). Estimated economic losses have been reported to be as high as \$3.5 million/year in Grenada, \$18 million/year in Trinidad and Tobago, and projected to be \$750 million/year in the United States if no control efforts are made once it spreads to all the southern States. Two species of exotic parasites, Anagyrus kamali originally from China and Gyranusoidea indica from Egypt were initially released in St. Kitts in August of 1996. By April of 1998, the parasites had reduced the PHM population density on hibiscus in St. Kitts by 94%. In the US Virgin Islands, PHM densities were reduced by 90% in St. Thomas and 94% in St. Croix within a period from July 1997 to February 1999. In Puerto Rico, PHM densities have been reduced by 93.8% on the mainland from May 1998 to May 1999; 84.3% in Vieques during this same period; and 96.4% in Culebra from January 1998 to May 1999. Parasitization has reached as high as 54.4%. Both parasites have a life cycle producing two generations for every one generation of the mealybug. The PHM has spread halfway across Puerto Rico from east to west much slower then anticipated, because of the impact of the parasites. A total of 80% of the new mealybug infested locations are also being found accompanied by the exotic parasite species, which appear to be moving with this mealybug. Anagyrus kamali, which is the dominate parasite, has been reported moving up to three miles from initial release points. PHM is under complete biological control in St. Kitts, and it is believed that the US Virgin Islands and Puerto Rico will have equal success.

Index terms: Anagyrus kamali, Gyranusoidea indica, parasites

[1588] ARTIFICIAL DIET FOR *DIABROTICA SPECIOSA* (COLEOPTERA; CHRYSOMELIDAE) REARING

J. M. Milanez¹, C. J. Ávila² & J. R. P. Parra³, ¹Centro de Pesquisas para Pequenas Propriedades - Epagri, 89801-970, Chapecó-SC, Brasil, E-mail milanez@epagri.rct-sc.br; Embrapa/CPAO, Caixa Postal 661, 79804-970, Dourados-MS, Brasil; ³Dep. Entomol., Fitop. e Zool. Agrícola, ESALQ-USP, 13418-900, Piracicaba-SP, Brasil.

The aim of the research was to develop an artificial diet for D. speciosa rearing, since no records on artificial media are available for the species. The development of the insect was evaluated through four diets containing the following protein sources: 1) beans and yeast; 2) corn flour, wheat germ and yeast; 3) wheat germ and casein; and 4) identical to 3 plus cellulose. The insect was also reared in a natural diet (corn seedlings), which was the standard treatment. Each treatment consisted of 150 insects maintained in glass or plastic containers, respectively, for the artificial and the natural diets, and the rearing was kept at 25°C, RH 60 ± 10% and 14-hour photophase. The only artificial diet in which the development of D. speciosa occurred was that based on wheat germ and casein containing cellulose, which provided a 34-day larva-adult period, approximately 14% higher in comparison with the standard treatment (natural diet). Since the number of instars was constant and equal to three in both environments, there is an indication of nutritional diets adequacy of the artificial diet, although the viability at the larva-adult period was lower in that medium. The rhythm of egg-laying and longevity were similar in both diets, although the number of egg-laying and eggs/female was higher in the natural dict. Morphologically, the insects were similar in both diets, however, the adults achieved under artificial diet showed paler coloration. Diet adjustments regarding cellulose amount and change of pupation site allowed the viability increase of the larva-adult period (56%) and insect fecundity (1367 eggs/females), even though these figures were even lower regarding the natural diet. With small changes in the physical characteristics of diets and containers, besides the adaptation of the insect after a few generations in laboratory, one believes that this diet is quite promising for D. speciosa rearing. Index terms: corn rootworm, rearing technique, biology

[1589] MASSPRODUCTION OF THE EGG PARASITOID, TELENOMUS PODISI, ON THE PENTATOMID, EUSCHISTUS HEROS, FOR BIOLOGICAL CONTROL OF PENTATOMID PESTS ON SOYBEAN IN BOLIVIA

E. Miranda¹ & O. Mochida¹ ¹CETABOL, Casilla 555, Santa Cruz, Bolivia: cetabol@daitec.scz.com.

Piezodorus guildinii, Euschistus heros, Edessa meditabunda, & Dichelop furcatus (Het., Pentatomidae) are major pests on soybean. Some egg parasitoids were observed on such Pentatomids; Telenomus podisi (Scelionidae), Trissolcus spp. (ditto) & Ooencyrtus submetallicus (Encyrtidae). Massproduction of T. podisi has been attempted on E. heros eggs since 1998. Rearing of the host: For 45 days, about 600 adults (d: 2=about 1:1) were kept for oviposition in each 60x60x120cm (in WxLxH) screen cage with 8 soybean plants potted together with soybean & peanut seeds as feeds at room temperatures of 25-35 with 14L:10D illumination. Six pieces of cloths, 3cm wide x 120cm long, were kept in the cage for oviposition. Eggs were removed from the pieces of cloths every 2 days & separated into 2 groups, one for repeating host generations & the other for parasitoid massproduction. Eggs were kept in Petri-dishes (10x2cm) for 3 days, transferred to larger ones (12X10cm) with soybean pods & kept for 4 days to hatch out. About 20 1st-instars were kept in each 300ml plastic cup containing soybean & peanut seeds together with a wet cotton pillar for 3 wks to grow to adults. Rearing of the parasitoid: Host eggs were kept at -1960 for 7 mins & stored at -120 for 3 mos. About 500 Pentatomid eggs were fixed on a piece of paper with glue & kept in a 500ml plastic bottle with 300-400 parasitoid adults (d:9=about 1:4) for 7 days. About 60-70% host eggs were parasitized. Parasitoid adults emerged from host eggs at 25-35 after 12-14 days; one wasp/host egg. Cost for breeding 10,000 wasps to suppress Pentatomids on soybean /ha: Two labourers were hired with US\$140 & 100/ mo, respectively. A total of 52,293 Pentatomid eggs was produced for about 45 days, whereas that of 35,438 (=52,293 eggs x 67.8% parasitism) parasitized eggs was obtained for 19-21 days. The Pentatomid took about 30 days to grow from egg to adult. These 3 processes were operated simultaneously. Production cost for 10,000 wasps to be released /ha/once was estimated at US\$41.67 without consid- eration of investments in facilities, when US\$1.00 was equivalent to 6.04B\$.

[1590] BIOLOGICAL CONTROL OF THE NANTUCKET PINE TIP MOTH (RHYACIONIA FRUSTRANA), A PEST OF THE GENUS PINUS

<u>P. A. Mojena</u>¹ & Ing. A. F. Vera², Pinar del Río University, Cuba. ² Research. Forest Experimental, Station Viñales. Pinar del Río, Cuba.

This paper describes the results obtained by employing the biopreparado Metarrhyzium anisopliae Metch (Sorokin), sublethal doses of Dipterex 80 % PH and

the predator Trichogramma pintoi as an important technique for controlling Rhyacionia frustrana (Comstock) in young plantations of Pinus caribaea Morelet Pinardel Río, Cuba. The results were obtained by comparing field applications of the biological product, the insecticidal chemical and the mixture of the predator with sublethal doses of the insecticide. The results of this first trial show that populations of Rhyacionia frustrana were reduced in the areas discussed down to minimal levels of infestation using a mixture of T. pintoi and sublethal doses of the insecticide , while the control plots using the biopreparado or the insecticide alone expressed a higher incidence of the pest. Statistic analysis (ANOVA) of the levels of infestation by the pest in treated areas, compared with controls (technical efficiency) proved that both the percentage of outbreaks and buds damaged by the pest were reduced to levels close to zero percent in the areas discussed when using the predator Trichogramma pintoi . Observing the stage of development of the pest enables us to plan the timing of the releases of the biological control agent with greater efficiency and economy.

Index terms: Pine Tip Moth, Rhyacionoa, control, Biological

[1591] DIVERSITY AND COMMUNITY STRUCTURE OF PARASITOIDS ASSOCIATED WITH ENTOMOGENOUS GALLS IN BRAZIL

F. Monteiro & M.A.P. Azevedo, Lab. Ecologia de Insetos: Depto Ecologia/IB/UFRJ CP68020 - CEP21941-590 Rio de Janeiro, Brazil / E-mail: monteiro@biologia.ufri.br

Parasitoids are one of the most important groups of insects. Due to the scarcity of studies, especially in the neotropical region, litlle is known about their diversity and importance. In this work we described some aspects of the parasitoid community associated with entomogenous galls. This study was carried out at two small areas, one at restinga (coastal scrub vegetation) and the other at Atlantic Forest, both near Rio de Janeiro city. A total of 15 plant species harbouring 55 galls were sampled. The overall parasitoid species richness obtained was about 120 species. The average number of parasitoid species per gall was 3, but there was a high variance as at least three gall types had over 20 species associated to each of them. Most gall types had a very high parasitism rate, sometimes making it difficult to find out the real gall inducer. Differently from other biogeographical regions, Eulophidae was by far the most common and diverse group of parasitoid wasps. In both ecosystems the percentage of Eulophidae species was about 46%, the second most important group being Eurytomidae, with 17% of the species. Although most parasitoid species were found in a single host gall type, one should be careful about concluding that they are specialist parasitoids, as there should be unsampled host galls in both areas. Finally, this study shows how complex the guilds studied are in the neotropical region; both parasitoids and gall makers presented a high richness of species, about 80% of which unknown in the literature.

Index terms: Insect galls, community structure, species richness.

[1592] OCCURRENCE OF BACULOVIRUS AND HEXAMERMIS SP. (NEMATODA, MERMITHIDAE) IN LONOMIA OBLIQUA (LEPIDOPTERA, SATURNIIDAE)

R.II.P.Moraes¹, <u>E. Berti-Filho</u>² & J.L.Wolff³, ¹Laboratório de Parasitologia - Instituto Butantan São Paulo, Brasil, rhenrique@uol.com.br;2Depto de Entomologia, Fitopatologia e Zoologia Agrícola - ESALQ/USP. Caixa postal 9, 13418.900, Piracicaba, SP.; ebert@carpa.ciagri.usp.br; 3Núcleo Integrado de Biotecnologia. Universidade de Mogi das Cruzes, SP. Brasil, jwolff@uol.com.br. Financial support: CNPq

The contact of setae of Lonomia obliqua caterpillars with the human skin may result in severe acquired haemorrhagic disorders. Accidents with this saturniid, have been quite frequent in the South and Southeast Brazil since 1989. The only effective treatment to revert the haemorrhagic process, is the application of the specific serum "Antilonomico", produced by the Institute Butantan of São Paulo, Brazil. This serum is obtained by cutting the setae of caterpillars, where the producing toxin glands are located. Caterpillars collected in Cotia, São Paulo-Brazil, were observed to contain a nematode (Hexamermis sp.) inside the alimentary canal. From another lot of caterpillars collected in São Miguel do Oeste, State of Santa Catarina, Brazil some specimens were killed by a virus identified as Lonomia obliqua Multiple Nucleopolyhedrovirus (LoobMNPV). These two natural enemies will certainly be useful in a program of biological control.

Index terms: hairy caterpillars, venomous setae, pathogens, biological control.

[1593] A SURVEY OF LACEWINGS (NEUROPTERA: CHRYSOPIDAE), IN COFFEE AGROECOSSYSTEM, IN LAVRAS, MG, BRAZIL

<u>A. A. Morais</u>¹ & B. Souza¹, ¹ Dept. of Entomology, Federal University of Lavras, 37200-000 Lavras, MG, Brazil, E-mail: a_morais@hotmail.com; brgsouza@ufla.br

The Chrysopidae are important polyphagous predators found in several crops of economic importance with a great influence in the biological control of phytophagous arthropods. Lacewings like other beneficial insects stand out by being voracious, having high search ability and a broad number of prey species. In coffee crop, they are important in controlling secondary pests such as scales and aphids. Larvae of lacewings were observed preying eggs and adults of *Oligonychus ilicis* and larvae of *Perileucoptera coffeella*. Sampling was carried out at 15-day intervals in a coffee field at the Federal University of Lavras. Egg, larva, pupa and adult lacewings collected were placed in plastic bags and entomological net. Immature forms were reared to the adult stage, wich were mounted, labeled and sent to specialists for identification. A total of 64 adults, 4 larvae and 41 eggs were collected from September 1998 to August 1999. The species found were: *Chrysoperla externa*, *Ceraeochrysa cincta* and *C. claveri*.

index terms: chrysoperla externa, ceraeochrysa cincta, ceraeochrysa claveri, predator, chrysopid.

[1595] EVALUATION OF THE PARASITISM OF TELENOMUS PODISI ON PIEZODORUS GUILDINII (HETEROPTERA: PENTATOMIDAE) EGGS, IN SOYBEAN CROP IN RORAIMA, BRAZIL

M. A. B. Moreira¹, B. S. Correa-Ferreira², L. C. Corso², ¹Embrapa Roraima, Brazil, 174, Km 08, Distrito Industrial, Boa Vista-RR, Caixa Postal, 133, CEP 69.301.970, Email: marcos@cpafrr.embrapa.br; ²Embrapa Soja, Cx. Postal 231, CEP 86001-970, Londrina-PR.

The mortality of at the egg stage *Piezodorus guildinii*, main soybean crop pest, was studied under field condition in Roraima, during the years of 1997, 1998 and 1999. The experiments were carried out in Boa Vista, Roraima, Brazil, during the soybean crop season. Egg masses found in the field were observed dayly in laboratory to check the total number of viable eggs and those parasitized. Two species of egg parasitoids were recovered: *Telenomus podisi* Ashmead and *Trissolcus urich* Crawford. The incidence of parasitism in eggs of *P.guildinii* was 53% in 1997, 66% in 1998 and 70% in 1999. In Roraima conditions, *T. podisi*, was considered the most important and frequent species of *P. guildinii* parasitoid eggs due to its high occurrence and parasitism level.

[1594] BIOLOGY, THERMAL REQUIREMENTS AND PARASITIZATION OF TRICHOGRAMMA PRETIOSUM STRAINS ON HELICOVERPA ZEA EGGS

J. O.T. Moreira¹ & J.R.P. Parra², ¹ Depto. de Tecnologia e C. Sociais, Univ. do Est. da Bahia, C. Postal 171, 48900-000 Juazeiro-BA-Brasil, E-mail: osmateles@bol.com.br; ² Esc. Sup. de Agricultura "Luiz de Queiroz"/USP, C. Postal 9, 13418-900 Piracicaba – SP-Brasil, E-mail: jrpparra@carpa.ciagri.usp.br.

The research is part of a program of Integrated Pest Management of tomato crop in the Northeast region of Brazil using *Trichogramma pretiosum* to control the corn earworm (tomato fruitworm), *Helicoverpa zea* and the moth *Tuta absoluta*. The research was developed in laboratory at the Insect Biology Laboratory, at the Department of Entomology, Plant Pathology and Agricultural Zoology, Escola Superior de Agricultura "Luiz de Queiroz" (ESALQ), University of São Paulo (USP), in Piracicaba, State of São Paulo - Brazil, in order to study biological aspects and thermal requirements of *T. pretiosum* strains the factitious hosts *Anagasta kuelniella* and *Sitotroga cerealella* and the eggs parasitization on *H. zea* under 18, 20, 22, 25, 30 and 32° C. The *T. pretiosum* strains were from Petrolina-Pernambuco-Brazil (lat.S 9° 24' 42" and long.W Greenwich: 40° 29' 55") and from Piracicaba-São Paulo-Brazil'(lat.S 22° 43' 31" and long.W Greenwich: 47° 38'55"). The origin of the *T. pretiosum* strain affected the biological development of the parasitization and its parasitization capacity. The thermal requirements were also dependent on the origin of the strain, ranguing from 152 to 163 degree days for Petrolina and Piracicaba strain, respectively.

Index terms: biological control, temperature, corn earworm

[1596] CLASSICAL BIOLOGICAL CONTROL OF IMPORTED FIRE ANTS BY PARASITOID FLIES

L. W. Morrison¹, S. D. Porter¹ & L. A. Nogueira de Sá², ¹ Center for Medical, Agricultural and Veterinary Entomology, USDA-ARS, P.O. Box 14565, Gainesville, FL 32604, USA; ² Lab. de Quarentena "Costa Lima", Embrapa Meio Ambiente, Cx.P. 69, 13820-000, Jaguariúna, SP, Brasil.

Phorid flies in the genus Pseudacteon are solitary parasitoids of ants. Development occurs inside the head capsule of the host worker, killing the ant in the process. Pseudacteon flies may also have relatively large indirect effects on colony-level foraging and interspecific competition, as the presence of a single phorid can modify the behavior of hundreds of workers. Two Solenopsis fire ant species, S. invicta and S. richteri, have been introduced into the United States from South America and are serious pests in their introduced range. The high population densities of these two exotic ants may be due in part to an escape from natural enemies. Pseudacteon phorid flies from South America have the potential to be used as classical biological control agents of imported fire ants in North America. Laboratory studies of one Pseudacteon species, P. tricuspis, and its interactions with S. invicta, revealed that the presence of this phorid decreased food retrieval by as much as 50%. The primary mechanism of this effect was a significant decrease in worker activity when phorids were present. The presence of phorids did not significantly affect interspecific interactions between S. invicta and its close congener, S. geminata. The overall effect of introduced Pseudacteon phorids on imported Solenopsis fire ants in the United States will be evaluated from field releases of the flies and monitoring of target ant and associated arthropod communities. We have exported select *Pseudacteon* species from the Brazilian Quarantine Laboratory at Embrapa Environment, Jaguariúna, São Paulo State, Brazil to the United States for laboratory evaluation and field release, as part of a cooperative program between Embrapa and the USDA-ARS. In northern Florida, we had established 5 field populations of *Pseudacteon tricuspis* by the end of 1999. One population has been in existence since October 1997. The introduced populations are increasing in abundance and expanding in size, with the largest population covering an area of almost 100 square kilometers. Adult P. tricuspis were found to be active in the release areas in every month of the year. Long term monitoring of release and control sites should elucidate the magnitude of the effect of these parasitoids on target fire ant and associated arthropod populations. Pseudacteon flies and other natural enemies will not eradicate imported fire ants in North America, but could reduce fire ant populations to lower densities.

Index terms: Pseudacteon tricuspis, Solenopsis invicta, parasite, Phoridae

[1597] HOST SELECTION CUES OF A POTENTIAL BIOLOGICAL CONTROL AGENT FOR THE LILY LEAF BEETLE, *LILIOCERIS LILII*

<u>C. Müller^{1,2}</u>, F. Vencl³, T. Morton⁴ & U. Schaffner², ¹ Boyce Thompson Inst., Tower Road, Ithaca, NY 14850, USA, e-mail cm227@cornell.edu; ² CABI Bioscience Centre, Delémont, Switzerland; ³ Dep. of State Univ. of New York at Stony Brook, USA; ⁴ Dep. of Entomology, Pennsylvania State Univ., USA.

The use of natural enemies to control invasive species has become an important tool in biological control. to reduce the risk of non-target effects, the host range of the control candidate should be extremely narrow. the lily leaf beetle, lilioceris lilii (coleoptera, chrysomelidae), has become an important ornamental pest both in part of its native european as well as in its naturalized north american range, one of its antagonists in europe is the larval parasitoid lemophagus pulcher (hymenoptera: ichneumonidae), which is supposed to be highly specific, in order to elucidate the chemical basis of the specificity, host selection cues of this parasitoid were investigated in olfactometer and contact bioassays, volatiles of both the l. lilii larvae itself and their faeces which they carry as a shield were attractive to naive and experienced I. pulcher females. also, plant volatiles of the larvaes host plant, *lilium martagon* (liliaceae), but not of other tested green plants, attracted *l. pulcher* females. in contact bioassays, *l. lilii* larvae with faecal shield, larvae without shield, and shields alone were regularly contacted and induced oviposition behaviour, the combination of larva and faecal shield being more attractive than either one alone. nevertheless, the faecal shield seems to be a major cue in the host acceptance, since larvae of a non-host species covered with the faecal shield of *l. lilii* were as attractive to the parasitoids as I. lilii. dummies treated with a methanol extract of the shields evoke oviposition behaviour in l. pulcher females. since also leaf sap of l. martagon on dummies was attractive for the females, it is suggested that some of the kairomones inducing oviposition behaviour in *l. pulcher* originate from the host plant. index terms: lemophagus pulcher, faecal shield, kairomone.

[1598] DEVELOPING A COMMERCIALLY VIABLE SYSTEM USING TRICHOGRAMMA CHILONIS FOR CONTROL OF COTTON BOLLWORM HELIOTHIS ARMIGERA IN INDIA

N. Muthukrishnan, R.K.M. Baskaran, P.J.S. Roy, T.R. Manjula, M.S. Venugopal & R. Janarthanan, Department of Agricultural Entomology, Tamil Nadu Agricultural University, Agricultural College and Research Institute, Madurai 625 104, Tamil Nadu, India. E-mail: nmuthu64@hotmail.com

We established a pilot plant for large-scale production and distribution of Trichogramma chilonis to mitigate cotton bollworm, Heliothis armigera in Tamil Nadu, India. Nucleus insect cultures obtained from Biocontrol laboratory, Tamil Nadu Agricultural University, Coimbatore, and Project Directorate of Biological Control, Bangalore were used for propagation. Experiments on host acceptance revealed that T. chilonis preferred eggs of Corcyra cephalonica and contributed better biological attributes as that of natural host H. armigera. Therefore, we used C. cephalonica eggs for continuous mass culturing. However, rearing the parasitoids on H. armigera once in 5-6 generations minimized quality deterioration. Development of T. chilonis from sting to adult emergence was 7d on C. cephalonica eggs. Longevity of male and female was 5.3d and 6.5d with fecundity of 16 progenies/day. Techniques were developed to produce 15 x 10⁶ parasitoids/week. UV irradiation of C. cephalonica eggs to 20m, and exposure of parasitoids and host eggs at 1:8 ratio resulted in greater parasitization and emergence, and lower super parasitization. T. chilonis highly preferred C. cephalonica eggs that derived from diet incorporated with multivitamin, protein hydrolysate or honey, and in combination with either clomiphene citrate or tocopheryl acetate for development. T. chilonis also contributed increased fecundity and longevity when its adult honey food was mixed with clomiphene citrate or tocopheryl acetate. Field evaluation was conducted in winter and summer seasons using laboratory-reared parasitized eggs cards attached to top leaves of plants. Six releases of T. chilonis at 15x10⁴/ha/release at 10-12d interval, with as few as 50 release sites, gave moderate control of H. armigera. However, release of T. chilonis in alternation with NPV of II. armigera, endosulfan, Chrysoperla carnea and neem oil resulted in minimum larval population and boll damage, and maximum yield. Release of T. chilonis either before or after the release of C. carnea was deleterious as T. chilonis parasitized the eggs of C. carnea in the field. Testing effects of pesticides on T. chilonis in laboratory, semi-field and field conditions will be presented.

Index terms: Trichogramma chilonis, Corcyra cephalonica, mass production, field release, field evaluation

[1599] DEVELOPING A COMMERCIALLY VIABLE SYSTEM USING CHRYSOPERLA CARNEA FOR CONTROL OF COTTON PESTS IN INDIA

N. Muthukrishnan, T.R. Manjula, P.J.S. Roy, L. Geethalakshmi, M.S. Venugopal & R. Janarthanan, Department of Agricultural Entomology, Tamil Nadu Agricultural University, Agricultural College and Research Institute, Madurai 625 104, Tamil Nadu, India. E-mail: nmuthu64@hotmail.com

A native species of Chrysopids, Chrysoperla carnea was collected from cotton fields and assessed for its suitability for commercial use against cotton pests. Effect on acceptance of host eggs indicated that C. carnea preferred eggs of Corcyra cephalonica. Development from egg to adult emergence was completed in 22d. Egg period was 3.5d. Larval period averaged for 11d, Pupal period lasted for 7.5d, Progeny had sex ratio of 1.05: 0.95, Preoviposition period was 4d. Average fecundity was 640 eggs in lifetime. Males lived for 26d and females for 39d. Feeding experiments revealed that a single larvae fed on an average, 33.4 eggs of Heliothis armigera and 0.54 egg mass of Spodoptera litura; 5.9, 3.5 and 6.9 first to second instar larvae of H. armigera, Earias vittella and S. litura; 33.3, 24.6 and 19.5 aphids, mealy bugs and white flies respectively in a single day. A feasible smallscale mass production system using easily available and inexpensive materials was developed. About 25 x 10^5 C. carnea eggs were produced/week and distributed for field release. An efficient storage condition for C. camea eggs at low temperature was established which delayed hatchability, but yielded better survivorship and reproductive performance. We studied and categorized effects of pesticides in laboratory. Insecticides, methyl-o-demeton, dimethoate, phosalone, quinalphos, ethion, chloropyriphos, endosulfan, fenvalerate, cypermethrin, decamethrin and carboryl; plant products, need oil, need seed kernel extract (NSKE) and nochi leaf extract; biocides, nuclear polyhedrosis virus (NPV) of H. armigera and S. litura; fungicides, sulphur, dicofol, copper oxy chloride, mancozeb, ziram, captofol, carbendazim, streptomycin + tetracycline mixture; and plant growth regulator, naphthalene acetic acid were harmless based on egg, larval and adult mortality, and reduction in reproductive capacity. Augmentation of four releases of laboratory-reared C. carnea eggs at 50, 000/ha/release on 30, 60, 90 and 120 days after sowing, with as few as 50 release sites; or integrating C. carnea release with the use of NPV of H. armigera, Trichogramma chilonis, endosulfan, and need oil were significantly effective in minimizing aphids, white flies, thrips, mealy bugs and small larvae of E. *vittella* and *H. armigera*, and also contributed higher yield. Field recovery was up to 60%. Field evaluation of pesticides revealed that most of them were harmless as evidenced by less than 10% mortality on adults and larvae, and no significant effects on the life cycle of C. carnen.

Index terms: Chrysoperla carnea, Mass production, Field release, Pesticide toxicity

[1600] THE ENCARSIA SPECIES - PARASITODS OF WHITEFLIES (HOMOPTERA: ALEYRODIDAE) IN MÉXICO

S. N. Myartseva^{1,2}, E. Ruíz-Cancino¹ and <u>J. M. Coronado-Blanco¹</u>, ¹UAM Agronomía y Ciencias, UAT. Cd. Victoria, Tam., 87149. México, ²National Institute of Deserts, Flora and Fauna. Ashgabat, Turkmenistan.

Recently, several whiteflies species in many countries are serious agricultural pests, attacking crops and causing millions of dollars of damage each year. among the most common damaging whiteflies throughout the subtropics and tropics are citrus pests aleurocanthus woglumi and aleurothrixus floccosus and bemisia (tabaci complex), pests of a wide variety of field crops, including vegetables. many years ago were introduced into méxico several parasitoids and predators for citrus whiteflies biological control from different countries, the most effective whiteflies parasitoids belong to the family aphelinidae, generally to the genus encarsia. eight species of this genus were introduced into méxico, six against citrus blackfly aleurocanthus woglumi and two for woolly whitefly aleurothrixus floccosus biocontrol: e. clypealis, e. divergens, e. merceti, e. pergandiella, e. perplexa, e. smithi, and e. brasiliensis and e. haitiensis, respectively. for bemisia (tabaci complex) biological control, e. formosa was introduced. the study of the history of biological control successes in different countries established than it is necessary a priori knowledge of the natural enemies attacking invasive pest species. during the last two years, we studied the mexican fauna of aphelinidae, general method of our study is parasitoids rearing from different homoptera hosts (coccoidea and aleyrodoidea), especially the more important pests. by our and literature data, 26 species of the genus encarsia are registered at present in méxico as parasitoids of whiteflies. from them, 17 species are parasitoids of serious whitefly pest species. in the state of tamaulipas, different aphelinids were reared from three of the above mentioned whitefly species, seven belong to the genus encarsia, only three of them are species introduced earlier. aleurocanthus woglumi is parasitized by e. perplexa. aleurothrixus floccossus is attacked by e. americana, e. formosa and e. perplexa. heuronnikus juccosans is actuated by e. citrella, e. meritoria, e. pergandiella and e. luteola. Index terms: hymenoptera, aphelinidae, tamaulipas

[1601] BASIC STUDIES ON TRISSOLCUS URICHI CRAWFORD HYMENOPTERA: SCELIONIDAE) RELATED TO EDESSA MEDITABUNDA FABRICIUS (HEMIPTERA: PENTATOMIDAE)

<u>N. C. La Porta¹</u>, ¹ Dep. of Vegetal Protection, Faculty of Agricultural Cs., Univ. Nac. of Córdoba, C.C. 509, 5000 Cba, Argentina, E-mail <u>nlaporta@agro.uncor.edu</u>.

Species of the genus Trissolcus are egg parasitoids of bugs of the family Pentatomidae. In Argenting many of these hosts are harmful pests on field crops such as soybean. Therefore, the species of Trissolcus are interesting as biological control agents. Egg masses of Edessa meditabunda and Dichelops furcatus parasited by T. urichi were collected on soybean crops, in Córdoba, Argentina. This study was carried out due to the fact that there were no references about its biology in the country. Aspects of life cycle, reproduction and fecundity of T. urichi reared on E. meditabunda eggs were studied under controlled conditions of 25 \pm 2 °C; 60 \pm 10 % RH and 16 h photophase. Survival and fecundity were analysed through life tables. The following results were obtained: life cycle length (egg to adult): 10,2 d (females) and 9,3 d (males); preimaginal mortality: 4 %; adult longevity: significantly longer (p < 0.05) for females (43,6 d) than for males (40,3 d); number of progeny (females and males): $127,3 \pm 23,1$ eggs; greatest specific fecundity (m_x): 30,3 female/female during the first 24- 48 h after adult emergence; sex ratio: 9: 1 (females: male); net reproductive rate (Ro): 116,4 females/ female; generation time (T): 13,5 d; intrinsic rate of natural increase (r): 0,353 females/ female/day; finite rate of increase (λ): 1.42 females/ female.

Index terms: Trissolcus urichi, Edessa meditabunda, life cycle, reproduction, fecundity

[1603] REQUIREMENT OF LIPOPHORIN AND ECDYSTEROID FOR *IN VITRO* DEVELOPMENT OF A LARVAL ENDOPARASITOID, *VENTURIA CANESCENS* (HYMENOPTERA: ICHNEUMONIDAE)

Y. Nakahara¹, J. Osaka², T. Iliraoka² & K. Iwabuchi², ¹National Inst. of Sericultural and Entomological Science, 1-2 Ohwashi, Tsukuba, Ibaraki 305-8634, Japan. ²Tokyo Univ. of Agri. and Tech., 3-5-8 Saiwai-cho, Fuchu, Tokyo 183-8509, Japan.

In the field of biological control using parasitoids, one of the greatest needs is to produce adult wasps and flies at a low production cost. So far, many species of parasitoids including hymenopterous and dipterous species have been reared in vitro successfully from embryo to adult, but successful in vitro rearing of hymenopterous larval endoparasitoids has not been reported. We studied in vitro rearing of Venturia canescens, a larval endoparasitoid of pyralid stored-products pests. In this wasp, embryos at the postgermband stage were successfully reared to the last (5th) larval instar in an insect cell culture medium, MGM-450, supplemented with lipophorin purified from the host pupae, 20-hydroxyecdysone (20-HE) and fetal bovine serum (FBS). If one of these factors was omitted, the larvae failed to reach the 2nd larval instar. Lipophorin is an insect specific lipoprotein. V. canescens grew and developed in the medium supplemented with chicken egg yolk lipoprotein instead of lipophorin, suggesting that its lipoprotein-requirement is not so specific. The amount of lipids supplied to the parasitoid may be critical. FBS may be a source of growth-promoting factor(s), although it is not of insect origin. The growthpromoting ability of FBS was not lost after heat-treatment (100 °C, 5 min), dialysis (cut off <6,000 M.W.), and incubation with dextran-coated charcoal. In addition to 20-IIE, the effects of ecdysone, 2-deoxy-20-hydroxyecdysone, polypodine B and cholesterol were examined. Any of these ecdysteroids promoted development of V. canescens, but cholesterol did not. 20-HE is likely to function as the molting hormone for the parasitoid rather than as a nutrient, because its effect on development was dose-dependent within a certain range and a dose above that range was deleterious. It is noted, however, that a few larvae developed to the 2nd larval instar in the hormone-free medium, suggesting that the first instar larvae could synthesize their own ecdysteroid. In fact, a small amount of ecdysteroid was detected from the hormone-free medium in which the first instar larva was cultured for 3 days. When juvenile hormone (JH) was added to the medium, the duration of the developmental period was slightly shortened, but this hormone turned out to be not essential as a component of the culture medium.

Index terms: Venturia canescens, endoparasitoid, in vitro rearing, lipophorin, ecdysteroids

[1602] ANALYSIS OF SURVIVAL AND FECUNDITY OF TRISSOLCUS URICIII CRAWFORD (IIYMENOPTERA: SCELIONIDAE) ON DICHELOPS FURCATUS FABRICIUS (HEMIPTERA: PENTATOMIDAE)

N. C. La Porta¹, ¹ Dep. of Vegetal Protection, Faculty of Agricultural Cs., Univ. of Córdoba, C.C. 509, 5000 Cba, Argentina, E-mail <u>nlaporta@agro.uncor.edu</u>.

Trissolcus urichi, a scelionid egg parasitoid of Pentatomidae, was captured in Córdoba, Argentina from *Edessa meditabunda* and *Dichelops furcatus* egg masses collected on soybean crops. Survival and fecundity of *T. urichi* reared on *D. furcatus* eggs were analysed under laboratory conditions of 25 ± 2 °C; 60 ± 10 % RH and 16 h photophase. Vital statistics such as the net reproductive rate (R_0), the generation time (T), the intrinsic rate of natural increase (r) and the finite rate of increase (λ) were computed. Time of development from egg to adult emergence was 10 ± 0.9 days. Adult longevity average 47.6 ± 22.2 and 41.2 ± 9.4 days for females and males, respectively; no significant differences (p> 0.05) were observed between sexes. Progeny production reached a peak during the first 24-48 hours after adult emergence. The number of progeny, males and females/ female, was 133.8 ± 14.6 eggs and the greatest specific fecundity (m_{χ}) was 29.2females/ female. Sex ratio was 13:1 (females/ male). Other results were: r= 0.274; R_0 = 113.1; T= 17.3 and $\lambda = 1.3$. No differences were observed when comparing these results with those obtained using *Edessa meditabunda* as host.

Index terms: Trissolcus urichi, Dichelops furcatus, biology, survival, vital statistics

[1604] HOST-AGE EFFECTS ON OVIPOSITION BEHAVIOR AND DEVELOPMENT OF AN EULOPHID LARVAL-PUPAL PARASITOID, OOMYZUS SOKOLOWSKII

Akiko Nakamura¹ and Takashi Noda², ¹Department of Bioscience and Technology, Faculty of Agriculture, Iwate University, Morioka 020-8550, Japan, E-mail akikon@tnaes.affrc.gojp; ²Tohoku National Agricultural Experiment Station, 4 Akahira, Shimo-kuriyagawa, Morioka 020-0198, Japan.

Many studies have shown that host stadium (or age) at parasitism affects parasitoid host acceptance behavior, development and survival rates, and clutch size. Talekar & Hu (1996) reported that Oomyzus sokolowskii (Kurdjumov) (Hymenoptera: Eulophidae) preferred third- and fourth-instar Plutella xylostella (L.) (Lepidoptera: Yponomeutidae) larvae over first- and second-instar hosts for parasitization. We reported here the results of a laboratory study on host age affects host selection of O. sokolowskii. Second-, third-, early and late fourth-instar larva, and pupa of P. xylostella were singly presented to female O. sokolowskii in the laboratory to investigate the effects of host age on oviposition behavior and development of the parasitoid. The sequence of oviposition behavior after contacting the host could be divided into three steps: (1) drumming by antennae, (2) ovipositor insert in and oviposition, and (3) host feeding. Host acceptance rates did not differ among the different host ages except for pupa. Time required for ovipositor insertion and oviposition tended to increase as the host became old. About one third to half of the wasps showed host-feeding behavior irrespective of the host age. Parasitism rates and clutch sizes for the fourth-instar host larvae were higher and larger than that for the second- and third-instars. For all host stages and clutch sizes, offspring sex ratios were extremely female biased. There were no significant differences among the mean development times of the wasp on the second-, third-, and fourth-instar larvae. In the fourth-instar hosts, however, those on the early fourth-instar hosts were significantly longer than on the late fourth-instar hosts (= prepupa). This suggested that the larval development of *O. sokolowskii* should be influenced by the host physiology.

Index terms: Oomyzus sokolowskii, parasitoid, oviposition behavior, host age, development time, clutch size, Plutella xylostella.

[1605] MULTIPLE OVIPOSITION BY THE PARASITOID FLY EXORISTA JAPONICA IS ADVANTAGEOUS IN INTERSPECIFIC COMPETITION WITH THE MICROTYPE-EGG STRATEGIST, PALES PAVIDA

<u>S. Nakamura</u>, International Centre of Insect Physiology and Ecology (ICIPE), P. O. Box 30772, Nairobi, Kenya. E-mail snakamura@icipe.org

The gregarious tachinids, *Exorista japonica* and *Pales pavida*, parasitize the same host species in common habitats, and thus could compete for hosts in the field. It takes a few days for macrotype eggs of *E. japonica* laid on a host cuticle to hatch, while microtype eggs of *P. pavida* hatch and parasitize a host soon after being ingested by the host. Laboratory experiments were conducted to elucidate the mechanisms of interspecific competition between the two species. Adults of the two species often emerge from hosts multiply parasitized by bth species. However, the relative success of emergence of both species depends on the timing of hatching. Progeny of species that happen to hatch earlier will develop to adults better than their competitors. The number of *E. japonica* adults that emerged per multiparasitized host also increased with increasing number of eggs laid per host. *E. japonica* females tend to oviposit on self-parasitized hosts, or multiply oviposited on the same hosts even when unparasitized hosts are present. Such multiple oviositions on the same hosts may be advantageous for *E. japonica* in situations where it is competing for hosts with *P. pavida*.

Index terms: Tachinidae, parasitoids, multiple oviposition, interspecific competition.

[1607] STUDY ON INTERSPECIFIC COMPETITON BETWEEN TWO LARVAL PARASITOIDS OF THE DIAMONDBACK MOTH

T. Noda¹ & A. Nakamura², ¹Lab. of Insect Pest Control, Tohoku National Agricultural Experiment Station, Morioka, Iwate 020-0198, JAPAN, E-mail nodat@tnaes.affrc.go.jp; ²Dept. of Bioscience and Technology, Iwate Univ., Morioka, Iwate 020-8550, JAPAN.

The eulophid parasitoid *Oomyzus sokolowskii* is a larval-pupal parasitoid of *Plutella xylostella*. This wasp is also known as a facultative secondary parasitoid of *Cotesia plutellae*, because there are some reports that *O. sokolowskii* emerged from field collected *C. plutellae* coccons. However, there have been no reports on when and how *O. sokolowskii* parasitize *C. plutellae*. Because *C. plutellae* is an endoparasitoid, *O. sokolowskii* must oviposit *C. plutellae* larvae inside the host or emerging larvae for spinning the coccon. To examine hyperparasitism of *O. sokolowskii*, *P. xylostella* larvae of one through ten days after parasitism by *C. plutellae* were presented to *O. sokolowskii* females in the laboratory. Results showed that *P. xylostella* larvae ten days before parasitized by *C. plutellae* were successfully parasitized by *O. sokolowskii*, but only *C. plutellae* emerged from the other aged hosts. This suggests that the secondary parasitism by *O. sokolowskii* occurred in case that the female oviposit in the body of *C. plutellae* larvae inside the host. Therefore, the timing of secondary parasitism by *O. sokolowskii* both in the laboratory and field will be demonstrated and the ecological meaning will be discussed.

Index terms: Oomyzus sokolowskii, Cotesia plutellae, Plutella xylostella, hyperparasitism

[1606] DISTRIBUTION OF WOLBACHIA INFECTION AMONG COTESIA SESAMIAE (HYMENOPTERA: BRACONIDAE) POPULATIONS IN EASTERN AND SOUTHERN AFRICA

A. J. Nei-Song & W. A. Overholt, The International Centre of Insect Physiology and Ecology (ICIPE), P. O. Box 30772 Nairobi, Kenya, E-mail angisong@ICIPE.org.

Cotesia sesamiae is the most common larval parasitoid of a variety of noctuid and pyralid stem borers in gramineous crops in sub-saharan Africa. Its major hosts include Busseola fusca and Sesamia spp. A recent report indicated that two biotypes of C. sesamiae that are partially reproductively isolated exist in Kenya. One biotype is encapsulated in *B. fusca* and harbors the symbiotic bacteria *Wolbachia*. The aim of the current work was to determine how widely spread was the infection by Wolbachia among the different C. sesamiae populations found in Kenya and some eastern and southern African countries. The presence of Wolbachia infections in C. sesamiae populations collected from Zambia, Zimbabwe, Mozambique, Uganda, Zanzibar, and Kenya, was tested using a PCR technique. DNA was extracted from five individuals from each population. In Kenya, populations from Mombasa and Machakos, in the east, were positive for the infection with Wolbachia and served as a positive control for subsequent tests. In all PCR reactions using the FTSZ Holden primers. For the populations from Kuja and Kitale areas, in the western part of Kenya, none of the Wolbachia specific primers produced any product. The parasitoids from Mombasa were double infected with both the Wolbachia of group A and group B. Cotesia sesamiae samples obtained from field surveys conducted in Uganda were not infected with Wolbachia. Samples from Zambia, Zimbabwe and Mozambique showed the infection. Samples from other East African countries including Malawi, Ethiopia, Zanzibar, are being tested. The occurrence of Wolbachia in some population of C. sesamiae within same region, causing unidirectional mating incompatibility, may have negative impact on the biological control of cereal stem borers in East Africa. Index terms: Incompatibility, biotypes, Busseola fusca, biocontrol.

[1608] MORPHOLOGICAL AND QUANTITATIVE STUDIES OF THE HEMOCYTES IN *DIATRAEA SACCHARALIS* (LEPIDOPTERA: PYRALIDAE) LARVAE PARASITIZED BY *COTESIA FLAVIPES* (HYMENOPTERA: BRACONIDAE)

C.C.C. Nunes¹, M.T.S Bombonato² & <u>E.A. Gregório¹</u>, ¹Centro de Microscopia Eletrônica, Inst. Biociências, UNESP, Campus de Botucatu. 18618-000, Botucatu, SP, BR; E mail elisa@ibb.unesp.br ²Dept. Ciências Biológicas, Fac. Ciências, UNESP, Campus de Bauru. 17033-360, Bauru SP, BR.

The hemocytes are considered to participate in the cellular encapsulation making layers of extremely flattened cells around foreign material implanted in the insect hemocoel. Although encapsulation provides the insect defense against many invading microorganisms, this defense is ineffective against certain parasitoids that successfully live within insects. The suppression of cellular immune reactions by entomopathogens remain largely misunderstood. The Diatraea saccharalis is the major pest of the sugarcane crop. This insect may be controlled, in nature, by the parasitoid wasp Cotesia flavipes. There are few investigations correlating the immune response along the parasitoid development and the morphology of the host insect hemocytes. In this work we studied the participation of different hemocyte types in the reaction of the D. saccharalis larvae against the C. flavipes. by morphological and quantitative analysis. The total hemocyte counts (THC) were estimated, under phase contrast microscope, in hemolymph of D. saccharalis larvae parasitized up to 144 h. For the morphological study, hemolymph of parasitized D. saccharalis larvae (6, 72 and 144 h) was collected directly in 2.5% glutaraldehyde solution; the pellets obtained by contribution were conventionally prepared for transmission electron microscopic analyses. A significant decrease in the THC was detected in parasitized *D. saccharalis* larvae along the infection. The parasitoid was recovered with the hemocytes, but no blood cell was visualized attached to the wasp surface. Initially the granulocytes showed a decrease in the amount of structured granules and the plasmatocytes exhibited many vacuoles with flocullated content. Later on, both cell types showed an increase in the rough endoplasmic reticulum and Golgi complex. The oenocytoid was strongly affected by the parasitism, being represented only by the nucleus surrounded by cytoplasm fragments. Close relationship of hemocytes (plasmatocyte, granulocyte, oenocytoid and spherule cell) and teratocytes was observed. These findings suggest that the host insect, D. saccharalis, is mobilizing its hemocytes against the invader C. flavipes, although the insect host was not able to avoid the parasitoid development. (Partially supported by CAPES)

Index terms: Diatraea saccharalis, Cotesia flavipes, hemocyte, ultrastructure, parasitoid

[1609] PARASITISM OF *HEXACLADIA SMITHII* ON THE NEOTROPICAL BROWN STINK BUG *EUSCHISTUS HEROS* DURING AND AFTER THE SOYBEAN SEASON

<u>M. C. Nunes</u>¹ & B. S. Corrêa-Ferreira², ¹Universidade Federal do Paraná, Departamento de Zoologia, Caixa Postal 19020, Curitiba, Paraná 81531-990, Brasil E-mail: clarice@cnpso.embrapa.br; ² Embrapa-Soja, Caixa Postal 231, Londrina, Pr, 86001-970, Brasil, E-mail: beatriz@cnpso.embrapa.br.

Euschistus heros is considered a major pest of soybean in Brazil. In the 1996/97 growing season, the parasitoid Hexacladia smithii was reported for the first time afecting adult populations of the brown stink bug E. heros at the region of Londrina, Paraná. In the 1998/99 growing season, the natural incidence was evaluated by colecting 50 female samples at 15 days intervals at Embrapa Soja experimental fields in Londrina. In the laboratory, the reproductive capacity of females was studied during and after soybean season, comparing healthy and parasitized females. From a total of 900 E. heros females collected from December 1998 to August 1999, 40.3% were parasitized by H. smithii. The parasitism varied from 93.3% to 0% with higher occurrence in the months of January and February. At the end of the soybean season the parasitism decreased down to zero by the end of August. When the reproductive potencial of females was evaluated the total average number of eggs layed by healthy females (1133.8) was 5.2 higher than those deposited by parasitized females (216.8) reaching a maximum diference of 9.5 fold in January. The size of egg masses and egg fertility were not influenced by H. smithii parasitism. Results indicated that parasitism by H. smithii was important for the reduction of the E. heros population during the soybean growing season but its effects was insignificant on the population on diapause. Parasitism also affected the reproductive potential of E. heros females, its influence being drastic on offspring of the populations in December and January, when it acted as a natural control agent.

Index terms: biological control, fecundity, natural incidence, Pentatomidae, Encyrtidae.

[1610] EFFECT OF PARASITSM BY *IIEXACLADIA SMITHII* ON SURVIVAL AND REPRODUCTIVE CAPACITY OF *EUSCHISTUS HEROS* FEMALES

<u>M. C. Nunes</u>¹ & B. S. Corrêa-Ferreira², ¹Universidade Federal do Paraná, Departamento de Zoologia, Caixa Postal 19020, Curitiba, Paraná 81531-990, Brasil E-mail: clarice@cnpso.embrapa.br; ²Embrapa-Soja, Caixa Postal 231, Londrina, Pr, 86001-970, Brasil, E-mail: beatriz@cnpso.embrapa.br.

Considering the importance of Euschistus heros a soybean pest and the high incidence of the parasitoid Hexacladia smithii on this host, its influence on the survival and reproductive potential was evaluated. These two factors were compared under laboratory conditions (25°C ± 2°C, 65% ± 10% RH, 14L:10D) using healthy and parasitized females at different development stages (1, 7 and 14 days of adult life). A strong influence of *H. smithii* parasitism on the reproductive capacity of *E. heros* females at the different ages studied was detected. Fecundity was drasticaly reduced when the parasitism occurred at the first day of female adult life, when they are reproductively imature. During ca. 46 days, healthy *E. heros* females deposited an average of 66.92 eggs, (11.31 eggs masses/female), statistically higher than the values obtained for females parasitized by H. smithii at 1, 7 and 14 days of adult life, when average values of 1, 8.86 and 14.10 eggs per female, respectively. In relation to egg masses size there was significant differences among treatments. Althoug data had shown a tendency for bigger egg masses (5.71 eggs) for healthy females as compared to H. smithii parasitized females (1 to 4.24 eggs/egg mass). E. heros egg fertility was not affected by H. smithii parasitism when this occurred at seven (60.41%) and 14 days of adult life (71.40%) as compared to healthy females (94.22%). Parasitism supressed adult survival after 45 days, compared to 32% survival of unparasitized ones. These results indicate that parasitism by H. smithii affected the reproductive capacity of E. heros in all stages tested being its influence higher when the insect was immature (1 day) reducing the offsprings and causing high mortality to the host.

Index terms: biological control, fecundity, Pentatomidae, Encyrtidae, soybean

[1611] PARASITISM OF THREE ENCARSIA SPECIES ON TRIALEURODES VAPORARIORUM (HEMIPTERA, ALEYRODIDAE)

M.R.V. Oliveira, Embrapa Recursos Genéticos e Biotecnologia. P.O Box 02372, CEP 70.849-970, Brasilia, DF, Brazil. E-mail: vilarin@cenargen.embrapa.br

The greenhouse whitely, Trialeurodes vaporariorum, is a key pest of many greenhouses in the temperate world, attacking over 279 plant species belonging to 83 botanic families. Although this species, in Brazil, is considered a secondary pest, it can be found in greenhouses, of central, south and Southeast regions of the country. However, it is a major pest in greenhouses of "Embrapa Recursos Genéticos e Biotecnologia". Natural enemies, endemic to the "Distrito Federal" region, have been prospected and analysed among the greenhouse whitely populations. Three species of Encarsia have been found, this is, formosa, hispida and lycopersici. Studies were conducted to compare instar preference for parasitization by each of the species collected. Tomato, cotton and tobacco were used as host plants. The adults of the there species of parasitoids (n=100) were kept feeding on water + honey and their longevity, determined. Results showed that E. formosa adult parasitoids lived 10.3 ± 13.1 days. Females laid 9 eggs/day in tomato, 8 in cotton and 4.70 in tobacco. Parasitism found in first and second instars nymphs were of 37.1%, in tomato; 27.2%, in tobacco and 19.5%, in cotton. For third and fourth instars, the parasitism were of 90.7%, in tomato, 73.7%, in tobacco and 73.4%, in cotton. E. hispida adult parasitoids lived 5.7 ± 5.9 days. Females laid 4.6 eggs/day in tomato, 5.5 in cotton and 6.9 in tobacco. Parasitism found in first and second instars nymphs were of 37.0%, in tomato; 32.0%, in tobacco and 14,3%, in cotton. For third and fourth instars, the parasitism were of 53.0%, in tobacco, 43.8%, in tomato; and 11.4%, in cotton. E. lycopersici adult parasitoids lived 7.14 ± 13.7 days. Parasitism found in first and second instars nymphs were of 51.2%, in tobacco; 46.4%, in cotton and 41.9%, in tomato. For third and fourth instars, the parasitism were of 56.2%, in cotton, 51.6%, in tomato and 27.2%, in tobacco. In these studies, E. formosa revealed a better performance when compared to the parasitoids analysed.

Index terms: Encarsia formosa, E. híspida, E. lycopersici, Traileurodes vaporariorum, parasitoids.

[1612] BIOLOGICAL STUDIES OF NEPHASPIS GEMINII (COLEOPTERA: COCCINELIDAE) A PREDATOR OF BEMISIA TABACI BIOTYPE B (HEMIPTERA: ALEYRODIDADE), IN BRAZIL

M.R.V. Oliveira¹, P.R.G. Vieira¹ & R.A. Laumann¹, ¹Embrapa Recursos Genéticos e Biotecnologia, Cx. Postal 02372, CEP 70.849-970, Brasília, DF, Brazil. E.mail: vilarin@cenargen.embrapa.br.

In recent years the B-biotype of Bemisia tabaci has become one of the most important pest in greenhouses and open fields, worldwide. In Brazil, this biotype was first recorded ca. of 1992, in the state of São Paulo, although now it has spread to all regions of the country. Important agricultural and vegetable crops like cotton, beans, tomato and fruits (cantaloupe and watermelon) are being attacked by the insect. Control strategies are based exclusively on insecticides. In order to reduce reliance on chemicals a project on biological control (parasitoids and predators) are under way. Studies were conducted to evaluate the biology of Nephaspis geminii (Coleoptera, Coccinellidae), a species endemic to central Brazil. Development, fecundity and consumption rates of the insect was assessed when fed on a diet of immature individuals of B. tabaci biotype B. The development time (days) found for eggs was of 5.96 (± 1.03); L1, 1.87 (± 1.11); L2, 1.77 (± 0.82); L3, 2.56 (± 1.18); L4, 4.21 (± 1.96) and for pupa, 5.40 (± 0.87). Some of the immature (n=9) presented an additional L5 stage, with development time of 3.75 (±2.05) days. The overall mortality of immature stages was elevated (50%). Preoviposition period was of 7.90 (± 0.69) days and a mean of 1.64 (\pm 0.11) eggs per day was laid. Predation rates of adults and larvae of two ages (old: L4-L5) and (young: L2-L3) were evaluated in relation to two host plants, cabbage (Brassica oleraceae) and melon (Cucumis melo). Predations rates were higher in cabbage, demonstrating host plant preference. Adults coccinelid was able to increment the predation rates in response to higher densities of whiteflies eggs and nymphs. In laboratory condition, N. geminii showed good potential for the biological control of B. tabaci biotype B.

Index terms: Nephaspis geminii, Bemisia tabaci, Coleoptera, predator, whitefly.

[1613] IMPACT OF A SYMBIOTIC GRASS-ENDOPHYTE ASSOCIATION ON INSECT HERBIVORES AND THEIR NATURAL ENEMIES

M. Omacini¹, <u>E.J. Chaneton</u>¹, C.B. Müller² & C.M. Ghersa¹, ¹Department of Ecology, Faculty of Agronomy, University of Buenos Aires, Av. San Martín 4453, 1417 Buenos Aires, Argentina; ²Department of Biology, Imperial College at Silwood Park, Ascot, Berkshire, SL5 7PY, UK.

The mutualistic association of fungal endophytes with certain grass species can change the quality of the food resource for different guilds of herbivorous insects, and therefore, influence their local abundances. In addition, effects of endophyte infection on herbivore populations could be transmitted to higher trophic levels, altering the diversity, species composition, and behaviour of secondary consumers. Such endophyte induced "bottom-up cascades" may be common in insect food webs of natural and agricultural systems, but have not yet been investigated. We recorded naturally occurring densities of leaf miners and aphids on replicated patches (50×50 cm) of the annual grass Lolium multiflorum, grown from seed infected with the fungus Neotyphodium sp. (E+) and from seed free of endophytes (E-). We also collected parasitised aphids ("mummies") to assess the parasitois (c), we assume that the parasitois approximate the parasitois (community structure on E_+ and E_- grass patches. The frequency of L. multiflorum shots attacked by leaf miners was significantly lower in E_+ patches. Endophyte infection decreased aphid densities, especially that of the dominant aphid species Rhopalosiphum padi. This effect was transmitted to the aphid parasitoids, as the mean density of parasitised aphids on E+ patches was 85% lower than that on E- patches. Moreover, parasitoid attack rates (proportion of parasitised aphids) were enhanced on grass patches lacking the endophyte. From the sampled aphid mummies we reared 3 and 4 species of primary and secondary parasitoids, respectively. There was no consistent difference in parasitoid diversity or species composition between E+ and E- grass patches, although the secondary/primary parasitoid ratio was higher on E- patches. This study shows that fungal endophyte infection of a food plant can strongly affect insect herbivore populations, whereas bottom-up effects of grass endophytes on higher levels of the food chain are subtle.

Index terms: aphid parasitoids, fungal endophytes, indirect effects, leaf miners, trophic interactions

[1614] THE ROLE OF LANDSCAPE STRUCTURE AND FARMING PRACTICE ON PREDATION OF APHID

<u>Ö. Östman¹</u>, B. Ekbom² & J. Bengtsson¹, ¹Dept. of Ecology and Crop Production Science, P. O. Box 7043, 750 07 Uppsala Sweden, E-mail: orjan.ostman@evp.slu.se; ²Dept. of Entomology, P. O. Box 7044, 750 07 Uppsala, Sweden.

The goal of conservation biological control is to enhance the action of naturally occurring pest enemies. Landscape structure and farming practices (conventional or organic) have been suggested to play an important role in this enhancement. We have measured the impact of the natural enemy assemblage on the growth rate and abundance of the bird cherry-oat aphid (Rhopalosiphum padi) in cereal, at ten farms with different landscape structure and farming practice around Uppsala, Sweden. Aphid abundance was measured, using a D-vac, in spring barley every third day, from the onset of the aphid attack to their departure. The aphid growth rate was calculated as the regression between days and the logarithm of aphid abundance. In every field we put out exclusion barriers where ground living predators could not enter. The impact of the natural enemies on aphid growth rate was calculated as the difference between the growth rate in the exclusion barriers minus the growth rate in the field. Aphid growth rate was significantly higher within barriers than in the field. The impact of the natural enemies was greater in simpler landscapes than in more complex landscapes. There was no effect of farming system. The peak abundance of aphids was not correlated with the impact of natural enemies. Instead, the colonisation rate had a significant effect on the peak aphid abundance. Colonisation rate was significantly negatively correlated to mean perimeter-to-area ratio of cultivated fields and was lower on organic farms than conventional farms. Unfortunately, we cannot tell if the lower colonisation rate was due to higher predation of newly arrived aphids or due to a lower aphid influx into cereals. From the impact of the natural enemies on aphid growth rate we calculated the economic benefits of natural enemies in terms of increased yield. Since the difference in colonisation rate could not unambiguously be ascribed to natural enemies we did not include this effect in the economic calculations. The mean increase in yield due to the impact of natural enemies on aphid growth rate was 61 kg/ha, which was equivalent to 5% of the yield 1999. However, there was variation in how much natural enemies increased the yield, which partly can be attributed to landscape structure. We conclude that there is potential to manipulate the landscape to decrease the losses from aphids in cereals. Index terms: Rhopalosiphum padi, biocontrol, economic benefit

[1615] HYMENOPTERAN PARASITOIDS ON FRUIT – INFESTING TEPHRITIDAE (DIPTERA) IN LATIN AMERICA AND THE SOUTHERN UNITED STATES: DIVERSITY, DISTRIBUTION, TAXONOMIC STATUS AND THEIR USE IN FRUIT FLY BIOLOGICAL CONTROL

<u>S.M. Ovruski</u>¹, M. Aluja², J. Sivinski³ & R. Wharton⁴, ¹ INSUE, CIRPON-FML, CONICET. M. Lillo 205 (4000) S.M. de Tucumán, Argentina. E-mail: alujam@ecologia.edu.mx;³ Center for Medical, Agricultural and Veterinary Entomology, USDA-ARS, Gainesville, FL 32604, USA. E-mail: jsivinski@gainesville.usda.ufi.edu; ⁴ Texas A&M University, Department of Entomology, College Station, TX 77843-2475, USA. E-mail: rawbaw@acs.tamu.edu

We first discuss the diversity of fruit fly (Diptera: Tephritidae) parasitoids Hymenoptera) of the Neotropics. Even though the emphasis is on Anastrepha parasitoids, we also review all the information available on parasitoids attacking files in the genera Ceratitis, Rhagoletis, Rhagoletis, Rhagoletis, Rhagoletis, and Zonosemata. We center our analysis in parasitoid guilds, parasitoid asemblage size and fly host profiles. We also discuss distribution patterns and the taxonomic status of all known Anastrepha parasitoids. We follow by providing a historical overview of biological control of pestiferous tephritids in Latin American and Florida (USA) and by analyzing the success or failure of classical and augmentative biological control programs implemented to date in these regions. We also discuss the lack of success of introductions of exotic fruit fly parasitoids in various Latin American countries. We finish by discussing the most pressing needs related to fruit fly biological control (classical, augmentative and conservation modalities) in areas of the Neotropics where fruit fly populations severely restrict the development of commercial fruit growing. We also address the need for much more intensive research on the bioecology of native fruit fly parasitoids.

Index terms: Anastrepha - Ceratitis - Braconidae - Figitidae - parasitoid guilds

[1616] INTRODUCTION OF THE PARASITOID AGENIASPIS CITRICOLA FOR THE BIOLOGICAL CONTROL OF CITRUS LEAFMINER PHYLLOCNISTIS CITRELLA IN BRAZIL

P.E.B. Paiva¹, <u>S. Gravena¹</u> & L.C.S. Amorim¹, ¹Gravena ManEcol Ltda, Rua Monteiro Lobato 856, 14870-000, Jaboticabal/SP, Brazil. E-mail gravena@asbyte.com.br

The citrus leafniner Phyllocnistis citrella was first detected in Brazil ocurring in citrus in march 1996. Since then this pest has rapidly spread throughout the major citrus area in state of São Paulo. Besides this pest has seriously damaged the young citrus leaves the main impact of the new intruder on citrus industry has been facilitated the citrus canker infection. Two native parasitoids were found attacking larvae and pupae of P. citrella. in the commercial groves in São Paulo, the eulophids Galeopsomyia fausta and Cirrospilus The parasitoid Ageniaspis citricola was collected from citrus groves in Florida SD.C. (USA) and imported into quarentine facilities of EMBRAPA- Meio Ambiente in Jaguariúna, São Paulo in July 1998 as part of a classical biological control program against *P. citrella* that has been supported by CNPq and Fundecitrus. After the quarentine procedures *A. citricola* has been reared at Gravena-Manecol in Jaboticabal/São Paulo and ESALO/USP in Piracicaba/São Paulo. The citrus leafminer and the parasitoid have been reared on controlled chambers with lime seedlings (Citrus limonia) as host and on greenhouses with sweet orange plants (Citrus sinensis). In 1999 approximately 25000 A. citricola were reared in Jaboticabal alone and 134 releases were made in São Paulo citrus groves. Some recoveries were made until february 2000 but the establishment has not yet been confirmed.

Index terms: classical biological control program ,citrus canker

[1617] PARASITISM EFFICIENCY OF THE BRACONIDAE WASPS, DIACHASMIMORPHA LONGICAUTA, ON LARVE OF MEDFLY IN GUAVAS

B. A. J. Paranhos^{1,2}, J. M. M. Walder^{1,3} & L. Blumer^{1,4}, ¹ Laboratory of Food Irradiation and Radioentomology, CENA/USP, P.O. Box 96, Piracicaba, SP 13400-970, Brazil, E-mail bajparan@cena.usp.br; ² Post-Doctor - FAPESP; ³ Associated Professor USP, CNPq-BP Fellowship; ⁴ CAPES graduated fellowship.

The efficiency of parasitism of the Braconidae wasps, *D. longicaudata*, were checked on four different varieties of guavas infested with larvae of medfly, *Ceratitis capitata*. The guavas were infested by introducing them inside of the cages of adult medflies for two hours. Data on fruit weight, dead larvae, pupae recovered, % emerged flies (males and females) and % parasitism (males and females) were collected. It was observed that medflies have preference on laying eggs in larger and greener fruits, resulting in larger offspring, but the parasitism rate was not affected. The parasitism rate did not present significant statistical difference annong varieties of guavas tested and ranged from 3.34% to 7.9%. Medfly and parasitoid females did not present oviposition preference for none of the varieties studied. There was significantly larger mortality of larva of flies in the c.v. Sassaoca in relation to c.v. Pedro Sato. The parasitoid *D. longicuudata* shown low efficiency, in lab conditions, to parasite guavas infested with medfly larvae.

Index terms: Parasitism rate, biological control, medfly, Diachasmimorpha longicaudata, guava.

[1619] FIRST APPROACH ON THE POTENTIAL ROLE OF DICYPHUS CERASTII (HEMIPTERA: MIRIDAE), AS NATURAL CONTROL AGENT IN PORTUGUESE GREENHOUSES

P. Passos, F. Luz, A. Mexia, Instituto Superior de Agronomia, DPPF, Secção de Protecção Integrada, Tapada da Ajuda, 13449-017, Lisboa, Portugal.

In this paper is given a first sample of data concerning the most common mirid bug of the Portuguese greenhouses of the Oeste region, the Dicyphinae *Dicyphus cerasii* Wagner 1951, (Hemiptera: Miridae). Along with seasonal evolution of the population on protected tomato, a laboratorial trial showed the potential to predate the leafniner *Liriomyza huidobrensis*. In the laboratory it was also posible to demonstrate that the necrophagy ocasionally observed in the field, is a adaptative advantage for this facultative phytophag and predator, since feeding cadavers from entomological nature increases the fertility. Keywords: Região Oeste of Portugal, biological control, greenhouse crops, (Hemiptera: Miridae) *Dicyphus cerastii* Wagner 1951

[1618] BIOLOGICAL CONTROL OF MEDFLY IN PEACH USING PARASITOID [DIACHASMIMORPHA LONGICAUDATA (HYMENOPTERA: BRACONIDAE)] INUNDATIVE RELEASINGS

B. A. J. Paranhos ^{1,2} & J. M. M. Walder ^{1,3}, ¹ Laboratory of Food Irradiation and Radioentomology, CENA/USP, P.O. Box 96, Piracicaba, SP 13400-970, Brazil, E-mail-bajparan@cena.usp.br; ² Post-Doctor - FAPESP; ³ Associated professor-USP, CNPq-BP fellowship.

The efficiency of parasitism of the wasp *D. longicaudata* in a peach orchard was evaluated, using 2 different peach varieties (c.v. Maravilha and c.v. Ouro Mel), located in tree different blocks (c.a. 1 ha each) in the field. The parasitoids were released weekly during 4 weeks period for c.v. Maravilha and 2 weeks for c.v. Ouro Mel. About of 24,800 adults were released every week in each block. Infested artificially peaches were used as baits. They were infested in laboratory, irradiated to avoid adult medfly emergence, and individually hang in a plastic net, among peach fruits in the trees during a 24 hours period. After that period, the bait peaches were taken to the laboratory to observation. The parasitism rate, in peach c.v. Maravilha, ranged from 18.28% to 47.89%, with an average of 31.31%. From emerged parasitoids, 59.60% were males and 40.40% were females. It was found for the peach c.v. Ouro Mel a parasitism rate of 11.52% after the first releasing and 53.83% after the second one. When increased the reason of parasitoids released/pupa recovered in the peaches "baits" (parasitoid: host), decreased the parasitism percentage in the field, perhaps doe to a factor of over parasitism

Index terms: Parasitism rate, fruit fly, peach, Diachasmimorpha longicaudata.

[1620] PREDICTABLE RISK TO NATIVE PLANTS IN WEED BIOLOGICAL CONTROL

R. W. Pemberton, US Dept. Agric. - Agric. Res. Service, Aquatic Plant Management Lab, 3205 College Ave. Ft. Lauderdale, FL USA 33314

Environmental safety is an important issue for biological control. Data on field host use of 112 insects, 3 fungi, 1 mite, and 1 nematode established for biological control of weeds in Hawaii, the continental U.S., and the Caribbean indicate that the risk to native flora can be judged reliably before introduction. Virtually all risk is bourne by native plant species that are closely related to target weeds. Fifteen species of insects introduced for biological control of wheels while 4 others belong to 2 closely allied genera. Only 1 of 117 established biological organisms uses a native plant unrelated to the target weed. Thus the elements of protection for the native flora is the selection of weed targets that have few or no native congeners and the introduction of biological control organisms with suitably narrow diets. biocontrol reform, biocontrol safety, natural enemies, non-target use

[1621] THERMAL REQUIREMENTS FOR DEVELOPMENT OF THE PREDATOR MACROLOPHUS PYGMAEUS (HEMIPTERA:MIRIDAE)

D. CH. Perdikis & <u>D. P. Lykouressis</u>, Lab. of Agr. Zoology and Entomology, Agricultural University of Athens, 75 Iera Odos, 118 55, Athens, GREECE, E-mail lykouressis@auadec.aua.gr.

Macrolophus pygmacus is a polyphagous predator preying on whiteflies and aphids on various vegetables like tomato, eggplant and pepper-plant and it can also complete its development feeding exclusively on plant sap. Egg and nymphal development as well as the length of preoviposition period of M. pygmaeus were studied on eggplant and tomato in the presence of insect prey, at 15, 20, 25, 27.5 and 30°C, with 65±5% RH and photoperiod of 16:8 (L:D) h. The aphid Myzus persicae was used as prey on eggplant whilst the whitefly Trialeurodes vaporariorum, on tomato. The temperature threshold and the thermal constant for egg, nymphal stages and oviposition of the predator were calculated. The above parameters for preimaginal and egg to egg development were also estimated. The temperature threshold for egg development was found 7.53 and 6.85°C, for nymphs 8.71 and 9.19°C, for oviposition 6.83 and 6.50°C, for preimaginal development 8.42 and 8.75°C and finally for egg to egg development 8.19 and 8.48°C on eggplant and tomato, respectively. The thermal constant of egg development was calculated as 180 and 185 day-degrees, of nymphs 270 and 261, of oviposition 108 and 103, of preimaginal development 447 and 435 and finally of egg to egg development 552 and 535 day-degrees, on eggplant and tomato, respectively. These results show that development of *M. pygmaeus* can begin at a temperature somewhat lower than other beneficial insects which feed on or parasitize at aphids and/or whiteflies on vegetables.

Index terms: developmental temperature threshold, thermal constant, nymphal development, egg development

[1623] REARING OF BROWN STINK BUG *EUSCHISTUS HEROS* AND GREEN STINK BUG *NEZARA VIRIDULA* AS HOSTS IN THE MULTIPLICATION OF EGG PARASITOIDS

W.A.A. Peres¹ & B. S. Corrêa-Ferreira², ¹Universidade Federal do Paraná, Departamento de Zoologia, Caixa Postal 19020, Curitiba, Paraná 81531-990, Brasil. Email: wilsimar@cnpso.embrapa.br., ²Embrapa-Soja, Caixa Postal 231, Londrina, PR, 86001-970, Brasil, E-mail: beatriz@cnpso.embrapa.br.

Experiments were conducted in Londrina, PR, Brazil, under rearing room conditions (25°C, 60% RH, 14hL:10hD), to evaluated the nymph development and the reproduction of brown stink bug Euschistus heros and green stink bug Nezara viridula (Hemiptera: Pentatomidae) as hosts in the eggs parasitoids multiplication. One hundred eggs of E. heros and N, viridula were put into the cage (50x50x70 cm) with soybean plant plus dry soybean and peanut seeds used as diet. Dialy observations were made until adult emergence, and the duration of nymph development time and the survival of adults were calculated. The nymph development time were 33 days for E. heros and 34 days for N. viridula, with survival average of 65% and 71.3%, respectively and there was no significant difference between the trataments. The reprodutive capacity of laboratory and field populations of E. heros and N. viridula were evaluated during February-April 1999. During 13 weeks the egg production per cage was studied with one hundred pairs of stink bugs/cage with the same diet. Dialy observations were made and egg masses were collected. Adults of E. heros reared under laboratory conditions produced 2.08 times more eggs than that collected in field, 5547 and 2262 eggs/ cage to laboratory and field rearing adults, respectively, being this population with high rate of parasitism by Hexacladia smithii, that reduced reproduction and longevity of adults. The N. viridula adults collected in field produced 1.75 times more eggs than adults reared in laboratory (6304 and 3609 eggs/ cage) and, in this period, it was observed low density of adults parasitized by tachinid flies in the field population.

[1622] BIOLOGICAL DATA OF SOME NATURAL ENEMIES OF THE SOURSOP BORER CERCONOTA ANONELLA (LEPIDOPTERA: OECOPHORIDAE) IN PLANALTINA, FEDERAL DISCTRICT, BRAZIL

M. J. B. Pereira¹, M.A.S. Oliveira², E. Berti-Filho¹, I. Icuma² & N.T.V. Junqueira², ¹Depto de Entomologia, Fitopatologia e Zoologia Agrícola-ESALQ/USP. Caixa postal 9, 13418.900, Piracicaba, SP. E-mail: mjbperei@carpa.ciagri.usp.br; ² EMBRAPA-CERRADOS, BR 020, Km 18, Rodovia Brasília - Fortaleza. 73301-970, Planaltina, DF. Financial support: CNPq

Soursop fruits (Annona muricata) infested by Cerconota anonella, were collected in Federal District orchards from May to November 1998 and taken to the Laboratory of Entomology of EMBRAPA-CERRADOS ($25.0 \pm 0.9^{\circ}$ C temperature; $64.5 \pm 7.3\%$ relative humidity). The fruits were opened and the C. anonella larvae were placed in Petri dishes (1 larva/dish) with pieces of fruits, while the pupae were placed in Petri dishes with humid towel paper. Upon emergence the adults were transferred to mating cages (15.0 cm x 25.0 cm)cm) covered with towel paper for the insect to lay the eggs, and a recipient with honey solution. The parasitoids collected and the percentages of parasitism were as follows: Apanteles sp. (25.3%) larval parasitoid, Xyphosomella sp.(2.0%) - larval parasitoid, Brachymeria annulata (2.0%) - pupal parasitoid, Trichospilus diatraeae (5.0%) - pupal parasitoid. C. anonella larvae of different ages were given to Apanteles females, however only the newly hatched larvae were parasitized, and the egg-adult period was approximately 15 days, but only males emerged. One to three day old *C. anonella* pupae were exposed for 24 hours to B. annulata females and the mean life span was 19 days, but again only males emerged. Newly formed C. anonella pupae were exposed to T. diatraeae females for 48 hours, and the egg-adult period was approximately 17 days, emerging 100 a 200 adults per pupa, with a sex ratio of 0.70. C. anonella larvae of different ages were exposed to Xyphosomella sp. females, but no parasitism was observed. T. diatraeae was the most promising species for laboratory rearing. However new methodologies should be developed for laboratory rearing of the other parasitoid species, namely Apanteles, the most frequent one in the collectings done during this research.

Index terms: larval parasitoid, pupal parasitoid, life span, biological control.

[1624] THE EFFECT OF THE ADDITION OF AMINO ACIDS TO THE TOXICITY OF BACILLUS THRUINGIENSIS AGAINST PLUTELLA XYLOSTELLA LARAVE

<u>A. D. Permana</u> and S. T. Rastrya, Department of Biology Institut Teknologi Bandung, Ganesa 10 Bandung 40132, Indonesia. E-mail : agus@bi.itb.ac.id

A study was conducted to observe the effect of alanine, arginine and leusine addition to the toxicity of the *Bacillus thuringiensis* var. Aizawai (Bt-A) and Bt var. Kurstaki (Bt-K) against early instar larvae of *Plutella xylostella* under laboratory condition. Bt-A and Bt-K were tested at 1 to 10,000 ppm by using the leaf dipping method. The results showed that the addition of alanine0.05% remarkably increased the toxicity of Bt-K at 1 to 100 ppm. The addition of arginine 0.05% was also increased the toxicity of Bt-A at 1 to 1,000 ppm. Comparative potency of the amino acids addition to increase the toxicity of Bt-K were alanine 0.05% > leusine 0.05% respectively. For Bt-A, the addition of arginine 0.05% pives the better toxicity compare with alanin 0.05% and leusine 0.05%. Index term: *Bacillus thuringiensis*, alanine, arginine, leusine, toxicity.

[1625] OCCURRENCE OF SCALES, WHITEFLIES AND NATURAL ENEMIES IN CITRIC PLANTS IN THE MUNICIPAL DISTRICT OF CÁCERES, MT, BRASIL

<u>J. M. Pinto¹</u>, F. A. A. Ferrara¹, V. A. Teixeira², S. R. S. Ventura³, A. G. Carvalho³ & P. C. R. Cassino⁴, ¹Dept. Fitotecnia, CPGF, UFRRJ, Seropédica, RJ, 23.890-000, Brasil. E-mail: jmiranda@ufrj.br; ²Dept. de Produção e Extensão, EAFC, C.P. 244, Cáceres, MT 78.200-000, Brasil; ³Dept. de Produtos Florestais, IF, UFRRJ, Seropédica, RJ 23.890-000, Brasil; ⁴Dept. de Entomologia e Fitopatologia, CIMP, UFRRJ, Seropédica, RJ 23.890-000, Brasil;

They are countless the scales registrations and Aleyrodidae damaging the citric plants, causing considerable damages due to the great amount of sap that they extract for its feeding. This provokes the decline and even death of the plant, besides other indirect damages. The study was accomplished in February of 2000, in an orchard with 18 years of age implanted in the limits of the Escola Agrotécnica Federal, municipal district of Cáceres, MT, Brasil, to an altitude of 118 m, which included the tangerines "poncā", "mexirica" and "murcote"; the oranges "pêra", "lima" and "valência" and the lemon "tahiti", totaling about 400 plants. The number of the sample was of 20 plants according to the precasualization extolled for the methodology of sampling binomial, "presence-absence", where 10 leaves per plant per quadrant was observed, therefore, 40 leaves per plant. The following insects associated with its respective occurrence degrees were observed: Scales: *Coccus viridis* (0,13%), *Pinnaspis aspidistrae* (0,13%), *Selenaspidus articulaus* (2,50%), *Orthezia praelonga* (8,13%) and *Chrysoperlas* pp. (30,00%).

Index terms: Citrus, Aleyrodidae

[1626] COEXISTENCE IN ONE FIELD OF DIFFERENT *TRICHOGRAMMA* SPECIES SHOWING DIFFERENT MODES OF REPRODUCTION AND DIFFERENT LEVELS OF *WOLBACHIA* INFECTION

B. Pintureau¹, E. Tabone⁴, P. Bolland¹ & F. Lassablière¹⁻³, ¹INSA-INRA (UA 203), Båt. 406, 20 Ave. A. Einstein, 69621-Villeurbanne, France; E-mail: pinture@jouy.inra.fr. ²INRA, Unité Santé vég. et environnement, 37 Bd. du Cap, 06606-Antibes, France. ³Present address: Univ. J. Monnet, Fac. Médecine, Lab. Biochimie, 42023-Saint Etienne-cedex 2, France

In summer 1998, eggs of *Plutella xylostella* (Lep.: Plutellidae) were collected in two fields of cabbage located in Pas-de-Calais, north France (coll. S. Sénéchal) and Valbonne, south France (coll. N. Sorbier-Lezcano). In another field of cabbage located in Hyères, south France, C. Vidal distributed and then collected patches of UV-irradiated *Ephestia kuehniella* (Lep. Pyralidae) eggs. Each *Trichogramma* from one patch of loss eggs was reared on *E. kuchniella* eggs. Collected *Trichogramma* were classified in four species (Table) and three groups of species (evanescens, pretiosum and pintof).

Region	Trichogramma Species and Wolbachia in- fected individuals	Number of parasitoids (fe- males or sets)	% of thely- tokous in- dividuals	% of thelytokous
Pas-de-Calais	T. evanescens	1	100	100
	T. semblidis	24	0	0
Valbonne	T. semblidis	5	20	20
	T. cacoeciae	14	100	0
Hyères	T. evanescens	31	3	3
	T. cacoeciae	2	100	0
	T. buesi	4	0	0

The most frequent species were T. semblidis in Pas-de-Calais (96%), T. cacoeciae in Valbonne (74%) and T. evanescens in Hyères (84%). All T. cacoeciae individuals and some T. evanescens and T. semblidis individuals showed a thelytokous reproduction. A high temperature (30° C) rearing produced males in thelytokous strains of T. evanescens and T. semblidis, but not of T. cacoeciae. This means that the thelytoky is induced by a heat-sensitive symbiont, Wolbachia, in the two first species but not in the third. The presence or absence of Wolbachia was confirmed by PCR (primers of FisZ gene). It is the first indication of such a rich Trichogramma biodiversity (in relation to the species composition, the mode of reproduction and the level of Wolbachia infection) in one field. It is also the first indication of a Wolbachia infection in T. semblidis.

Index terms: Bacteria, Biodiversity, egg parasitoid, symbiosis, thelytoky.

[1627] COLLECTS AND IDENTIFICATION OF RACES OF *TRICHOGRAMMA* IN COMMERCIAL FIELDS OF TOMATO, IN DIFFERENT ALTITUDE

<u>D. Pratissoli¹</u>, A. M. Holts¹, A. B. Chioramital¹, H. B. Zago¹ & R. T. Thuler¹, ¹CAUFES, P. O. Box 16, ZIP CODE: 29500-000, Alegre, Brazil, E-mail direcu@npd.ufes.br.

seven experimental fields were installed in altitude that varied of 200 to 1050 meters, located in the municipal districts of afonso cláudio and venda nova do imigrante in espírito santo state, brazil. in all the commercial fields of tomato it was just collected *trichogramma pretiosum*. in the first year of collection the medium number of sample, of egg-cards with parasitism, as well as the medium number of parasitized eggs, they presented an inverse relationship when compared with the areas of altitude among 200 to 850 meters. in the areas of smaller altitude (200, 380 and 450m) a constant presence of that parasitoid of eggs was observed in all the areas inspect. In the second year of collection the same behavior was not observed in relation to the first, tends the medium values of the inferior parameters, with the medium number of eggs parasitized by cards, reduced by the half. Its two years results showed that the aggressiveness of the races of *t. pretiosum* was differentiated in function of the areas.

index terms: biological control, trichogrammatidae, tomatoes, eggs parasitoids

[1628] THE USE OF SUCTION TRAP TO COLLECT TRICHOGRAMMA SPECIES

<u>R. B. Ouerino</u> & R. A. Zucchi, Dep. de Entomologia, Fitopatologia e Zoologia, Univ. de São Paulo, ESALQ, Av. Pádua Dias 11, C. Postal 09, 13418-900, Piracicaba, São Paulo, Brasil, E-mail rbqsilva@carpa.ciagri.usp.br

Several studies with Trichogramma have been conducted for biological control of insect pests in the world, and consequently most species in agroecosystems have already been studied. Therefore, relatively little is known about Trichogramma species in other habitats. Several hosts occur in habitats not explored commercially and certainly many Trichogramma species can be found in these habitats. A common way to collect Trichogramma is to sample host eggs on plants. However, because host eggs usually are not found in natural habitats, indirect methods have been used such as: screened sweep nets, yellow pan traps, fine meshed-malaise traps, and vacuum samplers. In this study an electrical suction trap stationary (model "Seção de Virologia do Instituto Agronômico de Campinas") was used to collect Trichogramma species. The trap was set in a forest reserve of the Tupi Experimental Station, in Piracicaba, São Paulo, Brazil. The collecting recipient with the solution of glycerine and alcohol (3:1) was replaced every week. The specimens collected were taken to the laboratory for separation of the Trichogramma species. Later on, Trichogramma species were slide-mounted using Hoyer's medium. The results are preliminary and represent six months of collecting, with a total of twenty-four samples. Two species were identified: *Trichogramma pretiosum* a common species) and Trichogramma lasallei (a species described recently), but identifications of other species are being carried out. The suction trap is a good method to collect Trichogramma species. The specimens are not damaged, and they can be used for preparation of microscopic slides. Therefore suction trap can be used to survey Trichogramma in natural habitats (research supported by FAPESP).

Index terms: Hymenoptera, Trichogrammatidae, collecting method, egg parasitoid.

[1629] CHARACTERIZATION OF THREE SPECIES OF THE GENUS TRICHOGRAMMA

R. B. Ouerino¹, **R. A. Zucchi¹**, **A. I. Ciociola Jr.¹**, **C. L. Canete²**, & **L. A Foerster²**, ¹ Dep. de Entomologia, Fitopatologia e Zoologia, Univ. de São Paulo, ESALQ, Av. Pádua Dias 11, C. Postal 09, 13418-900, Piracicaba, São Paulo, Brazil, E-mail rbqsilva@carpa.ciagri.usp.br. ² Dep. de Zoologia, Universidade Federal do Paraná, C. Postal 19.020, 81531-990, Curitiba, Paraná, Brazil.

The separation of the species Trichogramma rojasi, T. lasallei and T. bruni based on morphological characters are discussed. T. lasallei (first record in Brazil) and T. rojasi were obtained from Anticarsia gemmatalis eggs on soybean, T. bruni was collected from Heliconius phyllis eggs (first host record) on wild passion fruit (Passiflora sp.) A morphometric study based on principal component analysis (multivariate statistical method) was conducted to characterize these three species and find out the characters which more contributed to distinguish them. The result shows that species are grouped differently and characters related to fringe setae of the forewing, setae scutellum and mesoscutum and male genitalia are more reliable to separate these species. T. lasallei and T. rojasi are dark species with a sclerotized genital capsule. T. lasallei can be separated by more anterior position of the ventral processes, the short setae posterior track of the hind wing and the ventral ridge linear, moderately long (anterior limits difficult to discern in slide material). In T. rojasi the ventral processes are positioned near to intervolsellar processes base, setae posterior track of the hind wing reaches the wing apex. T. bruni is yellow and differs primarily by having scutellum with the shorter anterior pair of setae difficult to see, ventral ridge linear more elongate (anterior limits visible), the shorter length of the posterior extension of the dorsal lamina and flagellum of antenna with basiconic peg sensilla (BPS) formula 2-2-2-0-1-1. However, in some specimens the BPS at 4th position can be found. Crosses (heterogamic and homogamic) between T. lasallei and T. bruni were developed and the results show incompatibility between them (research supported by FAPESP).

Index terms: Hymenoptera, Trichogrammatidae, Systematic, Egg parasitoid.

[1630] PARASITOIDS OF CITRUS PESTS IN REUNION ISLAND (INDIAN OCEAN)

S. Quilici, CIRAD-FLHOR Réunion, Laboratoire d'Entomologie, BP180, 97455, Saint-Pierre Cedex, France. E-mail quilici@cirad.fr

Reunion Island is a French overseas department in the west of the Indian Ocean. Citrus crops, which have been developped there since the last thirty years, are attacked by a variety of pests. The Citrus Greening Disease (CGD) has long been a major limiting factor of citrus growing. Until the 1980's, it was transmitted by the african psylla Trioza erytreae and the asian psylla Diaphorina citri. Among major pests are aphids transmitting the CTV (Citrus Tristeza Virus), particularly Toxongra citricidus and Aphis gossypii, different species of fruit flies (Ceratitis rosa and C. capitata), the Citrus Rust Mite (Phyllocoptruta oleivora), the South African Citrus Thrips (Scirtothrips aurantii), the Citrus Flower Moth (Prays citri), and various species of scale insects. More recently, the Citrus Leafminer (Phyllocnistis citrella), has been recorded in the island. The Wooly Whitefly, Aleurothrixus floccosus, for a long time a major pest, has been successfully controlled biologically. During the last thirty years, parasitoids have been used in classical biological control programs conducted by CIRAD scientists against citrus pests. The programme against the vectors of CGD can be considered a case-study of successful biocontrol in an island. While the introduction of the eulophid Tamarixia dryi (1974) allowed the eradication of T. erytreae at the beginning of the 80's, the introduction of Tamarixia radiata (1978) led to a drastic reduction in the populations of the asian psylla. A very favorable biological equilibrium also followed the introduction of Cales noacki against the Wooly Whitefly in 1976. More recently, the successful introduction of Ageniaspis citricola in 1997 enabled us to improve the natural control of the Citrus Leafminer. Indigenous parasitoids may play a prominent role in the natural control of various citrus pests, as in the case of the large parasitoid complexes associated with lecanid or diaspid scales. The Margarodidae Icerya seychellarum is under very good control by the combined action of the ladybird Rodolia chermesina and the dipteran parasitoid Cryptochetum sp.. Five indigenous parasitoids play a major role in the control of the Citrus Leafminer. Aphids are also attacked by various species of Aphidiidae and Aphelinidae, with a variable degree of control. In other cases, the contribution of parasitoids to the natural control of the pest seems much less effective, like for fruit flies, for which parasitoids contribute as a minor mortality factor on wild host-plants. The possible side-effects of classical biocontrol must be thoroughly considered before any operation, particularly in the case of fragile island ecosystems. Current and future programmes will only consider the possibility of using parasitoids with the narrowest possible host-range. In the meantime, the knowledge of the local entomofauna has considerably progressed, allowing a better prevision of possible side-effects.

[1631] TEN YEARS OF STUDIES ON PARASITODS OF THE PEAR PSYLLA, CACOPSYLLA PYRI, IN SICILY (RHYNCHOTA PSYLLOIDEA)

<u>C. Rapisarda¹</u>, G. Siscaro¹, S. La Morella¹, S. Beninato², G. Campo², ¹Dip. di Scienze e Tecnologie Fitosanitarie, Sez. Entomologia agraria, Univ. of Catania, Via Valdisavoia, 5, I-95123 Catania, Italy, E-mail rapicar@mbox.unict.it; ²Osservatorio per le Malattie delle Piante, Corso Umberto, 114, I-95024 Acircale, Italy.

Studies on the parasitic complex of pear psylla, Cacopsylla pyri (L.), are carrying on from 1990 in Sicily, mainly in fruit orchards occurring in the area of Mount Etna. Springsummer observations have been based on periodical collections from foliage of parasitized nymphs of the psyllid and their isolation up to parasitoid emergence; similarly, winter studies have been carried on parasitized psyllid nymphs collected from branches and trunks of the plants, inside the bark cracks. For evaluating the total parasitization, adult emergence has been compared between C. pyri and its parasitoids, in stocks of 200 infested leaves collected during summer-autumn. Among primary parasitoids, the occurrence has been evidenced in the investigated area of three species of Hymenoptera Encyrtidae: Prionomitus mitratus (Dalman), P. tiliaris (Dalman) and Trechnites psyllae (Ruschka), all reported to develop on various pear- and hawthorn-feeding Cacopsylla species. Both the two species of Prionomitus are biparental, while T. psyllae is supposed to be parthenogenetic and no males have been ever collected in Sicily. Relative incidence of the three species showed to be variable in the investigated area. Compared to central European and North Italian environments, *P. mitratus* seems to have a lower diffusion and its occurrence never exceeded the 30% of the total parasitoid population; it has been mostly obtained from C, pyri nymphs during summer [June-July] and only in a few cases it overwintered on this host (rarely representing more than 10% of the overwintering parasitoid population). A higher frequence has been showed by P. tiliaris and T. psyllae, but with patterns of distribution and abundance differing even between close biotopes. P. tiliaris appeared to be the prevalent species (from 70 to 100% of total parasitoid population, both in summer and in winter) in orchards where IPM is applied, but showed lower levels, and very rarely exceeded 30% of the total parasitoid population, in orchards frequently sprayed with wide spectrum insecticides, where it seems to be replaced by T. psyllae. A different behaviour is shown by the two species also in their autumnal resurgence, after summer treatments: T. psyllae has a hasty start and may be abundantly recovered from mid September; on the contrary, P. tiliaris takes a longer time and its action significantly starts again from mid of October. Total parasitization, due to the whole complex of the three mentioned species, highly depends on peculiar ecological situations: in orchards where IPM is applied it may reaches values close to 46%.

Index terms: Prionomitus mitratus, P. tiliaris, Trechnites psyllae, parasitic activity.

[1632] PREDATORS IMPAIRING PARASITOIDS IN THE NATURAL BIOLOGICAL CONTROL

<u>R. Reis Jr.</u> O. DeSouza & E. F. Vilela, Depto Biologia. Animal Universidade Federal de Viçosa. 36571-000, Viçosa - MG. E-mail: crysopa@insecta.ufv.br .

There are many situations in which strategies of the natural biological control are not technically effective, failing to keep insect pest populations below damaging levels. We analyze a well known case of this insuccess: the puzzling coexistence of the coffee leaf miner (Leucoptera coffeella) and its natural enemies. Despite being a suitable prey to eight parasitoid species and three wasp species, all occurring simultaneously, the coffee leaf miner too often presents populations far above the damaging level for the coffee plantation. The experiment was carried out in three commercial coffee plantations in the region of Vicosa, state of Minas Gerais, Southeastern Brazil. The coffee leaf miner have not been subjected to any non-natural kind of control in these plantations, for the last 10 years. A total of thirteen 100m rows of continuous coffee plants were chosen within the selected plantations, so that three rows were located in the smaller plantation and the other two plantations held five rows each. Rows were chosen so as to cover the widest spatial range within each plantation, observing a minimum inter-row distance of 100m along lines of coffee plants, and 50m across lines. Statistical analyses inspected the relationship between presence of predators and presence of parasitoids, at the local scale; and the pattern of resource exploitation by predators and parasitoids. Regression lines were fitted to the data, along with control variables, as appropriate. It is demonstrated that wasps and parasitoids interact negatively ($F_{[1;11]} = 7.98$; P= 0.0165), possibly because wasps kill parasitized miner's larvae. In doing so, wasps indirectly kill parasitoids, thereby impairing the efficacy of the natural biological control. Patterns of resource exploitation by predators and parasitoids overlap partially, with predators exploiting mines which are slightly larger than the mines attacked by the parasitoids (Predators $F_{11:6j}$ = 43.99; P= 0.0006; t^2 = 0.88. Parasitoids: $F_{11:6j}$ = 1165.18; P< 0.0001; r^2 = 0.99.). It is warned that biological control programs should be based on knowledge of food web interactions, rather than simply on strategies involving introduction of exotic natural enemies.

Index terms: Leucoptera coffeella, interguild interactions, coffee.

Symposium and Poster Session

[1633] EFFECT OF THE PREY DENSITY ON THE FUNCTIONAL AND NUMERICAL RESPONSE OF TWO SPECIES OF PREDACEOUS MITES

P.R. Reis, E.O. Sousa, A.V. Teodoro & M. Pedro Neto¹, ¹EPAMIG-CTSM, P. O. Box 176, Lavras, MG, 37200-000, Brazil, E-mail: rebelles@utla.br.

The mites of the Phytoseiidae family are the most important and studied natural enemies of pest-mites. A question raised is that whether phytoseiid may reduce high densities of phytophagous mites and the studies which bring that answer are that of functional response (number of preys consumed per unit of time) and numeric response (offspring produced per unit of time or another change in the predator density). It was objective of this work to evaluate the predation potential of *Iphiseiodes zuluagai* and *Euseius alatus* (Acari: Phytoseiidae) as biological control agents of the phytophagous mite Brevipalpus phoenicis (Acari: Tenuipalpidae) vector of citrus leprosis and coffee ringspot. The bioassays were performed in laboratory at 25 ± 2 °C, 70 ± 10 % of RH and 14 hours' photophase. An adult female of each predator, in independent experiments, was confined in 3 cm diameter arena made with citrus leaves, floating on water inside a Petri dish. Immature phases of *B. phoenicis*, preferred by phytoseiid for predation were placed at the following amounts / arena: 1, 2, 5, 10, 20, 30, 35, 45, 55, 70, 100, 125, 200 and 300. The number of preys consumed and eggs laid by the predator were evaluated every 24 hours when the number of prey was replaced to the initial amount, for eight days. To both the predator mites, a positive and highly significant correlation was found between the number of mites consumed and the ones given. The number of eggs/day increased in terms of the number of preys consumed with a positive and highly significant correlation. The number of B. phoenicis consumed per day by the predator mite I. zuluagai increased in terms of the number of mites given, reaching a maximum percentage of predation around 55 mites / day. The number of mites *B.* phoenicis consumed per day by the predator mite *E. alatus* also increased in terms of the number of preys offered, reaching a maximum amount between 5 and 35 mites / day, less than, therefore, that presented by I, zuluagai. At the lowest densities, E. alatus proved more efficient in predation than I. zuluagai. It may follow also that E. alatus may prevent the increase of the population of B. phoenicis even at low densities of the phytophagous mite. The results showed that I. zuluagai was a predator more efficient than E. alatus at the highest prey densities. The fact for E. alatus to need less prey than I. zuluagai suggests that its survival may be better than that of I. zuluagai under low prey densities in the field.

Index terms: Iphiseiodes zuluagai, Euseius alatus, Brevipalpus phoenicis, citrus, coffee

[1635] EVALUATION OF BIOLOGICAL CONTROL – BACILLUS SPHAERICUS 2362, EFFECTIVENESS AGAINST MALARIA VECTORS IN AMAZONIA

<u>I. B. Rodrigues¹</u>, W. P. Tadei¹ & J. M. S. C. Dias³, ¹ Instituto Nacional de Pesquisas da Amazônia, caixa postal 478, Manaus, AM, Brasil, E-mail brandao@inpa.gov.br; ²Embrapa – Cenargen Brasília, Brasil. Funding: PPG7-FINEP / ABBOTT

The occurrence of malaria reports in the Amazonian region has shown an increasing number of cases, despite everything that has been done, in order to fight it, partly, due to the easimess of the development of mosquitos vectoring this disease within this region. Laboratory bioassays indicated Bacillus sphaericos as a promosing agent for controling species in this region, (Rodrigues et al. 1999), as na alternative for controling these vectors in their larval stage. Studies were carried out in this paper on the effectiveness of varied formulations of Bucillus phaericos 2362 in different natural breeding sites. The types of breeding site tested were: the ones in the wild , tanks in fish cujtures, the ones close to the headwaters and along the motorway. These selected breeding sites are the ones more frequently found within urban and rural areas in this region. Formulations of Bacillus sphaericos 2362 tested in these experiments are already industrialized in liquid and granulated form and applications occurred through the conventional method used by National Health Foudation. Formulations were SPHERICO^R - Geratee do Brasil, VECTOLEX from the United States, GRISELESF - Labiofam de Cuba and dosings used were differenciated according to breding site. Results obtained pointed out that the predominant species were A. triannulatus (42%), A. nuneztovari (34%), and A. albitarsis (24%) for the fishculture tanks, species classified as eusinatropic (Forattini et. al., 1993;1995). For breding site close to the headwaters the predominant species was A. darlingi (90%) the main vector for malaria in Amazonia and A. argyritarsis (10%). Formulation Spherico^R being effective in the dose 0.2ml/m2 in readings of up to 72 hours and for a fortnightly reaplication period. For breading sites along the motorway a relevant observed aspect lies in the residual lasting capacity of Vectolex found in these conditions which is fifteen days before the appearence of younger instars larvae and thirty days for recolonization of the breeding site, observed by two months of testing. The most effective formulations were Vectolex and Spherico, the former one presenting a greater risidual lasting capacity than the rest for the kinds of breeding sites that were studied. The formulated Grisselesf needs further testin for better conclusions.

Index Terms: Malaria, Bilogical Control, Anopheles.

[1634] FIRST RECORD OF CHRYSOPERLA EXTERNA PREYING THE CITRUS LEAF MINER PHYLLOCNISTIS CITRELLA

LJ.Ribeiro¹, E. Berti Filho¹ & M. B. Antonio¹, ¹Departamento de Entomologia, Fitopatologia e Zoologia Agrícola, Escola Superior de Agricultura Luiz de Queiroz, Universidade de São Paulo, Avenida Pádua Dias, 11, Piracicaba, SP, 13418-900, Brasil, Email lribeiro@carpa.ciagri.usp.br.

The Citrus Leaf Miner (CLM) *Phyllocnistis citrella* (Lepidoptera: Gracillariidae) was detected for the first time in Brazil, in the south of São Paulo State, in 1996. Now it is distributed all over the country, in citrus orchards with different varieties and ages. The Lacewings are important predators in citrus orchards, but, to date only two species have been registred attacking CLM: *Mallada boninensis* and *Mallada basalis*. Among the species present in Brazilian orchards, *Chrysoperla externa* (Neuroptera: Chrysopidae) is the most frequent one, preying mainly aphids, scales, mealybugs, spider mites and white flies. The predation of the CLM eggs, larvae of the first, second and third instars, and pupae by first, second and third larval instars of *C. externa* is recorded for the first time. New tests with other species have been carried out in laboratory to establish the importance of lacewings on the control of the CLM.

Index terms: CLM, lacewing, predator, biological control, citrus

[1636] PARASITISM RATE BY LYSIPHLEBUS TESTACEIPES (HYM.: APHIDIDAE) ON SCHIZAPHIS GRAMINUM AND APHIS GOSSYPH (HEM.: APHIDIDAE)

<u>S. M. M. Rodrigues</u>¹ & V. II. P Bueno¹, ¹Dept. of Entomology, Federal Univ. of Lavras, P.O. Box 37, Lavras-MG-BR, 37.200-000, E-mail: smmorais@ufla.br, vhpbueno@ufla.br

This work aimed to estudy the parasitism rate of the parasitoid Lysiphlebus testaceipes on Schizaphis graminum and Aphis gossypii with and without choice tests. For the tests, 10 colonies of S. graminum and 10 of A. gossypii with 20 nymphae of 2^{nd} and 3^{nd} instars were utilized. A female of L. testaceipes one day old, previously mated and without prior oviposition experience was utilized, its stayed in contact with the aphids for 24 hours. In with choice test, the parasitism rate was 67 and 46% for S. graminum and A. gossypii, respectively. In without choice test, a parasitism rate of 76% was obtained for S. graminum and a parasitism rate of 56% for A. gossypii. The aphid S. graminum showed more suitable for multiplication of the parasitoid L. testaceipes. Index terms: aphidis, aphidiid, biological control.

Symposium and Poster Session

[1637] LARVAL ENDOPARASITOIDS OF EPINOTIA APOREMA (LEPIDOPTERA:TORTRICIDAE) IN THE PROVINCE OF BUENOS AIRES, ARGENTINA

G. C. Rojas & G. G. Liljesthröm, CEPAVE. Calle 2 N° 584 (1900). La Plata. Argentina. E-mail cepave@museo.fcnym.unlp.edu.ar

Epinotia aporema feeds on different leguminosae and is one the most serious pest species of soybean. The larvae develop through 5 instars, which commonly live protected in a sort of cartridge constructed by the apical leaflets that remain attached one another by a silken web. In this preliminary study the incidence of larval endoparasitoids on cultivated (Glycine max and Trifolium pratense) and spontaneous (Galega officinalis and Melilotus albus) leguminosae were analysed in the localities of Magdalena and La Plata. Between January'97 and January'2000, 10-40 2^{nd} -3rd instar larvae were collected every 15 days and reared in the laboratory. The number of parasitoids and living pupae were recorded. With respect to the parasitism detected on larvae feeding on the diffferent leguminosae, the preference index Forage Ratio was calculated from the total number of parasitoids and larvae collected on each plant. A total number of 772 larvae were collected: 44.9% on G. Officinalis; 39.8% on M. albus; 11% on G. Max and 4.3% on T, pratense. The overall parasitism was 35.5% (n=274) detected from mid-spring until mid-winter, and parasitism on the different leguminosae was, respectively: 28.5%; 45.5%; 29.4% and 33.3%. Two endoparasitoids were found: *Bassus* sp (Hymenoptera:Braconidae) (n=114) and an undetermined species of Icheumonidae (Hymenoptera) (n=160). The *Bassus* sp. was detected on *M. albus* (n=112; FR=2.5) from November until July and *G. Max* (n=2; FR=0.02) in January. The Ichneumonid species was found on hosts feeding on all leguminosae: G. Officinalis (n=99; FR=1.34); G. Max (n=23; FR=1.3); T. Pratense (n=11; FR=1.6) and M. albus (n=27; FR=0.42), and except on M. albus (where parasitism was detected from mid-February until July), on the other leguminosae the parasitism was detected from November until July. These results suggest that the endoparasitoids coincide rather poorly spacially and that the spontaneus leguminosae would be important reservoirs for these endoparasitoids.

Index terms: Epinotia aporema, parasitoids, Bassus sp, Ichneumonidae, host plant.

[1638] ANALYSIS OF THE BIOLOGICAL CONTROL OF THE *DIATRAEA* SACCHARALIS AT DIFFERENT SPATIAL SCALES: LACK OF CONTROL OR POOR DATA SET?

M. N. Rossi¹, H. G. Fowler², M. B. Thomas¹ & H. C. J. Godfray¹ Leverhulme Unit for Population Biology and Biological Control, NERC Centre for Population Biology and CABI Bioscience, Imperial College, Silwood Park, Ascot, Berks. SL5 7PY, U.K., E-mail mrossi@ic.ae.uk;² Dept. of Ecology, Unesp, P.O. Box 199, Rio Claro, S.P. 13506-900, Brazil.

The biological control of Diatraea saccharalis is regarded as one of the best examples of successful classical biological control in Brazil. Since the introduction of the exotic parasitoid, Cotesia flavipe, from Pakistan at the end of 1970's, the decrease in the D. saccharalis infestation in sugarcane fields has been attributed to the effectiveness of this agent. Recently, the native Tachinid flics (Lydella minense and Paratheresia claripalpis) have also been implicated in the success, although they are less abundant than C. flavipes in sugarcane fields. Quantitative data confirming the actual contribution of these different agents to control of D. saccharalis is, however, rather scant. The purpose of this study was to investigate if there is any evidence of temporal density dependence between D. saccharalis and its parasitoids operating at different spatial scales. To answer this question, a large data set comprising information collected from two sugar cane mills (Barra and Sao Joao sugarcane mills, Sao Paulo State, Brazil) was analysed. The data set contained information on the number of *D. sacharalis, C. flavipes* and Tachinid flies sampled monthly per 'Talhao' (smallest spatial resolution level) from 03/1984 to 03/1997 and 01/1983 to 12/1996 for the Barra and Sao Joao sugar mills, respectively. Regression analyses were conducted on host density against the rate of parasitism per month of the different parasitoids during the whole period of the samples. These regressions were done at three spatial levels: global scale (the whole sugarcane mill); regional scale (the sugarcane mills divided into four smaller areas); and an intermediate scale (the sugarcane mills divided into seven small areas). The results revealed no clear evidence of direct density dependence at any spatial scale for any parasitoid species. Rather, there was evidence for inverse density dependence operating in the parasitoid-host interactions. Unfortunately, the nature of the data set and the way the data were collected limits the extent of the analysis and the ecological insights to be gained. Thus, to answer whether the parasitoids mentioned above have really decreased the density of D. saccharalis in sugar cane fields over the last twenty years, better time series are required, combined with experimental investigations on specific aspects of spatial and temporal population ecology. Index terms: Cotesia flavipes, Tachinidae, density dependence, spatial scale

[1639] FUNCIONAL AND NUMERICAL RESPONSE OF ORIUS INSIDIOSUS (HEMIPTERA:ANTHOCORIDAE) FED ON APHIS GOSSYPII (HEMIPTERA:APHIDIDAE)

<u>S. M. Mendes¹</u> & V. H. P. Bueno¹, ¹Depto. de Entomologia, Univ. Fed. de Lavras, Caixa Postal 37, Lavras, MG, 37200-000, Brazil, E-mail smmendes@ufla.br

The effect of densities 10, 20, 30, 40, 50 and 60 nymphs of 1st, 2nd and 3rd instars of *Aphis* gossypii Glover on food consumption of *Orius insidiosus* (Say) was studied in climate chamber at a temperature 25 ± 1 °C, $70 \pm 10\%$ RH and 12h photophase. Nymphs of 2nd instar showed a linear increase on prey consumption, showing a type I functional response. However, nymphs of 1st, 3rd, 4th and 5th instars and adults presented an increase prey consumption according to the density, tended to stability (type II functional response). There were a significant influence on search time and handling time at different densities, both to adult and different instars of *O. insidiosus*. In general, shorter times were recorded at higher prey densities. Concerning the numerical response, the viability of nymphs were 46,67; 67,65; 46.20, 82.35, 77.78 and 75.78% at different densities analized. There were no significant differences for pre-oviposition and oviposition periods at different densities of *A. gossypii*, which were 4.80 and 8.90 days respectively. The percentage of females which oviposited were 16.67, 50.00, 70.00, 90.00 and 66.67%. The number of eggs laid per females was affected by the different prey densities, which were 2.00, 11.33, 10.67, 21.30, 17.89 and 53.38 eggs. The viability of those eggs also showed influence of the different densities of *A gossypii*, which were 0.00, 50.11, 62.46, 57.86, 58.14 and 72.89%. Index terms: predation, prey density, aphid

[1640] BIOLOGICAL ASPECTS AND PREDATION OF ORIUS INSIDIOSUS (ILEMIPTERA: ANTIIOCORIDAE) ON CALIOTHRIPS PHASEOLI (THYSANOPTERA: THRIPIDAE)

<u>S. M. Mendes</u>¹ & V.II. P. Bueno¹, ¹Depto. de Entomologia, Univ. Fed. de Lavras, Caixa Postal 37, Lavras, MG, Brazil, E- mail smmendes@ufla.br

The biological aspects and consumption of Orius insidiosus (Say) fed on Caliothrips phaseoli (Hood) were studied in climate chamber at a temperature 25 ± 1 °C, $70 \pm 10\%$ RH and 12h photophase. The nymphal development period was on the average, 10.2 days, and not showing any significant difference for both males and females. The young phase consisted of 5 instars, each one lasting, on the average, 1.93, 1.72, 1.38, 1.80 and 3.10 for the 1st, 2nd, 3rd, 4th and 5th instars respectively. The nymphal viability was 68.46 %, with the greatest mortality occurred at the 2nd (16%) followed by 1st (13.67%) and 3rd (4.67%). O. insidiosus preyed, on the average, 73.72 C. phaseoli throughout its young phase. The total average consumption of nymphs increases with the successive instars, its being 6.09, 8.96, 11.38, 16.75 and 29.30 thrips from 1st to 5th instars, respectively. The females oviposited, on average, 77.82 eggs with a viability of 71.60% and an average embryonic period of 5.26 days. The females' longevity was significantly longer (21 days) than the males was 60.67 thrips.

Index terms: thrips, biological control, prey consumption

[1641] POS-INTRODUCTION OF THE NATURAL ENEMY AGENIAPIS CITRICOLA IN CITRUS GROVES IN JAGUARIÚNA AND AGUAÍ REGIONS, SÃO PAULO STATE, BRAZIL: PRELIMINARY RESULTS

L. A. N. de Sá¹, V. A. Costa², F. J. Tambasco¹, W. P. de Oliveira³, G. R. de Almeida¹ & R. A. A. Pereira¹, ¹ Lab. de Quarentena "Costa Lima", Embrapa Meio Ambiente, Cx.P. 69, 13820-000, Jaguariúna, SP, Brasil, lans@cnpma.embrapa.br; ²Lab. de Controle Biológico, Instituto Biológico, Cx.P. 70, 13001-970, Campinas, SP, Brasil; ³CNPq Fellowship Brasília, DF, Brasil.

Phyllocnistis citrella (Lepidoptera: Gracillariidae) is a pest of economic importance to the Brazilian citriculture because it is associated to the increase of citrus canker. In 1998, as part of a classical biological control program, the exotic parasitoid Ageniaspis citricola was imported from Florida, USA, in a partnership among Embrapa Environment (Brazilian Quarantine Laboratory), Gravena Manecol, ESALQ/USP and Fundecitrus. The objective of this work was to study the field control of P. citrella by this parasitoid, in comparison with the native and most abundant parasitoid Galeopsomyia fausta in citrus groves of Jaguariúna and Aguaí regions, State of São Paulo. In each grove, 3 releases of A. citricola adults were done at monthly intervals in Jaguariúna, and weekly intervals in Aguaí. The parasitoid was released in a central point of the orchard. To check parasitism, 100 leaves attacked by P. citrella were collected monthly in each area. It was observed that the native species number changed according to the region. In Jaguariúna, parasitism by A. citricola was 20.0% and by G. fausta only 5.6%, while in Aguaí A. citricola achieved values of 3.0% and G. fausta 22.1%. As the temperature and relative humidity were similar in both localities, this difference should be explained by the period of the releases combined with the vegetation of the area. In Jaguariúna, A. citricola was released at the beginning of the citrus branching process, when the occurrence of *P. citrella* was higher, thus helping its establishment and multiplication. The situation in Aguaí was different because the branching process was not on its course when the parasitoids were released. Also, the vegetation was more abundant in this locality than in Jaguariúna, and because G. fausta is a native parasitoid, possibly it was easier to find alternative hosts to multiply and survive. Collection of data from those areas will continue to verify how the parasites proportion will be in the next years.

Index terms: Phyllocnistis citrella, Galeopsomyia fausta, comparison, classical biological control.

[1642] SURVIVAL AND FECUNDITY OF ANAGYRUS KAMALI (ENCYRTIDAE) UNDER DIFFERENT STORAGE CONDITIONS

L. A. Sagarra¹, <u>C. Vincent²</u> and R. K. Stewart³, ¹ P.R.T. Ltd, Orange Grove Estate, Tacarigua, Trinidad & Tobago, West Indies (present address: 7, rue de Plaisance, 94130 Nogent-sur-Marne, France); ² Horticultural Research and Development Centre, Agriculture and Agri-Food Canada, 430 Boul. Gouin, Saint-Jean-sur-Richelieu, QC, Canada J3B 3E6; ³ Department of Natural Resource Sciences, Macdonald Campus of McGill University, 21,111 Lakeshore, Ste-Anne-de-Bellevue, Quebec, Canada H9X 3V9

The parasitoid, Anagyrus kamali Moursi [Hymenoptera: Encyrtidae], has been recently introduced into the Caribbean as a biological control agent against the hibiscus mealybug (HMB), Maconellicoccus hirsutus Green [Homoptera: Pseudococcidae]. Storage of A. kamali as part of a biological control program against M. hirsutus should not affect the longevity of female and male parasitoids when kept at $20\pm2^{\circ}$ C and fed ad libitum with droplets of pure honey, these were 40.3 ± 14.07 and 31.7 ± 9.57 days, respectively. Increase of the storage temperature from $20\pm2^{\circ}$ C to $27\pm2^{\circ}$ C decreased the longevity of insects fed on pure honey by about 10 days. Fed females did not resorb eggs during the first two weeks of storage at $20\pm2^{\circ}$ C. Parasitoid ovigenesis ceased when ovarioles/lateral oviducts were full. The lifetime fecundity of parasitoids stored at $20\pm2^{\circ}$ C wan ot significantly affected by a storage period of up to 14 days. Foraging activities and oviposition were the main factors influencing the lifespan of female A. kamali since regardless of the storage period, parasitoid oviposition period was not significantly different.

Index terms: Anagyrus kamali, Encyrtidae, Hibiscus mealybug, Maconellicoccus hirsutus, Pseudococcidae, survival, storage conditions. parasitism

Symposium and Poster Session

[1643] THE INFLUENCE OF TEMPERATURE ON DEVELOPMENT AND LONGEVITY OF APANTELES SUBANDINUS AND ORGILUS LEPIDUS (HYMENOPTERA: BRACONIDAE)

L. Salehi¹ & M. A. Keller², ¹Dept. of Crop Protection, The Univ. of Guilan, Rasht, Iran, E-mail: salehi@kadous.gu.ac.ir; ²Dept. of Applied and Molecular Ecology, The Univ. of Adelaide, Waite Campus, Glen Osmond, South Australia, 5064, E-mail: mkeller@waite.adelaide.edu.au

The rate of development and longevity of the two braconid endoparasitoids of larval potato tuber moth (PTM)), *Phthorimaea operculella* (Lepidoptera: Gelechiidae) was assessed at five constant temperatures: 15, 20, 25, 30 and 35°C under 24hr light and 50%RH. Parasitised and unparasitised larval PTM were reared in modified cages and supplied with excess potato tubers. *Apanteles subandinus* is better adapted to very low and high temperatures than *Orgilus lepidus*. At 35°C most *O. lepidus* did not complete development, dying mostly in the pupa stage. At high temperatures *A. subandinus* had an advantage over its host, while growth of *O. lepidus* was retarded compared with that of PTM. The results of this study predict that *A. subandinus* and *O. lepidus* should be well-adapted to the South Australian environment over the range of temperatures from 15°C to 35°C and the species are complementary due to their differing responses to temperature . The results suggest that parasitism could be increased by inoculative releases of *A. subandinus* are cooler and *O. lepidus* could be released later when weather is warmer.

Index terms: Apanteles subandinus, Orgilus lepidus, Phthorimaea operculella, temperature.

[1644] REPRODUCTIVE CAPACITIES OF TWO PARASITOIDS OF POTATO TUBER MOTH

L. Salchi¹ & M. A. Keller².¹Dept. of Crop Protection, The Univ. of Guilan, Rasht, Iran, E-mail salehi@kadous.gu.ac.ir; ²Dept. of Applied and Molecular Ecology, The Univ. of Adelaide, Waite Campus, Glen Osmond, South Australia, 5064, E-mail mkeller@waite.adelaide.cdu.au

Reproductive capacities of two braconids, Apanteles subandinus and Orgilus lepidus, endoparasitoids of larval potato tuber moth (PTM), Phthorimaea operculella (Lepidoptera: Gelechiidae) were investigated. The results showed following advantages of the two parasitoids when their reproductive capacity is compared: 1) The realised fecundity of O. lepidus is higher than A. subandinus when they are exposed to various densities of PTM at $24^{\circ}C$; 2) female O. lepidus has a greater number of ovarioles that allow it to produce more eggs than A. subandinus; 3) female O. lepidus does not decrease in size in laboratory, but A. subandinus becomes smaller when kept in continuously laboratory culture, perhaps due to inbreeding; 4) fecundity of female A. subandinus is higher than O. lepidus at high temperature; 5) A. subandinus has the advantages of shorter developmental time and more generations per annum than O. lepidus; 6) in both species, there is essentially no preoviposition period; 7) both species have greater fecundity than their host. The results indicate that these species should cause complementary mortality of PTM and thereby increase the degree of biological control than either species alone

Index term: Apanteles subandinus, Orgilus lepidus Phthorimaea operculella, reproductive.

[1645] PARASITISM OF *APHIDIUS COLEMANI* VIERECK (HYMENOPTERA: APHIDIIDAE) IN DIFFERENT DENSITIES OF *MYZUS PERSICAE* (HEMIPTERA: APHIDIDAE)

M. V. Sampaio¹, V. H. P. Bueno¹ & R. Pérez-Maluf¹, ¹ Dept. Entomologia, Univ. Fed. de Lavras, Caixa Postal 37, Lavras, MG, 37.200-000, Brasil, E-mail vhpbueno@ufla.br.

The green peach aphid, Myzus persicae, is an important pest in Brazil. This species cause significant crop losses in potato, sweet pepper, and tomato by feeding activity and virus transmission. The aphid parasitoid Aphidius colemani, is a efficient natural enemy of green peach aphid and the host density may significantly influence in enemy-host dynamics, sex ratio, and search behaviour of the parasitoid. The objectives of this research are to determine the functional response of the parasitoid *A. colemani*, by the number of mummies formed and it sexual ratio at a temperature 21±1°C and densities 20, 40, 60 and 80 M. persicae on sweet-pepper leaves into a glass tube (25cm x 4cm). Ten mated females A. colemani (24h old) were tested for each density, for a period of 2h. Also were evaluated it functional response to the number of hosts accepted, as well as it search behaviour with observations made on a stereoscopic microscope, at a temperature 23±1°C, densities 0, 4, 8, 16 and 32 *M. persicae* on leaf discs of sweet-pepper leaves (43mm) into a Petri dish (50mm). One mated female A. colemani (24h old) was then introduced for a period of 30min (15min for parasitism and 30min for first visit time) into a Petri dish. Ten females parasitoids were observed for each density. A. colemani's functional response was of type II, both to the number of mummies formed (12.4; 22.7; 33.0 and 31.6) as to the number of hosts accepted (0; 4.1; 6.8; 13.2; and 19.2), with a gradative increase in the number of hosts utilised with the increase in host density till this became stable. The sexual ratio tended to favour the females (57.2; 52.44; 62.6 and 54.38% of the emerged parasitoids), not showing any significant influence in host densities (P≤0,05). The number of touches made by the parasitoid's antennae on their hosts (encounters) continued to increase with the increase in host density, showing a brusque increase at the highest density (32 hosts), indicating an increase in the parasitoid's search where the density of M. persicae was highest. The time of the first visit of A. colemani showed no alterations at the different densities when the hosts were present (varying from 1526.9 to 1638.0 seconds) however the parasitoid remained on the leaf disk for less time (340.1 seconds) when no hosts were present.

Index terms: Biological control, parasitoid, aphid, host density

[1646] HOST PREFERENCE OF APHIDIUS COLEMANI VIERECK (HYMENOPTERA: APHIDIDAE) FOR MYZUS PERSICAE (SULZER) AND APHIS GOSSYPHI GLOVER (HEMIPTERA: APHIDIDAE)

<u>M.V. Sampaio¹</u>, V.II.P. Bueno¹ & J.C. van Lenteren², ¹Depto. de Entomologia, Univ. Fed. de Lavras, Caixa Postal 37, Lavras, MG, 37200-000, Brasil, E-mail vhpbueno@ufla.br, ² Laboratory of Entomology, Wageningen University, P.O. Box 8031, 6700EH, Wageningen, The Netherlands.

The majority of Aphidiidae parasitoids attack a range of host species. The aphid parasitoid Aphidius colemani accepts Aphis gossypii and Myzus persicae as a host and is considered a potential biocontrol agent against these aphids. The host preference of A. colemani for 2nd and 3rd instar nymphs of M. persicae and A. gossypii was evaluated by determining the percentage of parasitized hosts and by observation of the search behaviour of parasitoids. Host preference by measuring the percentage of parasitized hosts in non-choice tests at a temperature 21±1°C and density 20 aphids on sweet-pepper leaves. Ten mated A. colemani females of 24h old were tested for each host species during a period of 2h. The observation of search behaviour in choice and non-choice tests, was evaluated by the number of encountered hosts, accepted hosts, the total number of larvae encountered and by the percentage of hosts with parasitoid's larvae inside. The observations were made with a stereoscopic microscope at temperature of 23±1°C, and a density of 16 aphids on leaf discs of sweet-pepper leaves (45mm) in a Petri dish (50mm). One mated female A. colemani (24-48h old) was then introduced for a period of 15 min into a Petri dish. Ten females parasitoids were observed for each treatment. All aphids were dissected 48h after parasitism. In non-choice tests parasitism was 52 and 75% for *M.persicae* and *A. gossypii*, respectively, and this points at a preference for the species A. gossypii. There was no difference in the percentage of emergence (85.95% for A. gossypii and 80.99% for M. persicae). There were no differences in the time of first visit and the number of encounters between the parasitoid and the two species of aphids in choice and non-choice tests. Preference can be concluded from the best acceptance of A. gossypii and by highest number of parasitoid larvae found on this aphid in both tests. The correlation between the number of stings of the ovipositor/host and the number of parasitoid larvae found in the host was positive and highly significant (R=0.92 and p=0.0001), thus showing that it is possible to estimate parasitism by observing the number of stings with the ovipositor (accepted hosts). Based on the percentage of hosts with larvae, no preference could be measured in the choice tests but in the non-choice test, A. colemani preferred A. gossypii. Concerning superparasitism, it was found that always only one larvae of A. colemani was found alive in a host and none of the parasitized hosts presented embryo nymphs inside them.

[1647] BIOLOGICAL ASPECTS OF EXOTIC PREDATOR CRYPTOLAEMUS MONTROUZIERI (COLEOPTERA: COCCINELLIDAE), REARED ON PLANOCOCCUS CITRI IN LABORATORY

N. F. Sanches¹, **E. S. Silva²**, **L. P. Santos² & R. da S. Carvalho¹**, ¹Embrapa Cassava and Fruit Crops, C.P. 007, Cruz das Almas, Bahia, 44.380-000, Brazil, E-mail: sanches@cnpmf.embrapa.br; ²College of Agriculture – Federal University State of Bahia – Cruz das Almas, Bahia, Brazil. Project granted by Banco do Nordeste S.A. – ETENE/FINEP

The exotic predator Cryptolaemus montrouzieri has been used commercially in programs of biological control of mealybugs and aphids in several countries. The objective of this work was to study some parameters of the biology of that exotic predador regarding to its multiplication. It was studied the capacity of laying eggs, the period of larval appearance, the duration of the larval, pré-pupal and pupal phases, the sexual maturity and total cycle of this exotic predador under laboratory conditions. The study was carried out in the Laboratory of Entomology of Embrapa Cassava and Fruit Crops, under temperature of 26±1°C, relative humidity of 65±10% and 12 hours photophase. After the individualization of the eggs and appearance of the larva of the predador in Petri plates (5 cm of diameter), it was offered as feeding substratum for the predator, nymphs, adults and ovissacs of the mealybug Planococcus citri reared in laboratory, using pumpkin Cucumis maximus Jacarezinho " as alimentary substract. The period for larval appearance lasted, on average, 5 days. It was observed that the larval phase presents 4 instars or stages with average duration of 15.5 days (minimum: 14 days and maximum:17 days). The pré-pupa phase lasted, on average, 2.5 days (min.: 01 day and max.: 04 days). The pupal phase lasted on average, 7.3 days. The total cycle (egg to adult's emergency) lasted, on average 30.2 days (mín.: 28 days and max.: 32 days). The adults' medium longevity was of 72.4 days (min.: 02 days and max .: 122 days). The sexual maturity was reached, on average, 2.7 days after adults' emergency. The females presented high laying eggs capacity. On average they laid 811.4 eggs (min.: 197 and max.: 2.220) during all their longevity. The average daily laying capacity was of 16 eggs (min.: 4.4 and max.: 26.4) and average viability was 62% thus demonstrating high reproductive capacity of that predator species when reared in laboratory.

[1648] FUNCTIONAL RESPONSE OF CYCLONEDA SANGUINEA (COLEOPTERA : COCCINELLIDAE) AT DIFFERENT DENSITIES OF THE APHID MYZUS PERSICAE (HOMOPTERA: APHIDIDAE)

L.V.C. Santa-Cecília¹, R. de C.R. Gonçalves-Gervásio¹, R.M.S. Tôrres¹, F.R. Nascimento¹ & , M.V. Sousa.¹, ¹EPAMIG-CTSM P.O.Box 176, 37200-000 Lavras, MG, Brazil. e-mail: soccilia@ufla.br

Among the coccinelides *Cycloneda sanguinea* (Linnaeus, 1763) stands out as an efficient predator, both at the larval and adult phase of several aphid species. With a view to studying the functional response, search and handling time of the prey by the predator *C. sanguinea*, an experiment was set up in climate chamber at 25 ± 2 °C, $70 \pm 10\%$ of RH and 12 hour's photophase. As the food, third stage nymphs of the aphid *Myzus persicae* (Sulzer, 1776) were given. For the study of the search and handling time, the randomized block design in factorial scheme, was employed, the factors being made up from 6 densities of the prey (40, 60, 80, 100, 120 and 140) and of the sex of the predator (male and female). In determining the intake, the same design was utilized, employing, however, the split plot scheme, in time, the plots being constituted of the different densities and the sub plots of the predator's sex, taking into consideration also the time factor (24 and 48 hours). The search time was longer for the males and decreased in a linear form with increase of the prey's density, the handling time was not affected either by the different densities and the site and or by the predator's sex. An increased consumption of preys in terms of the increase of its density was found.

Index terms: Insecta, predation, functional response.

ABSTRACT BOOK I – XXI-International Congress of Entomology, Brazil, August 20-26, 2000

[1649] BEMISIA TABACI BIOTYPE B (HEMIPTERA: ALEYRODIDAE) AND ITS PARASITOIDS: GUADELOUPE ISLAND AS A REPRESENTATIVE SITE OF THE CARIBBEAN

N. Snuvion¹, C. Pavis¹, A. Hue⁴, M. Rousseau⁴, G. Deivare⁴, F. J. Martine Boissot¹, ¹INRA, Centre Antilles-Guyane, Domaine Duclos, 97170 Petit-Bourg, C²27DAD Av Agronolis, BP 5035. , C. Pavis¹, A. Huc¹, M. Rousseau¹, G. Delvare², F. J. Morales³ & N. Guadeloupe, F.W.I., E-mail: sauvion@antilles.inra.fr ²CIRAD, Av. Agropolis, BP 5035, 34032 Montpellier Cedex 1, France ³CIAT, A.A 6713 Cali, Colombia.

Over the past decade, the whitefly Bemisia tabaci Gennadius has caused extensive damage to cucumber, melon and tomato on the Caribbean island of Guadeloupe (Lesser Antilles). Recent collaborations have led to the characterization by RAPD, with primers H9, H16 and F12, of B. tabaci from Puerto Rico, Guadeloupe, Martinique and Trinidad. We have observed the population dynamics of B. tabaci, on experimental plots of squash (Cucurbita moschata), and we have also identified their parasitoids. The study areas were located at two sites on Guadeloupe: Petit-Bourg (INRA-Duclos) exhibits acidic oxisols with low fertility, humid tropical climate; annual rainfall 2.8 m, annual PET 1.3 m, average temperature 23.5°C, while Petit-Canal (INRA-Godet) is characterized by neutral swelling clay soils, humid tropical climate with a marked dry season; annual rainfall 1.6 m, annual PET 1.5 m, average temperature 26°C. Both sites are surrounded by a mosaïc of sugarcane, food crop parcels and natural forest at less than one kilometer. It is of special value to perform such studies on Guadeloupe, because this one island exhibits a suite of vegetation, climatic and geographic conditions that are more often found individually on the other Caribbean islands. Our RAPD results show that Bemisia from Puerto Rico, Guadeloupe, Martinique and Trinidad is biotype B - the same as that found in Australia, Colombia, France and the USA. The observation of population dynamics revealed that the Bemisia populations at Duclos are small throughout the year - less than five adults per leaf. At Godet, however population sizes were generally larger, particularly during July, when as many as 20 adults per leaf could be found. Eight species of parasitoids were found at Duclos (Encarsia transvena, E. formosa, E. tabacivora, E. strenua group, E. parvella, E. aff. hispida, E. aff. basicincta and Amitus bennetti) and only three at Godet (E. transvena, E. tabacivora and E. nigricephala). At Duclos, E. transvena is the most abundant species throughout the year, and thus seems to be better adapted to humid conditions. From January to July, E. aff. basicincta and E. tabacivora are present and competing with E. transvena. The others are quite rare. Studies such as these will aid in developing a biological control component in a management strategy which will limit direct damages due to B. tabaci biotype B on cucurbitaceae or to minimize impact of begomovirus on tomatoes in Lesser Antilles and other world regions as well.

[1650] COEVOLUTION OF CONTRARY CHOICES IN HOST-PARASITOID SYSTEMS

S. J. Schreiber¹, L. R. Fox², & <u>W. M. Getz²</u>, ¹ Department of Mathematics, Western Washington University, Bellingham, WA 98225, USA; ²Department of Biology, University of California, Santa Cruz, CA 95064, USA; ² Division of Insect Biology— California, Berkeley, CA 94720. USA, email: University of EPSM. getz@nature.berkeley.edu

Our study investigates host egg-laying and parasitoid search preferences in patchy environments. Previous work showed that when only host traits were allowed to vary among patches, populations playing an ESS strategy conform to an ideal-free distribution, make congruent choices (i.e. hosts and parasitoids preferentially select the same patches) and exhibit direct density-dependence in percent parasitism. However, host-parasitoid systems in the field show a range of density relationships and behavioral studies have shown that host-parasitoid systems can exhibit contrary choices (i.e. hosts avoid the patches favored by the parasitoids). We extend previous ESS analyses by permitting life history traits of the parasitoid as well as of the host to vary between patches. The results confirm the central role of reproductive ideal free distributions in evolutionarily stable systems. Specifically, if N_i and P_i respectively are the host and parasitoid equilibrium densities when the habitat only consists of a single patch of type i, then the ESS strategy for the host population in the patchy habitat is to lay the proportion $N_{i}(N_{1}+..+N_{n})$ of its total egg production in patch *i* and the ESS strategy for the parasitoid population in the patchy habitat is to spend the proportion $P_i(P_1+..+P_n)$ of its total search time in patch *i*. From these expressions, we show how variations in life history traits between patches lead to contrary choices or congruent choices, or lead to direct density-dependence, inverse density-dependence or density-independence in the distribution of percent parasitism. For instance, if there is a patch which is marginal for the hosts and parasitoids (i.e. the intrinsic rate of growth of the host and the survivorship rate of the parasitoid are low), then the populations exhibit contrary choices. We perform a stability analysis of the ESS and show that when a patch is marginal for the hosts and parasitoids, populations playing the ESS always stabilize intrinsically unstable within-patch dynamics. Index terms: evolutionarily stable strategy, ideal free distribution

[1651] PREDATORS OF FRUIT FLY ANASTREPHA SPP (DIPTERA, TEPHRITIDAE) COLLECTED WITH PIT FALL TRAPS IN PSIDIUM GUAJAVA ORCHARDS UNDER REGULAR APPLICATION OF INSECTICIDE

K.C.A. Senô¹ & J.C. Galli¹, ¹ Dept. of Fitossanidade, University of São Paulo State. Rod. Prof. Paulo D. Castellani – km 5, CEP 14884-900, Jaboticabal-SP, Brasil. E-mail: seno@asbyte.com.br; jcgalli@fcav.unesp.br

Due to the lack of information about natural biological regulation of Anastrepha spp (Diptera, Tephritidae) fruit fly population in Brazil, which difficult the implementation of integrated control programs for these insects, and the sanitation of fruit production, this research was developed in Vista Alegre do Alto, São Paulo State, and University of São Paulo State, in Jaboticabal-SP. This research was carried out with two objectives: a) to study the performance of apparatus for the capture of fruit fly predators (pit fall traps) in the soil; b) to study the fluctuation of predators. For a period of 12 months, starting on March 1999, insects of the Labiduridae family and other predators were captured. It was not observed statistical differences between populations of Labiduridae in areas treated and not treated with insecticide fenthion. The population fluctuation and influence of relative humidity on predators were discussed.

Index terms: Dermaptera, trap, natural enemies.

[1652] EFFECTIVE PRESERVATION METHODS OF THE ASIAN LADYBIRD, HARMONIA AXYRIDIS (COLEOPTERA: COCCINELLIDAE), APPLICATION STRATEGY FOR BIOLOGICAL CONTROL OF APHIDS COCCINELLIDAE), AS

& Y. N. Youn¹, ¹dept. Of Agriculture Biology, Coll. Of Agriculture, M. J. Seo¹ E-Mail 305-764. Korea. National Univ. Taejon, Chungnam Youngnam@Hanbat.Chungnam.Ac.Kr

progress in the knowledge of mass rearing and preservation methods of aphid predators has been considered as one of the most important conditions for the realization of their control potential, coccinellids have been widely used in biological control for over a century, and methods for using these predators have remained virtually unchanged. to use of a ladybird beetle for the biological control of insect pests properly, mass collection and efficient preservation of ladybird beetle overwintering population is very important, the asian ladybird, harmonia axyridis, is easily collected annually at overwintering sites from mid november to march in the next year, so it is able to store as adults without any special rearing methods, as a result of considering the effective preservation methods of h. axyridis, it was possible to preserve ladybird overwintering population in fabix plastic box or milk paper pack at 4°c and 8°c without diets over 4 months showing the 84% survival rate. also, in the case of preserving the 3rd and 4th instar larva with microwave popcorn, it was able to decrease cannibalism by reducing contact frequency between individuals. although preserving efficiency somewhat decreased, it was possible to store ladybird larva with microwave popcorn up to 10 days without preys, after preservation with microwave popcorn in the incubator at 10°c, the feeding ability related to preservation was investigated. in result, there was no difference in ability of prey feeding between the normal and preserved individuals. finally, the 3rd and 4th instar larva which were preserved with microwave popcorn were released in a strawberry greenhouse where the strawberry capitophorus aphid and the strawberry root aphid were occurred. after released, for a month, aphid densities were investigated per 1 week, that was a result of concentrative predation by released ladybird larva in that aphid density continuously decreased and then there was no rising of aphid density again after release.

[1653] EFFECT OF ANT TENDING ON BIOLOGICAL CONTROL OF THE PINK HIBISCUS MEALYBUG ON ST. CROIX, US VIRGIN ISLANDS

M. S. Serrano¹ & <u>S. L. Lapointe²</u>, ¹ USDA, ARS, U.S. Horticultural Research Laboratory, PO Box 3008 Kingshill, St. Croix VI 00851, USA; ² USDA ARS, USHRL, 2001 South Rock Road, Ft. Pierce FL 34945, USA, E-mail slapointe@ushrl.ars.usda.gov.

The pink hibiscus mealybug Maconellicoccus hirsutus was introduced to the Caribbean basin in 1993. Subsequently, it has spread throughout the Lesser Antilles, Puerto Rico and Northern South America. Recently it was detected in the US mainland as well as in Mexico, Belize and other Central American countries. Most Caribbean countries where the post has been detected have established biological control programs based on several natural encinies including the predatory coccinellids Cryptolaemus montrouzieri and Scymnus coccivora and the parasitoids Anagyrus kamali, Gyranusoidea indica and Leptomastix sp. (Hymenoptera: Encyrtidae). An introduced mealybug species can be considered a new resource for resident ant species commonly found tending native mealybug species. On St. Croix, US Virgin Islands, we have observed that pink hibiscus mealybug colonies are tended by at least three ant species. It is known that ant-tending can affect the effectiveness of parasitoids. Parasitism by A. kamali was reduced by 15 20% in ant-tended mealybug colonies compared with colonies not yet adopted by ants, or colonies where tending ants were artificially removed with an insecticide treatment. The impact of ant tending on the effectiveness of biological control on the island ecosystems of the Caribbean has been largely overlooked. Implementation of a biological control program should consider the potential of ants to disperse mealybugs and to contribute to pest outbreaks by diminishing the effectiveness of biological control agents. The impact of ants on biological control of M. hirsutus will be discussed.

Index terms: Maconellicoccus hirsutus, biological control, parasitoids.

[1655] A MICRO-OVIPAROUS TACHINID PEXOPSIS PILOSA (DIPTERA: TACHINIDAE) PARASITIC ON SCARABAEID BEETLES IN JAPAN

II. Shima & R. Ichiki, Biosystematics Lab., Graduate School of Social and Cultural Studies, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810-8560, Japan, E-mail shimarcb@mbox.nc.kyushu-u.ac.jp.

Pexopsis species of the tribe goniini are known as tachinid parasitoids of scarabaeid beetles, and are characterized by the micro-oviparous habit. female flies of this tribe lay incubated microtype eggs on the host plants of host insects. when eggs are swallowed by host insects, they hatch in the host midgut and first instar larvae penetrate the host haemocoel. pexopsis pilosa is commonly found in japan during may to early july, but its host has been unknown, we observed the oviposition habit of this fly and conducted an experiment in which adults of a scarabaeid beetle, pledina castanea, were parasitized. pexopsis pilosa lay microtype eggs on flowers, as well as leaves, of chrysanthenums. this suggests that flower eating scarabaeids may serve as hosts together with leaf eating bcetles. when broad leaves were supplied, female flies tended to oviposit on the marginal area of leaves. eggs are very peculiar in shape: elongate, 0.56-0.6 mm long and 0.36-0.4 mm wide; chorion covered with transparent secretion; black hardened area on anterior 3/5, bullet-shaped in dorsal view, with posterior margin enlarged and strongly serrate, bearing weak reticulation dorsally; posterior area of egg soft and translucent, slightly narrowed to rounded posterior apex, second instar larvae were found in the thorax of host beetles with respiratory funnel attached to the host thoracic spiracle or spiracular tube. no larva was found in other parts of the host body. it is possible that fly larvae fed on host thoracic muscles, when more than two eggs were consumed by a host, at most two reached 2nd instar, but only one mature larva survived and emerged from the dorsal intersegmental membrane of the host abdomen. females of p. pilosa have 173-192 ovarioles per ovary. in mature females four oocytes were found in an ovariole, of which one is developed. in addition, the vagina is well developed and coiled containing 1,143-2,102 eggs in mature females.

index terms: parasitoid, tachinidae, oviposition, ovarioles, pledina castanea.

[1654] COMPATIBILITY OF ENTOMOPATHOGENIC NEMATODES AND F-1 STERILITY FOR MANAGING SPODOPTERA LITURA (LEPIDOPTERA, NOCTUIDAE) : PARASITOID RESPONSES AND HOST SUITABILITY

R. K. Seth & V. Baweja, Department of Zoology, University of Delhi, Delhi 110007, India.

Potential of entomopathogenic nematodes (EPNs) in conjunction with inherited (F-1) sterility technique, was assessed for evolving an effective control strategy for a serious Indian pest, Spodoptera litura. Substerilizing gamma doses (100Gy, 130Gy) employed in the F-1 sterility technique were evaluated for determining the suitability of F-1 progeny of irradiated insects as potent hosts for the EPNs infectivity. The entomogenous nematodes belonging to families Heterorhabditidae and Steinernematidae were evaluated in the present studies. Infectivity tests were conducted using filter paper bioassay and soil Per cent host mortality in unirradiated S. litura larvae bioassay. caused hy Heterorhabditis sp. was higher (>90%) than the mortality caused by Steinernema glaseri (ca. 80%). Per cent parasitization in F-1 progeny of S. litura, at 100Gy, by H. bacteriophora, H. indicus and S. glaseri, were observed to be 80.3%, 72.5% and 60.0%, respectively. The parasitization efficiency was further reduced at 130Gy. Harvesting potential of the nematodes was reduced in F-1 hosts at both the doses, in comparison to normal. The emergence of dauers indicated a different pattern in different species. The harvesting was significantly more in Heterorhabditis sp. than in S. glaseri. For instance, in normal (unirradiated) insects, the harvesting of dauers of H. bacteriophora from host was up to the level of 3.64 x 10⁵, and dauer emergence was 1.27×10^5 in case of H. indicus, whereas dauer emergence was about 3.07×10^4 in case of S. glaseri. Soil bioassays were conducted to ascertain the searching efficiency of the EPNs towards F-1 host larvae, in comparison to EPNs responses towards unirradiated hosts. The interaction of host density and radiation was assessed on bioinfectivity of EPNs. Host searching efficiency was determined in terms of area of discovery. The searching efficiency was increased with increase in host density in normal as well as F-1 host larvae. Although the normal insect hosts elicited better parasitization response by EPNs than F-1 insect hosts, but the suitability of F-1 insects was reasonably demonstrated. This reduced response of parasitization in F-1 insect hosts could be attributed to the deleterious effects inherited in the F-1 progeny of sub-sterilized insects employed in F-1 sterility technique for pest suppression. These studies indicate that biocontrol strategy using EPNs might be integrated with F-1 sterility technique for the management of S. litura.

Index terms: Entomogenous nematodes, Heterorhabditis, Steinernema, integrated pest management, inherited sterility

[1656] CONTROL OF PLANTHOPPERS AND LEAFHOPPERS IN RICE BY THE SPIDER ATYPENA FORMOSANA

L. Sigsgaard¹, S. Toft² & S. Villareal¹, ¹Entomology and Plant Pathology Division, International Rice Research Institute, P.O. Box 3127, MCPO 1271 Makati City, Philippines, E-mail: l.sigsgaard@cgiar.org; ²Univ. Aarhus, Dept. of Zoology, Bldg. 135, DK-8000 Aarhus C, Denmark.

Atypena formosana (Araneae: Linyphiidae) is the most important linyphiid in the rice ecosystem and surrounding areas such as levees, bunds and grassy areas, and is already in the rice field shortly after crop establishment. Both adults and immatures are found in the rice stem or at the base of rice hills, with more spiders in the canopy at night. A. formosana hunt for nymphs of planthoppers and leafhoppers, Collembola, and small dipterans, and may be a significant predator of small-bodied pests such as hopper nymphs, being a possibly important part of the complex of natural enemies that check hoppers in unsprayed irrigated rice. Studies of functional and numerical responses of A. formosana have demonstrated its potential to control populations of brown planthopper (BPH), Nilaparvata lugens (Hemiptera; Delphacidae) and green leafhopper (GLH), Nephotettix virescens (Hemiptera: Cicadellidae). The predation rates of A. formosana on BPH and GLH are high when assessed in cage experiments. The best fit was obtained with Hollings type II equation using the random predator model. Biological control of BPH and GLH may depend on a high density of predators in the field early in the cropping season. In order to support a high density of Linyphilds in the field, a community of alternative prey would be advantageous, depending on the quality of the alternative prey. We assessed the survival and development time of A. formosana on four different diets; BPH, GLH, Collembola (Entomobryidae), a mixed diet, and a control of no food. Survival differed significantly among the diets. Survival to adult was poor on pure diets of GLH and BPH, and best on Collembola and mixed diets. Spiders developed fastest on the mixed diet and the Collembola diet. Fecundity of adult spiders was lowest on pure diets of BPH, GLH, and BPH and GLH mixed, while diets of alternative prey (Collembola, Drosophila) and other prey mixtures resulted in higher fecundities. The relevance of these findings to biological control of hoppers in rice will be discussed.

Index terms: Nilaparvata lugens, Nephotettix virescens, Collembola, biological control, alternative prey
Session 08 - ENTOMOPHAGOUS INSECTS AND BIOLOGICAL CONTROL

[1657] EVALUATION OF THE PREDACIOUS CAPACITY OF CRYPTOLAEMUS MONTROUZIERI (COLEOPTERA: COCCINELLIDAE) IN ORTHEZIA PRAELONGA, PLANOCOCCUS CITRI AND DYSMICOCCUS BREVIPES

E. S. Silva¹, <u>N. F. Sanches²</u>, L. P. Santos¹ & R. da S. Carvaiho², ¹College of Agriculture - Federal University State of Bahia – Cruz das Almas – Bahia; ²Embrapa Cassava and Fruit Crops, P. O. Box 007, Cruz das Almas, Bahia, CEP: 44.380-000, Brazil, E-mail: sanches@enpmf.embrapa.br.

Cryptolaemus montrouzieri is a predator largely used on biological control of mealybugs and aphids. The objective of this work was to evaluate the predacious capacity of this predator on three cochineals species: Orthezia praelonga, Planococcus citri and Dysmicoccus brevipes . The experiment was carried out at the Entomology Laboratory of Embrapa Cassava and Fruit crops, under temperature of 26±1°C, 65±10% RH and 12 hours photofase and under environmental conditions (temp.: 28±1°C ; 75±5% RH). Specimens of C. montrouzieri recently emerged were individualized in Petri plate (5 cm diameter). Twenty individuals of C. montrouzieri (10 individuals/each environment) were evaluated for each one of the studied species of cochineal. The mealybugs P. citri and D. brevipes were obtained by growing them in laboratories, using as substratum pumpkin Cucumis maximo. The cochineal O. praelonga was obtained from infested plants of barbados cherry grow under green house conditions. O. praelonga: the predator C. montrouzieri consumed on average 0.7 nymphs in the 1st instar, 1.8 nymphs in the 2nd instar. The predador fed exclusively on O. praelonga doesn't complete the ecdise process, ocurring death in all the observed larval phases. In the adult phase it was able to predate O. praelonga in all phases of its cycle. On average it consumed 26.3 nymphs; 4.6 adults and 6.1 ovissacs of the female. The medium longevity of the predator was of 2.3, 6.3 and 7 days, in the 1st and 2nd instar and adult phase, respectively. Under environmental conditions there were no significant alterations. *P. citri*: during its larval phase the predator consumed, in average 0.1- 3.2 - 12.9 and 25.3 adults of P. citri, respectively. In the adult phase the predator consumed daily, on average, 3.92 adults cochineals. The medium number of ovissacs predated by the 1st, 2nd and 3°s. larval instars of C. montrouzieri were 2 - 3.8 and 3.3, respectively. The medium duration of the larval phase of the predator was 13.3 days. D. brevipes: during its larval phase the predador consumed in average, 2.9- 5.8 - 8.8 and 31.2 adults of D. brevipes, respectively. In the adult phase the predator consumed daily, on average, 3.8 adult cochineals. The medium duration of the larval phase of the predator was 13.3 days. Under environmental conditions there were not significant alterations. Nymphs and adults of C. montrouzieri were able to feed on all three cochineals species, however on O. praelonga only the aduit phase of the predator showed efficiency.

Index terms: Insecta, biological control, predator.

[1658] PYRROLIZIDINE ALKALOIDS (PAS) ANTI-PREDATOR ACTIVITY AGAISNT INVERTEBRATE AND VERTEBRATE PREDATORS

K. L. Silva & J. R. Trigo, Depto. de Zoologia, IB, UNICAMP. P.O. Box 6109, Campinas, SP, Brazil. CEP 13033-970. E-mail: klucas@uol.com.br; trigo@obelix.unicamp.br

PAs are secondary plant compounds with an unique role in the tritrophic relationship among plants, herbivore insects and their natural enemies. PAs-plants are visited by adults of Ithomiinae and Danainae butterflies. These are warning colored butterflies and sequester PAs mainly on the families Boraginaceae (Heliotropium) and Asteraceae (Senecio and Eupatorium), and use them either as precursor of male pheromones or for chemical defense against vertebrate and invertebrate predators. The aim of this study was test the anti-predator activity of different structures of PAs in different concentrations against the golden orb-weaving spider Nephila clavipes (Tetragnathidae), a model of invertebrate predator usually found simpatrically with these butterflies, and against chickens Gallus gallus, a model of visually hunting predator. On this study we performed bioassays using 1,2-unsaturated PAs: integerrimine:senecionine (macrocyclic PA) in a proportion 89:11 (I*), the monoester senecicylretronecine (SR*), and the nccine base retronccine (R*). All were presented in free base (*BL) and N-Oxide (*NO) forms. In Nephila bioassays, pure PAs was dissolved in MeOH, and 10 (I were topically applied in 4 different concentrations (0.38x10-4, 1.53x10-4, 24.50x10-4, and 392.90x10-4 (moles/mg, N=30 each) on individual palatable preys (frozen bees Apis melifera). In chickens bioassays, 5 (1 of the PAs with the same concentration as above was applied on diptera palatable prey (larvae of Chrysomya putoria) in 3 different concentrations (98.2x10-4, 392.9 x10-4 and 1571.4x10-4 (moles/mg, N=20 each). INO was more effective against N. clavipes than IBL; all preys with 392.9x10-4 (moles/mg of these PAs were released by the spiders. In the same concentration, chickens released only 15% of preys with those PAs forms. Both RBL and RNO was ineffective against N. clavipes and chickens, even in the highest concentration. SRBL had lower effectiveness against N. clavipes than IBL; the same results were found in the bioassays with chickens. The responses of N. clavipes and G. gallus to PAs concentration were different: spiders were more sensitive to small quantities of PAs than chickens. But in both experiments, macrocyclic PAs had a superior anti-predator activity in relation to monoester PAs; in the same view, *NO forms had a superior activity against these predators than *BL forms of macrocyclic PAs. In fact, PAs are found in the N-oxide forms in insects and plants. By the way, the ineffectiveness of necine base against predators can explain the production of callimorphine, a insect-PA never observed in plants and biosynthesized from retronecine.

Index terms: Nephila clavipes, Gallus gallus, PAs concentration, PAs structure.

Symposium and Poster Session

[1659] PARASITODS OF PHYLLOCNISTIS CITRELLA IN RIO DE JANEIRO STATE, BRASIL

P.R.R.Silva^{1,2}; O.R.F.Azevedo¹; R.Silva-Fiiho¹; W.C.Rodrigues¹; V.A.Costa³; S.S.P.Sousa¹ & P.C.R. Cassino¹, ¹Dept. de Entomologia e Fitopatologia, Centro de Manejo de Pragas "Cinciunato Rory Gonçalves", UFRP, BR 465 Km 07, Seropédica, RJ, CEP 23890-000, BR., E-mail:pr.cassino@uol.com.br; ²E-mail:pramalho@fst.com.br; ³Instituto Biológico de São Paulo, Seção de Controle Biológico das Pragas, Rodovia Heitor Penteado Km 3.5, Campinas, SP, CEP:13001-970, E-mail: valmir@acuarium.com.br.

The use of natural enemies has became increasingly frequent as a technique of pest management. In addition to reducing the use of pesticides and their noxius effects, this technique also reduces production costs. Since its introduction in Brazil, the citrus leafminer (*Phyllocnistis citrella*) has been controled basically through the use of insecticides. In order to identify the natural enemies of *P. citrella* occurring in the state of Rio de Janeiro, leaves with larvae and/or pupae were collected in the cities of Rio Bonito and Araruama, located in the citrus-producing region of the State. The samples were taken to the laboratory of the "Centro Integrado de Manejo de Pragas Cincinnato Rory Gonçalves" at "Universidade Federal Rural do Rio de Janeiro", where they were placed in petri dishes in a climate controled room at $25 \pm to 2^\circ$ C, 70% humidity with 12 hour photophase. After a period approximately 20 days, adult pest and their natural enemies emerged. The parasitoids identified in the samples from Rio Bonito were *Galeopsonyia fausta* (Tetrastichinae) and *Cirrospilus* sp.(Eulophinae). In addition to these two parasitoids, *Horismenus* ap. (Entedoninae) was also identified in the samples from Araruama.

Index terms: Phyllocnistis citrella; Tetrastichinae; Eulophinae; Entedoninae; Integrated Management

[1660] EFFECT OF NEEM PRODUCTS APPLIED AS SPRAYS TO PARASITISED HOST EGGS ON ADULT EMERGENCE AND LONGEVITY OF TRICHOGRAMMA SP. NR. MWANZAI

S. Sithanantham & A.T.Haile, International Centre Of Insect Physiology & Ecology, P.O. Box 30772, Nairobi, Kenya Ssithanantham@Icipe.Org.

The egg parasitoid, Trichogramma sp. nr. mwanzai, is known to occur commonly on the eggs of Chilo partellus in Kenya. Studies were undertaken on the effect of three necm products applied as sprays to parasitised eggs of host (Corcyra cephalonica). The effect of the timing of the sprays at 1,4 and 7 days after parasitisation on adult emergence and longevity of Trichogramma sp.nr mwanzai was assessed. The neem products - Neem kernel cake powder (NKCP) @ 50g/l, neem seed oil (NSO) @ 30ml/l and crude neem seed kernel extract (NSKE) @ 50g/l - were compared with two synthetic insecticides - carbaryl @ 2.03g ai/l and lambdacyhalothrin @0.06g ai/l - and with an unsprayed check. In general, the neem products sprayed at 1 and 7 days after parasitisation did not affect the adult emergence. However, when applied at 4 days after parasitisation, two neem products NKCP and NSO - resulted in significantly lower adult emergence (44 and 66%) compared to the check (77%). Adult emergence in treatments with the two synthetic pesticides was, however, much lower than with the neem products at all the intervals tested. The longevity of the emerged adults was also not affected by the neem products when sprayed on host eggs at one day after parasitisation. When sprayed at 4 or 7 days, Nevertheless, these NSO and NSKE resulted in significant reduction in longevity. reductions in adult longevity were much less severe than observed with the two synthetic insecticides at the three intervals tested. The results indicated that sprays of neem products differed in their extent of effect on adult emergence and longevity, depending upon the interval between date of host egg parasitisation and spraying. All the neem products tested were much less adverse in their effect on adult emergence and longevity of the parasitoid in comparison to the two synthetic pesticides.

Index terms: Trichogramma, neem, adult emergence, longevity.

[1661] FRUIT FLY BIOLOGICAL CONTROL IN LATIN AMERICA: MINIMIZING THE RISKS POSED BY TEPHRITIDAE IN MEXICO AND CENTRAL AMERICA TO THE CONTINENTAL UNITED STATES

<u>I. Sivinski¹</u>, M. Aluja², K. Bloem³, T. Holler⁴, S. Lux⁵, R. Messing⁶, P. Rendon⁷, & R. Wharton⁸, ¹USDA-ARS, CMAVE, P.O. Box 14565, Gainesville, FL, USA, jsivinski@gainesville,usda.ufl.edu; ²Instituto de Ecologia, 91000 Xalapa, Veracruz, Mexico; ³USDA-APHIS-NBCI, 429 Meadow Ridge, Talhahasee FL 32312, USA; ⁴USDA-APHIS-PPQ, 1913 SW 34 St, Gainesville, FL 32614, USA; ⁵Center for Insect Physiology and Ecology, P.O. Box 30772, Nairobi, Kenya; ⁶Dept. of Entomology, University of Hawaii, 7370 Kuamo'o Rd., Kapa'a, HI 96746, USA; ¹USDA-APHIS-PPQ, 4A Ave., 12-62, Zona 10, Guatemala City, Guatemala; ⁸Dept. of Entomology, Texas A&M University, College Station, TX 77840, USA.

Dense populations of Mediterranean fruit fly (=medfly), Ceratitis capitata (Weid.), occur throughout Central America and much of South America. The northward spread of the medfly into Mexico, and ultimately into the continental United States, has been prevented by a sterile insect (=SIT) / bait-spray barrier maintained along the Guatemalan/Mexican border by the international organization MOSCAMED (United States, Mexico, and Guatemala). Recently, the barrier has become increasingly permeable. Additional control methods are necessary, and biological control may be one alternative. In addition to medfly, there are several pest species of the genus Anastrepha in Mexico and Central America. Biological control could aid local subsistence farmers and help protect the USA from pest-invasion. -- Classical biological control: There is an ongoing exploration for new parasitoids in the medfly's area of origin, east Africa. At present one species, Psyttalia near concolor, is colonized in Guatemala. Two species of Fopius are also being collected in Kenya. One is an egg-pupal parasitoid, and since it attacks a particularly vulnerable stage of the host it may be valuable in biological control. -- Conservation of natural enemies: Unlike the medfly in Latin America, Anastrepha spp. are attacked by a large number of native parasitoids. Increasing their numbers and focusing their foraging might amplify the effect of these parasitoids. One means of doing this is to plant native trees whose fruits are infested with non-pest species of Tephritidae. These harmless species share parasitoids with pests, and act as a reservoir and multiplier of natural enemies that can then move into agricultural environments. --Augmentative releases: Combined augmentative parasitoid releases combined with SIT can have a greater effect on fly numbers than either used alone. This synergistic 2-pronged attack may be an alternative to chemical controls where insecticides are difficult to apply (urban areas, organic-growing areas, nature preserves etc.). In Guatemala, 3 species of the genus Diachasmimorpha are being reared and released against medfly.

[1662] THE COMMON EARWIG FORFICULA AURICULARIA; BENEFICIAL OR PEST IN ORCHARDS?

<u>M. G. Solomon</u>, J. D. Fitzgerald, R. L. Jolly, & N. Pepper, Dept. of Entomology & Plant Pathology, Horticulture Research International, East Malling, Kent, ME19 6BJ, UK, E-mail mike.solomon@hri.ac.uk

Modern apple and pear trees are relatively small and smooth-barked, offering few sheltering sites for beneficial insects. Experiments were conducted to investigate the practicability of manipulating the numbers of beneficial insects in orchards by providing artificial refuges in the trees. The most commonly found species in the refuges was the common earwig, Forficula auricularia L. In orchard experiments to examine the impact of this insect on populations of the pear psyllid Cacopsylla pyricola, carwigs were removed and excluded from some trees, and numbers were artificially enhanced in others. Within three weeks of the beginning of the experiment, numbers of psyllid eggs and larvae on the 'earwigs added' trees were consistently lower than the numbers in the 'earwigs removed' trees (in most cases the numbers were halved). Laboratory studies have shown that earwigs are capable of consuming large numbers of psyllid eggs. Earwigs also consume plant material, and for this reason are sometimes regarded as a pest in apple and pear orchards. In the above experiments there was no evidence of damage to pear fruits. In laboratory experiments designed to investigate the propensity of earwigs for causing primary damage to apples, fruits of three apple varieties of contrasting skin toughness and tissue hardness were artificially ripened and earwigs were confined in boxes with individual fruits. The resulting damage was negligible in all but the most over-ripe fruits of the variety that had the weakest skin. This suggests that earwigs cause little primary damage to fruit in the orchard. It is evident that plant feeding by earwigs does not negate their value as predators.

Index terms: Forficula auricularia, Cacopsylla pyricola, predator, orchard, apple.

[1663] OCCURRENCE AND REDESCRIPTION OF *MEGAMELUS SCUTELLARIS* BERC (HEMIPTERA: FULGOROMORPHA: DELPHACIDAE) IN ARGENTINA, A CANDIDATE FOR BIOCONTROL OF WATERHYACINTH

A.J. Sosa¹, A.Marino de Remes Lenicov², R. Mariani² & <u>H. Cordo¹</u>, ¹ USDA, ARS, South American Biological Control Lab. (SABCL). Bolivar 1559 (1686) Hurlingham, Buenos Aires, Argentina. E-mail: hacordo@rnail.retina.ar; alesosa@infovia.com.ar; ² Facultad de Ciencias Naturales y Museo de La Plata (UNLP). Dep. Científico de Entomología. Pasco del Bosque s/n (1960) La Plata, Buenos Aires. E-mail: amarino@ museo.fonym.unlp.edu.ar; mariani@nuseo.fonym.unlp.edu.ar.

Megamelus scutellaris is a promising candidate for the biological control of waterhyacinth (Eichhornia crassipes). Two years of studies at SABCL showed that it appears to be strictly monophagous on waterhyacinth which suggests that - after all screening tests are completed - it will become a new agent for biocontrol of waterhyacinth. This is highly desirable since more agents are needed to complement those already in use in fighting this worldwide troublesome plant invasive in most countries with tropical climates. The genus Megamelus has 42 species of which 5 occur in the Neotropical region: M. bifurcatus (Brazil), M. electrae (Brazil and Puerto Rico), M. iphigeniae (Brazil), M. scutellaris (Argentina) and M. timheri (Guyana). M. electrae was mentioned in Trinidad as a candidate for biocontrol of waterhyacinth but its study was discontinued. M. scutellaris was found by SABCL in Argentina, from Buenos Aires to Formosa, and in Iquitos, Perú. There are no records about the host plants of the other three neotropical species of Megametus. M. scutellaris was described by Berg in 1883 based upon only one macropterous female specimen collected in Corrientes, Argentina, which is in the collection of the Museum of La Plata. Since this description is elementary and devoid of illustrations, we redescribe it adding the male (macro and brachypterous) and the brachypterous female. The diagnose characters used were the whole coloration pattern of body, relative lengh of rostrum, relative lengh of antennal segments I and II, lengh and denticulation of metatybial spur, configuration of anal segment and genital structures of male and female. We collected M. scutellaris in the provinces of Buenos Aires, Chaco, Entre Rios and Santa Fé of Argentina and in several sites on the Amazon river in Iquitos, Perú

Index terms: Waterhyacinth, biological control, Delphacidae, planthopper

[1664] INFLUENCE OF ISOLATED OR GROUFED CLIMATIC FACTORS ON CHRYSOPERLA EXTERNA (NEUROPTERA: CHRYSOPIDAE) ADULT POPULATIONS

B. Souza & C. F. Carvalho, Dept^o. de Entomologia, Univ. Federal de Lavras, C.P. 37, Lavras, MG 37200-000, Brasil, E-mail: brgsouza@utla.br

The influence of a particular climatic factor (rainfall, relative humidity, maximum, minimum or average temperatures) on a single day as compared to periods up to 30 days before sampling dates, on population density of *Chrysoperla externa* adults was studied. Sampling was made weekly with an entomological net on 20 citrus trees in an area of ca. 2 ha, between 13:00 and 17:00 h, from May 1992 to April 1996. Daily weather records were obtained from the UFLA's climatological station. Correlation studies between the number of adults caught and prevalent climatic conditions both on a single day or in periods up to 30 days before sampling dates were made, with evidence that the climatic factors studied influenced its population density in both situations. The greater the number of adverage climatic factors on the adult population density of *C. externa* adults was most affected by minimum and average temperatures regardless of the way the data were analyzed (single or more days) before sampling dates. A tendency was found for an increase in the correlation coefficient, as data of more individual days were included for the analysis in the 30-day period before sampling dates.

Index terms: green-lacewing, predator, rainfall, relative humidity, temperature.

[1665] FOOD AND CARCASS ANALYSES OF THE PREDATORY BUG HARMONIA AXYRIDIS (COLEOPTERA: COCCINELLIDAE) AS REFERENCES FOR THE ELABORATION OF ARTIFICIAL DIETS

O. Specty¹, C. Piotte², G. Febvay¹, B. Delobel⁴, J. Guillaud⁴, J.F. Pageaux³, A. Ferran² & <u>S. Grenier²</u>, ¹Labo. Biologic Appliquée, UA INRA 203, INSA Bât. 406, 20 av. Einstein, 69621 Villeurbanne France, E-mail specty@jouy.inra.fr; ²Entomologie et Lutte Biologique, SPE, INRA BP 2078, 06606 Antibes, France; ³Labo. Biochimie et Pharmacologie, INSA Bât. 406, 20 av. Einstein, 69621 Villeurbanne France.

The predatory coccinellid Harmonia axyridis feeds on aphids as natural food and can be produced on Ephestia kuehniella (E.k.) eggs as substitution food. But the mass rearing of this coccinellid on E.k. eggs is too expensive for a large scale use in biological control. In order to define artificial diets, we estimated the nutritional needs of the predator by analyzing the two kinds of foods and we evaluated the impact of each food on the body composition of the coccinellid. Biochemical analyses were mainly conducted on proteins, lipids and carbohydrates. E.k. eggs as well as young aphids (Acyrthosiphon pisum) are rich in amino acids (12 % of the fresh weight). E.k. eggs are 3 times richer in lipids than aphids, but on the contrary the aphids are 1.5 times richer in glycogen than E.k eggs content. Compositions of the coccinellid feeding either on E.k eggs or on aphids were compared at amino acids and fatty acids level revealing a strong influence of the food on predator. In a second step, according to available substrates, different diets will be formulated partly by computation. The quality of the predators obtained on newly developed diets or on adjustments of already available diets will be compared with that of control predators. These researches were conducted with the support of the European Commission via contract FAIR6 CT98- 4322.

Index terms: Harmonia axyridix, Ephestia kuehniella, Acyrthosiphon pisum, entomophage

[1667] SYNOMONAL EFFECT OF CHICKPEA VARIETIES ON THE EGG PARASITOID TRICHOGRAMMA CHILONIS (TRICHOGRAMMATIDAE: HYMENOPTERA)

M. Srivastava¹, A. V. N. Paul¹, <u>A K. Singh²</u>, & P. Dureja³, ¹Div. Entomology, Indian Agric. Res.Inst., New Delhi-110012; ² Dept. Zoology, University of Delhi, Delhi-110007; ³Div. Agric. Chem., Indian Agric. Res. Inst., New Delhi-110012, India

Chemical previously identified as synomones utilized by parasitoids have been found in significant quantities in food plants of host insects. In the present studies hexane extract of ten different varieties of chickpea (Cicer arietinum) L.) obtained from vegetative and flowering phase were assayed for the synomonal response from the egg parasitoid, Trichogramma chilonis Ishii. Hexane extract of different varieties of chickpea were analyzed by Gas Liquid Chromatography for determining their hydrocarbon profile which showed the presence of straight chain saturated hydrocarbons ranging from C14 to C29 in both phases. Different varieties of chickpea contained varying number and concentrations of these chemicals, which enhanced the activity of parasitoid. The quantity of individual hydrocarbons ranged from 0.002 to 11.036 mg/gm in the vegetative phase and 0.003 to 49.309 mg/gm in the flowering phase. In general, the hexane extract of flowering phase of chickpea varieties evinced better synomonal response as compared to vegetative phase from the parasitoids. The better response observed in certain varieties and at a particular phase could be attributed to the presence of higher concentration of favorable hydrocarbons or appropriate proportion of favorable and unfavorable hydrocarbons present in the varieties. Heneicosane in the vegetative phase and, heneicosane and tricosane in the flowering stage seem to be critical as observed in different chickpea varieties for the synomonal activity. Variety 'Pusa 256 RL: 1985' at the vegetative phase and variety 'Pusa 1003' at the flowering stage elicited highest response from the parasitoids. These findings could be used for integrated pest management programme. Index terms: Hydrocarbon profile, biological control, heneicosane, tricosane.

[1666] BIOLOGICAL CONTROL AGENTS: IMPLICATIONS IN HOME AND INTERIOR PLANTSCAPES

D. D. Sreenivasam & J. C. Luhman, Minnesota Dept. of Agriculture, 90 West PlatoBlvd., St. Paul, MN 55107-2094, USA, E-mail: dharma.sreenivasam@state.mn.us.

In Minnesota, most plant feeding insects live outdoors and reproduce during warm seasons when their host plants are growing. Several of these plant feeders move in and thrive indoors on plants in homes and offices. This study focuses on four common pests infesting indoor plantscapes, their host plants and biological control agents. They are: Citrus mealybug, Planococcus citri, longtailed mealybug, Pseudococcus longispinus, and obscure mealybug, Pseudococcus affinis; cotton aphid, Aphis gossypii, potato aphid, Macrosiphum euphorbiae, and pea aphid, Acyrthosiphon pisum; brown soft scale, Coccus hesperidium, hemispherical scale, Saissetia coffeae; and the twospotted spider mite, Tetranychus urticae. Some of the biological control agents being investigated at our new Biological Control Facility completed in August 1998 are: lady beetles most used as biological control agents, an exotic Cryptolaemus monstrouzieri to control mealybugs and scales and Hippodamia convergens to control aphids; a minute pirate bug, Orius insidiosus to control mites, aphids, mealybugs and scale crawlers; and a predator mite, Phytoseiulus persimilis to control spider mites. Primary plants currently used for rearing pests are: potato for mealybug, miniature rose and Hibiscus for aphids, Diffenbachia and citrus for hemispherical and brown soft scale, respectively, and bush and fava beans for twospotted spider mite. This research has quantified the methods developed for insect/mite and plant rearing under controlled conditions such as temperature, light, and relative humidity approximating home and office interior conditions. The results of this study are easily applicable to any interior plantscapes.

[1668] THE ENTOMOPIIAGUE TRICHOGRAMMA SPP. (INSECTA, HYMENOPTERA) A CHANCE OF BIOLOGICAL CONTROL IN THE TRID MILLENNIUM, IN ROMANIA

<u>Ciochia Victor¹</u> & Stanca Cristina², ¹ Str. Pavilioanelor CFR, Nr. 30, 2200 - Braşov, România, Europa; ²Str. Calea Cinsădiei, Nr. 23, bl. 104, sc. B, ap. 26, 2400 - Sibiu, România, Europa

To healthy life is conditioned by large - scale application or even generaliyation of biological and biotehnological means for phytophsgous insect population limitation. Entomophague of the *Trichogramma* genus as well as biopreparations are but a "small weapon" to be use by Man in his struggle to achieve a rational and responsible integration of all known means to limit the damage produced by different life froms of the animal and vegetable kingdoms as well as bacteria and viruses. The entomophagous insect *Trichogramma spp.* together with other biological insecticides reprezents a control tool for an ecological farming created for the purpose of Man's welfare, according to his creative power, without the survival of all life forms on the ball of dust called "Earth".

Symposium and Poster Session

[1669] SUITABILITY OF AUSTRALIAN *TRICHOGRAMMA* SPECIES (HYMENOPTERA: TRICHOGRAMMATIDAE) FOR BIOLOGICAL CONTROL OF STORED PRODUCT MOTHS

J. L. M. Steidle¹, **D. Rees² & E. J. Wright²**, ¹FU Berlin, Inst. f. Biologie, Angew. Zoologie / Ökol. d. Tiere, Haderslebenerstr. 9, 12163 Berlin, Germany, E-mail steidle@zedat.fu-berlin.de; ²SGRL, CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia

The three Trichogramma species T. brassicae, T. pretiosum and T. carverae were assessed for their suitability as biological control agents against Ephestia cautella and E. kuehniella. These moth species are important pests in food manufacturing and processing facilities in Australia. Parameters examined were longevity, fecundity on eggs of E. kuehniella, walking speed of adult wasps, reaction to moth scales, and host acceptance and host suitability of eggs of E. cautella and E. kuehniella. T. pretiosum and T. carverae performed better than T. brassicae in all traits examined apart from fecundity. T. pretiosum and T. carverae differ mainly in higher fecundity and host acceptance in T. pretiosum, and a better host finding ability (walking speed, reaction to moth scales) in T. carverae. The suitability of the Trichogramma species for use as control agents is discussed with respect to these results

Index terms: Trichogramma species, Ephestia species, parasitoids, biological control, stored product pests, suitability

[1671] UTILIZATION OF EOCANTHECONA FURCELLATA (HEMIPTERA: PENTATOMIDAE) FOR AUGMENTATIVE BIOLOGICAL CONTROL OF COMMON CUTWORM SPODOPTERA LITURA IN TARO FIELD IN THAILAND

<u>W. Suasa-ard</u>, National Biological Control Research Center Central Regional Center, Kasetsart University/National Research Council, P.O. Box 1 Kampaengsaen, Nakhon Pathom 73140, THAILAND

The predatory pentatomid *Eocanthecona furcellata* (Hemiptera: Pentatomidae) is found as the potential predator for biogical control of lepidopterous pests. Investigation utilization of this predator was conducted at the NBCRC-CRC, Kampaengsaen, Nakhon Pathom. Approximately 20,000 third instar nymphs were produced every month. Two locations of taro field in Nakhon Pathom province are selected as investigation site, 2 plots in each site, released and control plot each plot covering an area of 2 acres. Approximately 2000 of third instar nymph were released every two weeks internal during April-August 1999 in released plots. After inoculative release the population of *E. furcellata* developed well and increased to higher level than those of in the control plot in both locations. Two month after release *E. furcellata* showed satisfactory evidence to control over the population of common cut worm, *Spodoptera litura* (Lepidoptera: Noctuidae) in the released plots. Keywords: potential, predator, inoculative release

[1670] FORAGING CUES FROM DIFFERENT HOSTS USED BY THE GENERALIST PARASITOID LARIOPHAGUS DISTINGUENDUS (HYMENOPTERA: PTEROMALIDAE)

J. L. M. Steidle & J. Ruther, FU Berlin, Inst. f. Biologie, Angew. Zoologie / Ökol. d. Tiere, Haderslebenerstr. 9, 12163 Berlin, Germany, E-mail steidle@zedat.fu-berlin.de.

Although various aspects of the foraging process of parasitoids are examined so far, there are almost no studies on the mechanisms by which generalist parasitoids are able to find and recognize their various plant-host complexes. Therefore the present study was initiated with the pteromalid wasp *Lariophagus distinguendus*, a parasitoid of larvae and pupae of at least 11 beetle species from 5 families that develop within seeds of different plants. In bioassays combined with comparative chemical analyses, we examined the hypothesis that chemical cues present in all plant-host complexes enable the broad host range of *L. distinguendus*.

[1672] NATURAL ENEMY COMPLEX OF THRIPS PALMI IN THAILAND

W. Suasa-ard & K. Charernsom, National Biological Control Research Center Central Regional Center Kasetsart University/National Research Council, P.O. Box I Kampaengsaen, Nakhon Pathom 73140, THAILAND

Field survey and evaluation of natural enemies of *Thrips palmi* carried out both in the laboratory at NBCRC-Central Regional Center, Kampaengsaen, Nakhon Pathom and under field conditions in many localities in Thailand. The investigation revealed that *Megaphragma* sp. and *Ceranisus menes* Walker were important egg and nymphs parasites. Anthocorid predator, *Wollastoniella rotunda*, *Wollastoniella parvicuneus* and *Orius* sp., were also found as important predators of *T. palmi* in Thailand. Keywords: natural enemies, *Thrips palmi* Thailand

[1673] ATTEMPTS OF USING INDICENOUS PARASITOIDS AS A CONTROL AGENT TO *LIRIOMYZA TRIFOLII* IN GREENHOUSES IN JAPAN

<u>T. Sugimoto¹</u>, K. Ohno², A. Ozawa³ & K. Takezaki⁴, ¹Lab. of Entomology, Kinki Univ., Nara 631-8505, Japan, E-nxail sugimoto@nara.kindai.ac.jp; ²Lab. of Entomology, Miyazaki Univ., Miyazaki 889-2192, Japan; ³Shizuoka Pref. Agric. Experiment Station, Toyota 438-0803, Japan; ⁴Kagoshima Pref. Agric. Experiment Station, Kagoshima 891-0116, Japan.

Liriomyza trifolii was accidentally introduced into Japan in 1990 and is now injurious especially to crops in greenhouses almost all over the country. Recently, two species of parasitic wasps have been imported from Europe for a seasonal incculative biological control to this pest in greenhouses. However, it is desired to use indigenous parasitoids as its control agent from the following reasons; first a profitability of species more tolerant to a high temperature in the greenhouse in western Japan and next a necessity of suppressing a risk of exotic organisms to an indigenous ecosystem. In Japan more than 200 species of Phytomyzidae are recorded and about 30 species of parasitic wasps are listed up as a parasitoid of L. trifolii. Of these parasitoids eulophids as an idiobiont arc extremely dominant. They kill hosts by both parasitization and host-feeding. We selected the following 3 candidates as a heat-tolerant and effective parasitoid from eulophids commonly found in western Japan, comparing the relationships of their development, reproductive ability and flying ability to temperature. Of eulophids tested, Neochrysocharis formosa, N. okazakii and Hemiptarsenus varicornis were most adaptive to a high temperature. Especially, N. formosa flew actively in the wider range of temperature than H. varicomis. This may mean that the former species can be effective as a control agent during a longer season every year. Furthermore, our culture of the former two species were thelytokous and so profitable not only to a mass-production but also as a control agent. The preliminary release experiments in greenhouses proved that these eulophids were hopeful as a control agent to L. trifolii. Now, further experiments are carried out to select the most adaptive species to the Japanese greenhouse out of these three parasitoids.

Index terns: Liriomyza trifolii, indigenous eulophids, control agent, heat-tolerant

[1675] TEN YEARS OF INTERNATIONAL EXCHANGE AND QUARANTINE OF BENEFICIAL ORGANISMS BY THE BRAZILIAN QUARANTINE LABORATORY FOR BIOLOGICAL CONTROL

<u>F. J. Tambascu¹</u>, L. A. N. de Sá¹, E. A. B. de Nardo¹, F. Lucchini¹ & J. L. da Silva¹, ¹ Lab. de Guarontena "Costa Lima", Embrapa Meio Ambiente, Cx. P. 69, 13.820-000, Jaguariúna, SP, Brasil, tambasco@enpma.embrapa.br

The Brazilian National Quarantine Laboratory "Costa Lima" Embrapa Environment is the only one in the country authorized, since 1991, by the Ministry of Agriculture and Supply (MA) to introduce natural enemies for pest control and also other beneficial organisms for scientific research. It is also one of the mandates of the Laboratory to interact with foreign institutions for export of biocontrol agents. The Main Services provided by the Quarantine Laboratory are: 1) To prepare documents for interested professionals needed for the request of Permits of importation to be issued by the Ministry of Agriculture; 2) To assist interested professionals in locating suitable sources of biocontrol agents for introduction; 3) To collect and Evaluate information concerning import and export of natural enemies; 4) To provide information to the Ministry of Agriculture concerning safety and scientific aspects related to the convenience of each introduction, in consonance with a supporting Technical Committee attached to it, 5)To provide quarantine service; 6)To monitor releases and evaluate efficacy; 7)To collaborate with the International Research Institutions in the exploration and exchange of native natural enemies under a previous cooperative agreement. During these ten years of activities the laboratory has processed 95 introductions of biocentrol agents and other microorganisms involving 13 species of insects parasitoids, 2 of predators, 7 of mites, 2 of nematodes and 47 of microorganisms. Also several international biological control projects have received cooperation from the quarantine laboratory, including USDA-ARS, University of Florida, IITA, IRD, CIAT, Amsterdam University and others. The other activities carried out by the laboratory are: To collaborate with the Southern Countries Phytosanitary Committee (COSAVE) in the harmonization of the regulation related to the Biological Control in the Southern Countries; To manage the International Information System on Biological Control via the Internet http://www.bdi.org.br/bdt/biocontrol, with a discussion list biocontrol-l@bdt.org.br; To maintain a Data Base about Biologicai Control Agents in Brazil; To alert the public on the bringing organisms into Brazil that are not officially approved, providing pamphlets, information brochures, meetings, videos and lectures. The Brazilian Quarantine facility intends to be an overseas laboratory for foreign research institutions around the world in order to promote biological control programs.

Index terms: classical biological control, introductions, exportations, cooperations.

[1674] HOST DEFENSE BEHAVIOR OF THE EGG PARASITOID PARATELENOMUS SACCHARALIS (ITYMENOPTERA:SCELIONIDAE) IN THE FIELD

Keiji Takasu, Faculty of Agriculture, Kobe University, Kobe 657-8501, Japan, E-mail takasu@kobe-u.ac.jp.

Females of Paratelenomus saccharalis, a solitary egg parasitoid of Megacopta punctatissimum, remain near a host egg mass after oviposition to defend the egg mass from conspecifics or interspecifics. I conducted field studies to determine effectiveness of host defense behavior in the kudze patches in Kobe, Japan. Host egg masses consisting of 20-50 eggs were daily laid from 11:30am to 3:30pm, while P. sacharalis female actively searched for or oviposited on host egg masses from 4:00pm to 7:00pm or sunset. Single females that had oviposited on an egg mass in the late afternoon, remained a host egg mass until sunset or the following morning. When a female approached the egg mass where another female was ovipositing, the resident aggressively chased the intruder out of the egg mass. However, intruders often stayed near the egg masses after being chased by residents, and repeatedly attempted to oviposit in hosts. Laboratory experiments showed that although each P. saccharalis female stayed near a host egg mass after oviposition for more than 3-8 h in light condition, it effectively defend the hosts from a conspecific intruder only for less than 2 h. In the field, however, residents do not have to defend their host egg masses more than 3 h. because they usually reach and start ovipositing on host egg masses within 3 h before sunset, and both residents and intruders are not active after sunset. Although intruders still may stay in the host patches and superparasitize the hosts in the following morning, progeny of residents laid a night before would have more chance to survive in such superparasitized hosts than that of intruders. Thus, P. saccharalis females could increase reproductive success even through host defense effective only for a limited time.

Index terms: Paratelenomus saccharalis, Megacopta punctatissimum, host defense, host searching, diurnal activity

[1676] NON-SUITABILITY OF THE BRAZILIAN SUGARCANE BORER, DIATRAEA SACCHARALIS, (LEPIDOPTERA: PYRALIDAE) AS A HOST FOR PEDIOBIUS FURVUS (HYMENOPTERA: EULOPHIDAE)

F. J. Tambasco¹, **F. Lucchini¹**, **L. A. N. de Sá¹**, **E. A. B. de Nardo¹** & **J. L. da Silva¹**, ¹ Lab. de Quarentena "Costa Lima", Embrapa Meio Ambiente, Cx.P. 69, 13.820-000, Jaguariúna, SP, Brasil, tambasco@cnpma.embrapa.br

Pediobius furvus, a gregarious endoparasitoid native of Africa has been recovered from a wide variety of hosts in the families Pyralidae and Noctuidae and has been introduced for biological control programs for stalkborers in several places. In 1995, the Sugar Cane Research Center, COPERSUCAR, Piracicaba, São Paulo, Brazil, requested a series of importation of this parasitoid through the Brazilian Quarantine Lab for Biological Control Agents, Embrapa Environment to complement its biological control program of D. saccharalis. The two first introductions came from Nairobi, Kenya, and the parasitoid came in pupae of Chilo partelus. (Lep: Pyralidae). From those shipments a total of 904 healthy parasitoids emerged and pupae of D. saccharalis and Anticarsia gemmatalis were offered as hosts. D. saccharalis pupae were offered in different ages and substrates such as: free in petri dishes; inside sugarcane logs, and attached in corrugated cardboard. Parasitism was not achieved in any of these tests. In the third shipment parasitoids came in pupae of Sesamia sp. (Lep: Noctuidae) and 2.334 parasitoids emerged. At this time there were offered 3.045 pupae of D. saccharalis, 194 of A. gemmatalis, 149 of Spodoptera frugiperda, 14 of Heliotis virescens and 4 of Thyrinteina arnobia. Few parasitoids emerged from A. gemmatalis and S. frugiperda only enough to maintain a colony until the forth generation under laboratory conditions. There was no emergence from D. saccharalis. Some pupae were dissected and we found completely developed dead parasitoid larvae inside, in other cases were encountered very small encapsulated larvae of the parasitoid. More importation of P. furvus from other regions in Africa was carried out in 1998. Parasitoids were received from IITA, Cotonou, Benin and from ICIPE, Nairobi, Kenya. The last shipment was the most successful, and some parasitoids emerged from, D. saccharalis and A. gemmatalis but the percentage of parasitism, was less than 1%. At this time there were offered 7000 pupae of D. saccharalis and 750 pupae of A. generatalis to the imported insects and the F1 generation was offered 3300 D. saccharalis and 650 A. gemmatalis. After the second generation, all the parasitoids were sent to COPERSUCAR to be mass reared, but they did not survive very long.

Index terms: introduction, parasitoid, Chilo partelus, Sesamia sp., Noctuidae.

[1677] HOST LOCATION BEHAVIOR OF THE PARASITOID FLY, EXORISTA JAPONICA (DIPTERA: TACHINIDAE)

C. Tanaka¹, <u>Y. Kainoh¹</u>, S. Nakamura² & H. Honda¹, ¹Inst. Agr. & For., Univ. Tsukuba, Tsukuba, Ibaraki 305-8572, Japan, E-mail (YK): parasite@sakura.cc.tsukuba.ac.jp; ²JIRCAS, Tsukuba, Ibaraki 305-8686, Japan.

We examined the response of female Exorista juponica to an herbivore-damaged plant in a wind tunnel and the effect of host frass or its extracts on the host location of females in a small cage. We used the common armyworm, Mythinna separata Walker (Lepidoptera: Noctuidae), as a host for this fly and as an herbivore to damage corn plants. Experienced flies conditioned to oviposit on the host/corn plant complex were attracted mostly to the host/plant complex and required a relatively short time to arrive at the plant. Damaged corn plants without host larvae and their frass were also attractive. However, only a few experienced flies were attracted to the undamaged plants. These two responses indicate that the damaged corn plants without the herbivore present emit an attenuated signal odor for female flies. Host searching time in the patch and the number of patch visits were analyzed by using a frass-containing patch (9cm in diam.) which was excreted from host larvae, and the patches to which host frass extracts with various solvents were applied. E. japonica females were arrested in response to the frass-containing patch after contacting the frass with their front tarsi, thereby they spent most of the time on searching the patch and continued to visit it. The females also exhibited area-restricted search on the methanol extract of host frass that was applied to a 9-cm filter paper. It is suggested that E. japonica females employ chemicals from host frass as arrestant in close-range host location.

Index terms: Exorista japonica, Tachinidae, Mythimna separata, Noctuidae, common armyworm, damaged plant volatile, host frass, arrestant.

[1679] BIONOMICS OF AMBLYSEIUS LONGISPINOSUS (PHYTOSEIDAE) AND ITS EFFICACY AS A BIOLOGICAL CONTROL AGENT OF EOTETRANYCHUS CENDANAI (TETRANYCHIDAE)

T. Thongtab¹, <u>A. Chandrapatya¹</u> & G.T. Baker², ¹Dept. of Entomology, Kasetsart Univ., Bangkok 10900, Thailand, E-mail agramc@ku.ac.th; ² Dept. of Entomology and Plant Pathology, Box 9775 Mississippi Sta. Univ., Mississippi State, MS, USA 39762

The egg, larval, protonymphal and deutonymphal stages of Amblyseius longispinosus (Evans) that fed on Eotetranychus cendanai, required 2.02 ± 0.13 , 0.57 ± 0.71 , 1.02 ± 0.27 and 1.16 ± 0.53 days. The total developmental time was 4.79 ± 0.61 days. Female longevity averaged 14.61 \pm 2.88 days where 19.54 \pm 6.36 eggs/female or 1.33 ± 0.29 eggs/female/day were laid. Highest predation rate was detected at a density of 40-50. Amblyseius longispinosus could be employed as biological agent of *E. cendanai* both in laboratory and greenhouse conditions at the predator: prey ratio of 1: 30-1:50. Index terms: Amblyseius longispinosus, Eotetranychus cendanai.

[1678] SPATIO-TEMPORAL DISTRIBUTION OF CITRUS LEAFMINER AND ITS NATURAL ENEMIES IN SÃO PAULO STATE, BRAZIL

S. Ternes¹, O. Bonato^{2,3}, <u>L. A. N. De Sá</u>³ & H. M. Yang⁴, ¹fecc/Unicamp, Embrapa Informática Agropecuária, C.P. 6041, 13083-970 Campinas, São Paulo, Brasil; ²ird (Ex-Orstom), França; ³embrapa Meio Ambiente, C.P. 69, 13820-000, Jaguariúna, São Paulo, Brasil, E-Mail Lans@Cnpma.Embrapa.Br ⁴imecc/Unicamp, C.P. 6065, 13083-970, Campinas, São Paulo, Brasil.

The citrus leafminer (clm) phyllocnistis citrella stainton (lepidoptera: gracilariidae) was reported in brazil in 1996. this pest became a real threat for national citrus crops because of its association with xanthomonas axonopodis pv citri, bacterial agent of the citrus canker, the objective of this work was to analyse during different seasons and growing periods the population fluctuations of immature stages of clms and of its most commun natural enemies, obtained data would also be used to validate a deterministic model (under development at present) describing the dynamic of parasitoid-pest interactions, the experiment was realized in a plantation located in cordeirópolis, são paulo state, to avoid heterogeneity, a 9 years-old experimental field of citrus variety 'pera' was selected and divided in 10 blocks composted of 18 plants each. at each sampling operation, conducted monthly from may 1999 to april 2000, one plant per block was randomly selected. the plant was divided in 3 equal strata (basal, medium and apical) and one branch per stratum was collected, each branch received identification (block number and stratum) and was kept in plastic bag for further lab observations, to analyse tree shade effect, cardinal position of branches was also recorded. in the lab, the 15th first leaves of each branch were analysed under stereomicroscope (the youngest leaf of branch being always considered as the first one). the number of eggs, larvae (1^{mt} and 2nd instars) and pupae of clm and galeopsomyia fausta (the most common natural enemy in the region) was counted, the presence of cirrospilus 'sp.' (other native natural enemy) and ageniaspis citricola (exotic parasitoid released in areas closed to our experimental field) was also recorded. spatiotemporal distributions of clm were statistically analysed, datas will also be used to validate the simulation model under development, informations resulting from different simulations would help to assess the impact of parasitoid-pest interactions and the efficacy of biological control in the field.

index terms: *phyllocnistis citrella, galeopsomyia fausta,* paresitoid-pest interactions, modelling, spatio-temporal distribution, citrus.

[1680] PERISTENUS PARASITISM OF LYGUS LINEOLARIS IN MULTIPLE PLANT HABITATS

K. J. Tilmon¹, M. P. Hoffmann², B. N. Danforth¹ & W. H. Day², ¹Dept. of Entomology, Cornell Univ., Ithaca, NY 14853, USA, E-mail kjt6@cornell.edu; ²Beneficial Insects Research Lab., 501 S. Chapel St., Newark, DE 19713, USA..

The habitat range across which a parasitoid can locate hosts is an important aspect of its biology, and also has clear implications for biological control. How effective is a parasitoid at targeting a pestiferous host when the host is a habitat generalist whose location may be more variable and less predictable than a specialist's? The host species in this study, Lygus lineolaris (Heteroptera: Miridae), is native to and occurs throughout North America. One of the broadest herbivore generalists, it has been documented on 328 plant species of 55 plant families in 30 orders. It is pestiferous on an unusually broad range of annual and perrenial crops. In North America, a suite of both native and intoduced parasitoid species include *L. lineolaris* in their host ranges. Three of these species are Peristenus digoneutis (Hymenoptera: Braconidae), P. pallipes, and P. pseudopallipes. P. digoneutis, a European species parositic on L. rugulipennis, was collected in European alfalfa and released in the U.S. for biological control of L. lineolaris. Its geographic range expansion has been monitored in alfalfa, and overlaps the geographic ranges of both P. pallipes and P. pseudopallipes. But given the broad range of plant habitats where L. lineolaris occurs, what is the parasitoid species richness and abundance encumbering the host taxon in different habitats? Stated another way, in which habitats will the various species track the host? The purpose of this study has been to survey patterns of parasitism in *L. lineolaris* in plant habitats other than alfalfa, the habitat of introduction for *P. digoneutis*. These habitats include strawberry (a high-value crop in which L. lineolaris is a key pest), weed species, rye/vetch cover crops, and old-fields. We are assessing parasitism by Peristenus species in these environments. Though sample analysis for all species and habitats was not complete at the time of writing, so far we have found P. digeneutis parasitism of L. lineolaris in strawberry, rye/vetch, and on Erigeron sp. in naturalized habitats. Thus, P. digoneutis finds and parasitizes its generalist host in multiple plant habitats.

Index terms: Peristenus digoneutis, Peristenus pallipes, parasitoid, host location

[1681] QUANTITATIVE MASS PRODUCTION OF THE STINKBUG PREDATOR PODISUS NIGRISPINUS (HETEROPTERA: PENTATOMIDAE)

<u>J.B. Torres</u>¹, W.S. Evangelista Junior¹ & J.C. Zanuncio², ¹DEPA-Fitossanidade, Univ. Federal Rural de Pernambuco, Av. Dom Manoel de Medeiros S/N – Dois Irmãos 52171-900 Recife, PE. E-mail: jorge@nelore.npde.ufrpe.br. ²DBA, Univ. Federal de Viçosa 36571-000 Viçosa, MG.

The stinkbug predator Podisus nigrispinus has been implemented for defoliators control in Brazil and other countries. Although, easily reared in laboratory on factitious preys, nymphs and adults maintenance in room environment is onerous due to time consuming and physical space required. Thus, this study aimed to evaluate the methodology developed by Manessman Fi-El Florestal using plastic box for nymphs rearing and adapt a new methodology to P. nigrispinus adults maintenance. Plastic boxes Sanremo™ 6-litter volume with food and water provided on cover were used for nymphs. Adults were hold in acrylic cages (20 x 20 cm), containing 10-cm absorbent paper strips for egg laying. Nyinphs were studied at 150, 200, 250 and 300 individuals per box; and adults at 8, 10, 12, 14 and 16 pairs per acrylic box. As food was used the same factitious prey provided in mass rearing Tenebrio molitor (Coleoptera: Tenebrionidae) larvae. For nymphs was evaluated the parameters nymph survivorship, developmental time, female and male body weight and food consumed. For adults was evaluated the total number of eggs produced and eggs per female, number of T. molitor larvae killed, female longevity and egg production as a function of killed prey. Based on Cluster analysis, 200 and 250 nymphs per box and 10 and 12 pairs per acrylic cage were the best densities. The female preference for egg laying was higher ($\chi^2 = 5.5^{\circ}$, p < 0.05) on paper strips than on acrylic box wall. Although nymph rearing in box provides reduction in labor and space, survival was low ranging from 25 to 75% according to density per box (r = -0.79, p < 0.01). Acrylic boxes used as recipient for adults maintenance showed adequacy for this purpose. However, in further investigations is recommended to use more strips of paper per cage to enhance egg collection. In addition, should be also considered the time of male in mating to increase female longevity and reduce food consume.

Index terms. Asopinae, biological control, mass rearing, oviposition.

[1683] CANDIDATE INSECTS FOR THE BIOCONTROL OF THE PLANT PILYTOPARASITE *PSITTACANTHUS* SP. (LORANTHACEAE) IN THE REGION OF THE PANTANAL, MATO GROSSO DO SUL STATE, BRAZIL

<u>M. A. F. Uchôn</u> & Caires, C. S. Laboratório de Controle Biológico de Insetos, Universidade Federal de Mato Grosso do Sul, Caixa Postal 04, CEP 79200-000 Aquidauana, MS, Brazil. E-mail <uchoa@nin.ufms.br>

The mistletoes, Psittacanthus spp., (Loranthaceae) are hemiparasitic plants that can be characterized as pests. They parasitize, and frequently, kill, wild plants, of urbane arborization and cultivated fruit trees, causing serious losses for the Brazilian fruticulture. The multiplication of this plant occurs only by seeds which are swallowed and spread by the feces of birds which feed on the fruits. Its control is very difficult, being carried out only by cutting the infested branches, because the use of herbicides damages the host plant. The objetive of this study was to investigate the occurrence of insects infesting fruits of Psittacanthus in the Cerrado and the south Pantanal region, with a view to using them as agents in the biological control of this pest. Unripe and mature fruits were collected in various localities of the muncipalities of Aguidauana (20° 30' S / 55° 47'40" W, 173 m) and Anastácio (20° 29' S / 55° 49' W, 170 m), Mato Grosso do Sul State, during the period of 29.07.1998 to 17.09.1999. Some 23.916 fruits (49 samples) of Psittacanthus sp. infesting 15 species of plantas from 10 Families were avaluated: Astronium sp., Myracrodruon sp. and Tapirira sp. (Anacardiaceae); Cordia sp. (Boraginaceae); Cecropia sp. (Cecropiaceae); Terminalia cattapa and Terminalia sp. (Combretaceae); Sapium sp. (Euphorbiaceae); Melia azedarach (Meliaceae); Acacia sp., Anadenanthera sp. and Enterolobium sp. (Mimosaceae); Artocarpus sp. (Moraceae); Psidium guajava (Myrtaceae) and Salix sp. (Salicaceae), totalizing a biomass of 59,016 kg, Some 1751 larvae were obtained, 1745 of Lonchaeidae (Diptera) and six of Lycaenidae (Lepidoptera). The adults were reared in the laboratory from last instar larvae, that were leaving fruits to pupate. Some 1520 adults of Neosilba McAlpine, 1962 (Lonchaeinae) and six adults of Thecla echelta Hewitson 1867 (Theclinae). The larvae of *T. echelta* occurred in fruits of *Psittacanthus* sp. parasitizing *Cecropia* sp. and *Anademanthera* sp. The only flies reared from the fruits of *Psittacanthus* sp. were of the genus Neosilba. However, the effect of the larvae of these lonchaeids on the germination of Psittacanthus sp. is still unknown. T. echelta feeds on the cotyledons, the embryo and on viscinia, hindering the germination of the seeds. This butterfly was seen to be the most promising as a candidate species for the biocontrol of Psittacanthus sp., although its incidence during the period was low.

Index terms: Neosilba spp., Lonchaeidae, Thecla echelta, Lycaenidae, mistletoe

[1682] PRACTICES OF IPM ON VEGETABLES IN HONG KONG

W. Tsang, Hong Kong Council of Early Childhood Education & Services, 103-6 Nam Wai House, Upper G/F, Nam Shan Est., Kowloon

The challenge for us all therefore is to increase agricultural productivity with a sustainable manner. However, higher productivity cannot be separated from ecological considerations. Integrated Crop Management means optimal farming practised in a sustainable manner. ICM is thus the only way ahead., and IPM is an important component of ICM. We implement organic farming for the production of green food, e.g. safe vegetable without contamination of chemicals, chemical pesticides are abandoned absolutely in the Garden farm of Hong Kong Council of Early childhood Education & Services (CECES). With a principle of sustainable development and decontamination of the environment, we have been cooperated with the Guangdong Entomological Institute on the implementation of an IPM program with biological control of vegetable pests in the Garden Farm since 1994. 1.Biological control by periodic releases of Trichogramma spp. (to control asian corn borer & diamond backmoth, white butterflies etc), entomopathogenic nematode (Steinernema carpocapsae, to control Debia undalis, Pieris rapae, Plutella xylostella, Prodernia litura, Phillotreta vittata), some predatory ladybirds & lacewings, sex pheromones traps (to kill adults of asian corn borer & daimonbackmoth), microbial insecticides (Bacillus thuringiensis, Beauveria bassiana & Nuclear polyhedrosis to control pests of Lepidoptera, Diptera & Coleoptera). Sometimes the botanical pesticides (such as garlic juice and derris) were used too. 2. Physical control was adopted also.(yellow pots, yellow sticky boards and silver gray plastic film were used for controlling aphids; sweet-and-sour liquor was applied as a trap-killer of tobacco cutworm). 3. Diversity in cropping. Crop rotation (Maize-radisheggplants; cucumber-onion-.peas; radish-spinach-cucumber) in the Garden Farm was applied as a husbandry method of precluding some vegetable pests and soil-borne diseases like Fusarium wilt on cucumber, tomatoes, and eggplants. Inter-cropping with a symbiotic mutualism manner (eggplant + onion; celery + peas; cabbage + onion; spinach + carrot) was implemented.

Index terms: IPM, ICM, organic farming, biological control, physical control, diversity.

[1684] CLASSICAL BIOLOGICAL CONTROL OF THE SPINY BLACKFLY, ALEUROCANTIIUS SPINIFERUS (HEM.: ALEYRODIDAE), AN ECONOMIC STUDY

M.A. Van den berg¹, G. Höppner² & J. Greenland¹, ¹ Institute for Tropical and Subtropical Crops, Private Bag X11208, Nelspruit, 1200, South Africa, E-mail jenny@itsc.agric.za; ²Inyoni Yami Irrigation Scheme, P.O. Box, Tshaneni, Swaziland.

The spiny blackfly, Aleurocanthus spiniferus (Hem.: Aleyrodidae) has been a major pest in some citrus orchards and home garden citrus and rose trees in Swaziland and South Africa since the early 1990's. Direct crop losses and control costs due to infestations by the spiny blackfly were studied at the Inyoni Yami Irrigation Scheme at Tshaneni, Swaziland. This amounted to R476 000 (= US \$79 000) for the 1995/96 season. Furthermore, it was estimated that the control costs incurred by home gardeners in the towns of Barberton, Nelspruit, and White River, South Africa, amounted to at least R100 000 (= US \$16 500). Classical biological control of A. spiniferus by the introduced parasitoid, Encarsia cf. smithi (Hym.: Aphelinidae) has been achieved with an average parasitism of almost 80%. Because of this classical biological control, no further crop losses occurred since the 1996/97 season and no chemical control was necessary for this pest during the following three seasons. However, in citrus orchards at Letaba Estate, Tzaneen and in Graskop town where the spiny blackfly spread to without the parasitoid E. cf. smithi being present, A. spiniferus remains an important pest. The amount spent to achieve biological control of the spiny blackfly, including the project overheads, amounted to R169 750 (= US \$28 000). If this amount is compared to the direct losses and control costs of a single season, the expenditure to establish biological control was exceptionally cost effective. A benefit ratio was calculated at 3.4.

Index terms: Aleurocanthus spiniferus, Encarsia cf. smithi, establishing cost, benefit ratio

[1685] BIOLOGICAL CONTROL OF GONIPTERUS SCUTELLATUS (COLEOPTERA: CURCULIONIDAE) IN PORTUGAL

A. Vaz, C. Valente & M. Serrão, RAIZ - Inst. de Investigação da Floresta e do Papel, Herdade da Torre Bela, apartado 15, 2065 Alcoentre - Portugal

The Eucalyptus Snout Beetle Gonipterus scutellatus Gyll. (Coleoptera: Curculionidae) is an Australian eucalypt defoliator that acquires pest status in all regions where introduction have occurred. This insect was recorded for the first time in Europe in 1976. Coming from the North of Spain it was detected in Portugal in 1995. Considering the economic impact of *Eucalyptus globulus* plantations in Portugal, the Research Institute for Forestry and Paper (RAIZ) began in 1996 to monitor the spreading area of the beetle. At that time the insect was present only in a small area of the NW of Portugal occurring now in approximately two thirds of the country. In 1997 RAIZ and the Forest Services (DGF) started a program aimed to control the beetle with the egg parasitoid Anaphes nitens Gir. (Hymenoptera: Mymaridae). Due to the reduced amount of available parasitoids a rearing facility was established in 1998. The first releases took place in 1997, in a systematic release point distribution along the NW region of the country, followed by releases in commercial eucalypt plantations. Since 1998 all releases where done in commercial forest, in cooperation with eucalyptus forest enterprises. Parasitism rates have been monitored since 1997 showing an increase in areas where parasitoids were released. Results are presented and discussed to evaluate the biological control program of *G. scutellatus* with *A. nitens*.

Index terms: Eucalyptus snout beetle, natural enemies, Anaphes nitens, Eucalyptus pests.

[1687] EFFECT OF DIATRAEA SACCHARALIS TREATED EGGS ON CRISOPIDS LARVAE

<u>L. Vicira¹</u>; G. Bissolli¹; P. Fortes¹, S. A. De Bortoli¹, J. E. Miranda¹ & A. T. Murata², ¹Dept. de Fitossanidade, Univ. Estadual Paulista, CEP 14884,900, Jaboticabal, SP, Brasil. ²Dept. de Biologia, Univ. de São Paulo, 14040-901, Ribeirão Preto, SP, Brasil (FAPESP Fellowship), E-mail: murataat@asbyte.com.br.

The crisopids are found in different agroecosystems, and they have great importance to the biological control. These insects are susceptible to the action of chemical products applied in the crop fields. This experiment had the objective to study the susceptibility of crisopids larvae to aqueous extracts of Azadirachta indica and Bougainvillea spectabilis. The extracts were made from leaves (0,5 Kg) and water (5 l). The work was carried out in lab conditions $(25 \pm 2 \,^{\circ}\text{C}, 70 \pm 10\% \,\text{RH}$ and 12 h photophase). It was used 3° instar larvae of Ceneochrysa cincta in multiple choice tests, being the larvae fed on Diatraea saccharalis eggs treated with plant extracts. The tests were accomplished in Petri dishes of 25cm of diameter releasing so larva at the dish center. It was evaluated the fatal number of larvae in each treatment during 10 minutes and the total number of consumed egg 24 h later. The results showed that 48.5% of insects went to the eggs treated with B. spectabilis extract, and 22.8% went to the eggs treated with A. indica, respectively. From this results it can be concluded that the two extracts have repellent to the crisopids larvae.

Index terms: Ceraeochrysa cincta; Azadirachta indica; Bougainvillea spectabilis insecticide.

[1686] EFFECTS OF CONVENTIONAL PESTICIDES ON THE PREIMAGINAL DEVELOPMENT OF *TRICHOGRAMMA CORDUBENSIS* (HYMENOPTERA: TRICHOGRAMMATIDAE)

Vieira, A. V.¹, <u>L. M. Oliveira</u>¹ & P. V. Garcia¹, ¹Univ. dos Açores, Dept^o. de Biologia, Rua da Mãe de Deus 58, P-9500 Ponta Delgada, Açores, Portugal. e-mail: ziza@notes.uac.pt

The effects of seven pesticides on different phases of egg to adult development (<24, 24/48, 48/72, 72/96, 120/144, 192/216 hours) of Trichogramma cordubensis (Vargas & Cabello) (Hymenoptera: Trichogramatidae) were analysed. One organophosphorus insecticide (Trichlorfon), one organochlorine insecticide (endosulfan), two pyrethroids (Deltamethrin and Lambda-cyhalothrin), a commercial formulation of Bacillus thuringiensis subsp. Kurstaki, and two fungicides (Acetamide+Dithiocarbamete and Basic copper sulphate) were selected. All the tests were carried out with fresh solutions of commercial insecticides, applied on the parasitized host eggs at the recommended concentration and an amount of water of 1000 l/ha. The controls were sprayed with distillate water. One Potter Tower equipment (Burkard, Rickmanswort, U.K.) was used for spraying parasitized host eggs. Analyses of variance (ANOVA) were conducted on all data. Where statistical differences existed between data sets (p<0.05), Student-Newman-Keuls tests were used to separate the differing treatments. The pesticides applied on different development phases did not affect parasitoid development times, except the endosulfan that delayed for one day the parasitoid preimaginal development. With few exceptions, the number of parasitized host eggs that turned black (i.e., with prepupa parasitoids) did not differ significantly between both the pesticides and the control. The first four pesticides (chemical insecticides) significantly affected the adult emergence rates, while for the other products the emergence rates were similar with the control values. Adult's longevity was very short when applied endosulfan or Trichlorfon (<1 and <2 days, respectively). With the other products longevity varied from 10 to 16 days. Globally, endosulfan was the pesticide more noxious to the preimaginal development of T. cordubensis, therefore the use of such product should be avoided when this species is present in the ecosystems.

Index terms: Trichogramma cordubensis, insecticides, fungicides

[1688] THE ITALIAN SPECIES OF ERETMOCERUS HALDEMAN (HYMENOPTERA: APHELINIDAE) AND THEIR ROLE AS BIOLOGICAL CONTROL AGENTS

<u>G. Viggiani</u>, Univ. Napoli"Federico II", Dept. Entomologia e Zoologia Agraria, Via Università, 100, 80055 Portici, Italia. E-mail: genviggi@unina.it

The genus Eretmocerus Haldeman includes 56 described species, but only about 40 are recognized as valid species. All of them are known as parasitoids of whiteflies. Taxonomic studies on this rather peculiar group of aphelinids increased last decade for the need of a correct identification of species, mostly potential biocontrol agents of Bemisia (tabaci complex), but we are rather far from a definitive characterization of several populations. At present the taxonomy of Eretmocerus is mostly based on the characters of the antennae and on the number of setae on the mid lobe of the mesoscutum. In fact, this group of parasitoids shows a relatively high interspecific morphological homogeneity in contrast to a pronuanced intraspecific variability. A survey on the Italian species of Eretmocerus started several years ago (Viggiani and Battaglia, 1983) and was continued in recent years with a sampling of parasitized whiteflies on wild plants, cultures in open field and on protected crops. Species of Eretmocerus have been obtained from the following hosts: Aleurolobus wunni, Aleurotuba jelinekii, Bemisia afer, Bemisia (tabaci complex), Parabemisia myricae, Siphoninus phillyreae and Trialeurodes vaporariorum. E. debachi, an introduced species, is the dominant parasitoid of the Japanese bayberry whitely Parabemisia myricae, at present a very rare pest in southern Italy (Viggiani, 1996). Another introduced species, E. eremicus, commercialized for the control of Bemisia tabaci complex, has been found on Trialeurodes vaporariom and in competition with the aphelinid Encarsia pergandiella. Another species, allied to E. roseni, as been obtained from the same host. E. longicornis resulted a rather rare parasitoid of Aleurolobus wunni and A. jelinekii, as E. roseni, parasitoid of B. afer. A dominant and widely spread parasitoid of Bemisia (tabaci complex) is Eretmocerus mundus. It shows variations in several characters (relative dimensions of the funicular segments, clava length, etc.), which are under study to clarify their biosystematic significance. E. mundus is active on several plants and causes naturally very high level of parasitization. Index terms: Bemisia, Parabemisia, Trialeurodes, parasitoid, whitefly

[1689] BIOLOGICAL STUDIES ON ENCARSIA PORTERI (IIYMENOPTERA: APHELINIDAE)

<u>M. M. Viscarret</u>, S. N. López & E. N. Botto, Insectario de Investigaciones para Lucha Biológica. IMYZA-CNIA-INTA Castelar. C. C. 25 (1712), Buenos Aires Argentina. Email: mviscarret@ciudad.com.ar.

Encarsia porteri is an heterotrophic parasitoid whose females develop as primary endoparasitoids of whiteflies nymphs, and the males as primary endoparasitoids of lepidopteran eggs. This wasp is the more frequently found attacking the ARG1 biotype of the Bemisia tabaci complex, a very important pest on cotton crops in the Argentinian Northeast. Knowledge about the biology of E. porteri is poorly known and its potential as a biological control agent for whiteflies has not been evaluated throughly. Therefore the objective of this study was to determine some biological parameters of this parasitoid. Host preference, developmental time and longevity for the female and the male of E. porteri were estimated on biotype ARG1 of B. tabaci complex and different species of lepidopteran eggs. The prefered nymphal stages of the whitefly by the parasitoid for oviposition and host feeding were 3 and 4. No female was observed to feed/oviposit on a nymph previously visited and used for the parasitoid. The mean developmental time (±SE, in days) for the female was: on tomato 19.2±0.40 and on cotton 23.40±0.58, being the first value significantly smaller than the second (K-W=19.46, P=0.00). Mean longevity (\pm SE, in days) of the female was: on tomato 18.59 \pm 2.68, and on cotton 20.55 \pm 1.59. There was no significantly differences between these values (F=0.44, P=0.51). The percentage of E. porteri males emerged from A. gemmatalis eggs (25%) was significantly greater than the percentage observed on eggs of Diatraea saccharalis (2.15%), Sitotroga cerealella (3.55%) and Cydia pomonella (7.72%) (F=5.01, P=0.03). Mean developmental time (±SE) of the E. porteri male on A. gemmatalis eggs (17.28±0.12 days) was smaller than the observed for the male emerged on D. saccharalis, S. cerealella, C. pomonella and Epinotia aporema. The developmental time on D. saccharalis was significantly greater than that observed on S. cercalella and E. aporema (D.s. 22.3 ± 0.64 days, S. c. 19.61 ± 0.44 days, C. p. 20.58 ± 0.40 days, E. a. 19.16 ± 0.13 days, F=49.85, P=0.00). The estimated mean longevity (\pm SE, days) for male of E. porteri was: on D. saccharalis 27.50±9.00, on A. gemmatalis 23.63±1.34, on C. pomonella 19.69±2.39, on E. aporema 15.71±1.36 and on S. cerealella 15.58±2.80.

Index terms: Encarsia porteri, heterotrophic parasitoid, host preference, developmental time

[1690] ENVIRONMENTAL AND PREY INTERACTION ON THE DEVELOPMENT AND REPRODUCTION OF THE STINKBUG PREDATOR PODISUS NIGRISPINUS

L.M. Vivan¹, J.B. Torres², F.S.L. Veiga² & J.C. Zanuncio³, ^{1.2}DEPA-Fitossanidade, Univ. Fed. Rural de Pernambuco, Av. Dom Manoel de Medeiros S/N, Dois Irmãos 52171-900 Recife, PE, E-mail Ivivan@yahoo.com; ³DBA, Univ. Federal de Viçosa, 36571-000 Vicosa, MG.

The stinkbug predator Podisus nigrispinus (Dallas) has been a source of natural control in various cropping systems in Brazil. It occurs widespread throughout the American continent under different environmental and prey conditions. Thus its development and reproduction were studied under laboratory ($28 \pm 1^{\circ}$ C, $53 \pm 5\%$ RH and 14 h of photofase) and open sided greenhouse (30 ± 5°C, 61 ± 23% RH and 12-13 h of natural photophase) conditions preying on tomato leafminer Tuta absoluta (Meyrick) caterpillars and the mealworm Tenebrio molitor L. pupae. Duration of the nymphal stage of this predator was similar between prey under laboratory conditions, however, it was delayed when fed on T. absoluta caterpillars in open sided greenhouse. Nymphs and adults of P. nigrispinus were heavier when fed with T. molitor in laboratory and greenhouse. Females and males showed similar weight with both preys and environmental conditions. Higher nymphs mortality was observed during 2nd instar for both prey and conditions, with viability from 32.3 to 50.0% for the nymphal stage. No differences were observed for female longevity between prey and environmental conditions. Number of egg mass, number of eggs and number of eggs per egg mass were similar between environmental conditions but higher for female fed on T. molitor than those females fed on T. absoluta. Females of P. nigrispinus maintained their body weight throughout lifetime between environmental conditions preying on the same prey, but higher body weight was observed at day 10 for females fed on T. molitor pupae under open sided greenhouse conditions. Oviposition rate was higher for females fed on T. molitor pupae than those fed T. absoluta in both conditions. *P. nigrispinus* decrease its performance preying on *T. absoluta* but it can develop and reproduce with this prey under fluctuating climatic conditions.

Index terms: Asopinae, biological control, temperature, Tuta absoluta, prey quality

[1691] FIELD AUGMENTATION OF ORIUS STRIGICOLLIS FOR THE CONTROL OF INSECT PESTS

C. L. Wang¹, C. T. Yseng² & P. C. Lee³, ¹Taiwan Agricultural Research Institute, Wufeng, Taichung, Taiwan, ROC, E-mail clwang@wufeng.tari.gov.tw; ² Tainan DAIS Poutzu Branch Station, Chiayi, Poutzu, Tainan, Taiwan, ROC; ³Kaohsiung DAIS, Kaohsiung, Taiwan, ROC.

Orius strigicollis is an effective predator of small insects with a feeding preference for thrips. This anthocorid bug can be found on many horticultural crops both in greenhouses and in open field, but usually at low densities. In the laboratory at 25[], one Orius bug ate more than 200 thrips (Thrips palmi), or 500-600 spider mites (Tetranychus kanzawai) during its whole life when sufficient prey was supplied. Mass rearing techniques for these flower bugs have been improved in recent years in Taiwan Agricultural Research Institute. Large numbers of flower bugs can be obtained in the laboratory by supplying O. strigicollis with bean (Glycine max) sprouts as plant food and ovipositional substrate, and flour moth (Ephestia cautella) eggs as preys. This facilitated studies on the effect of mass releasing of O. strigicollis as biological control agent under field conditions. Field experiments were conducted on eggplants grown in open fields in central Taiwan in 1998 and 1999. Depending on the size of the eggplants, thousands of 2-3 days old Orius nymphs were released to produce an average density of approximately one Orius nymph per leaf. In this way, Orius flower bugs were released every week for a period of 6 weeks. The number of Orius increasing with each release and reaching a maximum density of 0.8 per leaf. Densities of thrips, spider mites and whiteflies (Bemisia argentifolii) declined gradually after release of the flower bugs, and differences between this treatment and chemical control areas appeared 4-6 weeks after the first release. The control effect lasted for at least two months. The surfaces of the eggplant fruits showed less insect damage were evidently better than those from the chemical control areas.

Index terms: Thrips palmi, Tetranychus kanzawai, Bemisia argentifolii, eggplant, biological control.

[1692] PRELIMINARY OBSERVATIONS ON DIETARY SELF-SELECTION BY MANDUCA SEXTA: DO PARASITIZED LARVAE CHOOSE NOT TO CHOOSE?

L.-W. Wang¹ & <u>S. N. Thompson</u>¹, 1 Anal. Chem. Instrumentation Facility & Dept. of Entomology, University of Calif., Riverside, CA., U.S.A., 92521

This study examined the self-selection behavior of terminal instar Manduca sexta larvae, parasitized by Cotesia congregata, in relation to blood trehalose level. Earlier investigations have established that parasitized larvae maintained on sucrose-free diets or on reduced sucrose diets have an equivalent blood sugar level as normal insects reared on the same diet. In parasitized larvae this is due to enhanced induction of gluconeogenesis and blood sugar formation. The maintenance of blood trehalose suggested that dietary selfselection based on blood sugar level is preserved during parasitism. The findings presented here, however, indicate that parasitized larvae may alter their self-selection behavior. Newly molted unparasitized fifth instar larvae given a choice between a sucrose diet lacking casein and a casein diet lacking sucrose, select, over a three day period, the protein and carbohydrate diets in a ratio of approximately 2:1. In contrast, parasitized larvae given the same choice, select a ratio of 1:1, the same ratio as control parasitized and normal larvae given a choice between two diets of the same mixed protein and carbohydrate composition. Although the results suggest the absence of self-selection behavior in parasitized insects, when larvae are preconditioned on the sucrose or protein diet they initially select the alternate diet, in the same manner as normal larvae treated similarly. This demonstrates that parasitized M. sexta larvae are fully capable of dietary selfselection, and that the final 1:1 ratio of protein and carbohydrate consumed represents a different intake target than that of normal larvae. The above findings were related to blood sugar formation in parasitized and normal larvae that were allowed to self-select on alternate diets.

[1693] RESOURCE PARTITIONING BY TWO ICHNEUMOND PARASITOID SPECIES (HYMENOPTERA) OF A LONGICORN PEST, OEMONA HIRTA (COLEOPTERA: CERAMBYCIDAE), IN NEW ZEALAND

O. Wang & C. Shi, Entomology and IPM Laboratories, Plant Protection, Institute of Natural Resources, Massey University, Private Bag 11122, Palmerston North, New Zealand, E-mail Q.Wang@massey.ac.nz

The longicorn borer, Oemona hirta (Fabricius), is a New Zealand native beetle. It has become an important pest of many introduced crops in New Zealand such as citrus, apple, persiminon, grape, etc. and shelter belt trees, such as poplar. This feature has made the species subject to overseas quarantine interest because it can quickly establish and attack trees and vine crops overseas once introduced accidentally. Because the borer larvae bore into the branches and trunks, making chemical control impractical, alternative control approaches including biological control need evaluating. Host utilization and sex allocation of two ichneumond parasitoids, Xanthocryptus novozealandicus (Dalla Torre) and Compoplex sp., of O. hirta were studied in New Zealand. These parasitoids are idiobionts and their secondary sex ratio is female-biased, which may be a function of host size. Females of both species are significantly larger than males, and females allocate the sex of offspring depending on the size of host larvae, laying female-producing eggs on significantly larger host larvae. X. novozealandicus is larger in body size and shorter in ovipositor length than Campoplex sp. and consumes late instar larvae or pre-pupae in shallow galleries while the latter attacks early to middle instar larvae in deep galleries. This pattern suggests that the parasitoids avoid competition as ecological homologs between species.

Index terms: Cerambycidae, Ichneumonidae, Oemona hirta, parasitoids, Xanthocryptus novozealandicus, Campoplex, sex allocation, host utilization

[1695] INDUCTION OF FEMALE-EGG OVIPOSITION BY HIGH ILLUMINATION IN A PARASITOID, HAPLOGONATOPUS ATRATUS (HYMENOPTERA: DRYINIDAE)

<u>Y, Y, Yamada</u> & K. Metsugi, Entomology Lab, Faculty of Bioresources, Mie Univ., Tsu, Mie 514-8507, Japan, E-mail yamada-y@bio.tnie-u.ac.jp

We discovered that a solitary parasitoid, Haplogonatopus atratus, host-specific to the small brown planthopper, Laodelphax striatellus, is likely to lay female eggs under high illumination. We provided a 3rd-instar host to a female parasitoid in a 4.5-ml transparent vessel. The female usually caught the host within a few minutes after it had been placed into the vessel, and laid an egg into it. We sexed the egg by videotaping the oviposition behaviour and observing the movement of the sting (Yamada & Kawamura, 1999). By using a light beam from a fiber optic ringlight and florescent lights we let the parasitoid lay an egg under illuminations of 200, 1500, 3000, 5000, 10000, 20000, 40000, 60000 lux. The parasitoid was placed under each illumination 5 min before a host was provided. The proportion of male eggs was on an average 80.2 % for 200 lux and 76.7% for 1500 lux, 62.3 % for 3000 lux. The proportion ranged from 26.7% to 36.7% under illuminations of 5000 lux and over. In the next experiment, the illumination was changed from low (200 or 1500 lux) to high (5000 and 40000 lux) or from high to low when the parasitoid stopped moving her abdominal tip and fixed it on a point on an intersegmental membrane between the host abdominal tergites to insert an egg into the host. The egg was usually laid 20-40 seconds after the abdominal tip was fixed. When the illumination was changed from high to low, the proportion of males was 51.3% for 40000 lux and 53.3% for 5000 lux. On the other hand, when the illumination was changed from low to high, the proportion of males was 46.7% for 5000 lux and 73.3% for 40000 lux. These suggest that it takes time for high illumination to have an effect on female-egg oviposition, that the time changes with intensity of illumination, and that high illumination retains an effect for some time after the high illumination is stopped. In the third experiment, high illumination (5000 and 40000 lux) was stopped just before a host was provided, and 5 and 10 min before. With increasing time spans, the proportion of males gradually increased for the two illuminations: 45.3%, 61.5%, and 71.7% for 5000 lux; 41.3%, 57.3%, and 71.7% for 40000 lux. The effect of high illumination almost disappeared about 12 min (10 min plus a few minutes after a host is provided) after the high illumination was stopped, irrespective intensity of illumination.

[1694] MASSIVE PARASITISM OF GRASSHOPPERS BY TACHINID MAGGOTS

D. W. Whitman, D. J. Otto, & M. A. Lamb, 4120 Dept. of Biology, Illinois State University, Normal, IL 61790, USA. dwwhitm@ilstu.edu.

In 1997, 82% of adult lubber grasshoppers (Romalea microptera) (fam.: Romaleidae) from south Florida. USA contained maggots of the tachinid parasitoid Anisia serotina (fam.: Tachinidae; subfam.: Goniinae) Ninety-two percent of 50 females and 72% of 50 males were parasitized. The number of maggots per grasshopper ranged from 0 to 63 and averaged 7.0 \pm 3.3 (SE). There was a strong trend, but no significant difference in the mean number of maggots per male (5.1 \pm 1.4 (SE) (n=50) vs. per female (8.9 \pm 1.8) (n=50). Parasitized grasshoppers had high mortality. The population density of this grasshopper fluctuates widely in nature. For example, the densities of grasshoppers (#/100 m²) at the most dense field sites in 1994, 1997, & 1998 were 900, 8, & 0.6 adults/100 m², respectively. This represents more than a 1000-fold decrease in grasshopper densities from 1994 to 1998. Perhaps the tachinid parasitoid is driving these strong changes in grasshopper population density.

[1696] FECUNDITY OF EURYGASTER INTEGRICEPS AND EURYGASTER AUSTRIACA IN LABORATORY CONDITION AND NATURE

T. Yilmaz¹ & <u>M. Kivan²</u>, ¹thrace Agric. Res. Inst., Edirne; ²dept. Of Plant Protection, Agric. Faculty, Univ. Of Trakya, 59030, Tekirdag, Turkey, E-Mail Tzfbitkikoruma@Superonline.Com.

The sunn pests, eurygaster spp. (heteroptera, scutelleridae) are among the most important insect pests of wheat in turkey, the most severe losses caused by e.integriceps and e. austriaca in thrace region, by e. integriceps in the southern anatolia and also by e. maura in central anatolia. overwintered adults, nymphs and new-generation adults cause damage by feeding on wheat throughout the plant's development. primary method for controlling sunn pests in turkey is chemical spraying which is conducted on all fields where sunn pest densities exceed the economic damage threshold, biology, ecology and control of e. integriceps have been studied in detail. however, economic threshold should be reviewed and improved; crop losses should be assessed and also reproduction of sunn pests according to insect species and different localities. so, this study was carried out to determine and compare that the fecundity and oviposion period of these two species at 27±2 °c, 65±5 % relative humidity and 16:8 hr photoperiod in laboratory and field conditions, which was recorded by thermohigrograph. as a result, the data estabilished were shown table 1. mean oviposition time and number of eggs and egg masses per female of two species were not different significantly in laboratory and also in nature (p>0.05). however, the fecundity in laboratory was lower than nature, because the conditions were different. average of 20.5 °c and 62 % relative humidity were recorded durig the experiments in the field, it was concluded that in terms of egg production and egg laying period differences between e. integriceps and e. austriaca were not significant in both conditions.
